$$-\mathrm{C}.\varepsilon^{px}.\sin qx+\mathrm{C}'.\varepsilon^{px}.\cos qx+\mathrm{C}''.\varepsilon^{-px}.\sin qx-\mathrm{C}'''.\varepsilon^{-px}.\cos qx,$$

and finally $\mathrm{X}=\mathrm{A}\cos it+\mathrm{B}\sin it=$

Expression for displacement of particles.

$$\frac{-(i^2-v^2m^2)\,\mathrm{H}}{(i^2-v^2m^2)^2+f^2i^2}\sin\overline{it-mx}-\frac{fi\,\mathrm{H}}{(i^2-v^2m^2)^2+f^2i^2}\cos\overline{it-mx}+\varepsilon^{px}\{\mathrm{C}.\cos\overline{it+qx}+\mathrm{C}'.\sin\overline{it+qx}\}$$
$$+\varepsilon^{-px}\{\mathrm{C}''.\cos\overline{it-qx}-\mathrm{C}'''.\sin\overline{it-qx}\}.$$

We shall now proceed to apply this expression to some particular cases.

Canal supposed indefinite, or returning into itself.

(322.) Problem.—To find the expression for the disturbance in a canal of indefinite length, or one returning into itself (as a canal surrounding the earth).

Here it is plain that we cannot have any of the terms multiplying ε^{px} and ε^{-px}, because, in the case of a returning canal, these terms would have different values on returning by a different number of circuits to the same spot. Hence

$$\mathrm{X}=\frac{-\mathrm{H}}{(i^2-v^2m^2)^2+f^2i^2}\{(i^2-v^2m^2).\sin\overline{it-mx}+fi.\cos\overline{it-mx}\}.$$

If $\tan\mathrm{D}=\frac{fi}{i^2-v^2m^2}$,

$$\mathrm{X}=\frac{-\mathrm{H}}{\sqrt{\{(i^2-v^2m^2)^2+f^2i^2\}}}\sin\overline{it-mx+\mathrm{D}}.$$

Upon this we have to remark as follows:

(323.) 1st. This expression never becomes infinite. It is greatest nearly when $i^2-v^2m^2=0$, or $i^2-gkm^2=0$. Then $\mathrm{D}=90^\circ$, and the expression for X is $\frac{-\mathrm{H}}{fi}\cos\overline{it-mx}$, which is very large if f is small.

(324.) 2nd. The expression for X is always less than that which is obtained by making f the coefficient of friction $=0$.

(325.) 3rd. The expression for V, the whole depth at any point in the disturbed state, is $\frac{k}{1+\frac{d\mathrm{X}}{dx}}=k-k\frac{d\mathrm{X}}{dx}$ nearly, and the fluctuation in height, or K, is therefore $-k\frac{d\mathrm{X}}{dx}$

$$=\frac{-km\mathrm{H}}{(i^2-v^2m^2)^2+f^2i^2}\{(i^2-v^2m^2).\cos\overline{it-mx}-fi.\sin\overline{it-mx}\}$$
$$=\frac{-km\mathrm{H}}{\sqrt{\{(i^2-v^2m^2)^2+f^2i^2\}}}\cos\overline{it-mx+\mathrm{D}}.$$

Tide is accelerated by friction.

This is maximum, or it is high water, when $it-mx+\mathrm{D}=\pi$, or when $t=\frac{\pi+mx-\mathrm{D}}{i}$. The force at the point in question vanishes, and the force on each side tends to draw the water towards the place, when $t=\frac{mx}{i}$. Consequently, high water follows the time of the force vanishing by $\frac{\pi-\mathrm{D}}{i}$. As the interval between high water and low water is $\frac{\pi}{i}$, it appears that high water is the next conspicuous phase which follows the evanescence of forces.

The acceleration is greater for a tide of longer period.

(326.) It appears here that high water is *accelerated* by the time $\frac{\mathrm{D}}{i}$, or $\frac{f}{i^2-v^2m^2}$ nearly. If then there were two forces acting at the same time, one depending upon $\overline{it-mx}$ and the other depending upon $\overline{(i-i'')t-mx}$, the tide depending upon the former would be accelerated by $\frac{f}{i^2-v^2m^2}$, and that depending upon the latter by $\frac{f}{(i-i'')^2-v^2m^2}$. The tide, therefore, depending upon $\overline{(i-i'')t-mx}$ would be more accelerated that that depending upon $\overline{it-mx}$ by $\frac{f}{(i-i'')^2-v^2m^2}-\frac{f}{i^2-v^2m^2}$, or (if i'' be small) $f\times\frac{2ii''}{(i^2-v^2m^2)^2}$. If $i^2-v^2m^2$ be small, this may be large enough to be very sensible. We shall hereafter find that this conclusion is most important.

(327.) 4th. If the water be so deep that v^2m^2 or gkm^2 is greater than i^2, the fluctuation in height or $-k\frac{d\mathrm{X}}{dx}=\frac{km\mathrm{H}}{(v^2m^2-i^2)^2+f^2i^2}\{(v^2m^2-i^2).\cos\overline{it-mx}+fi.\sin\overline{it-mx}\}$. Making $\tan \mathrm{D}'=\frac{fi}{v^2m^2-i^2}$, this becomes $\frac{km\mathrm{H}}{\sqrt{\{(v^2m^2-i^2)^2+f^2i^2\}}}\cos\overline{it-mx-\mathrm{D}'}$. This is maximum, or it is high water, when $it-mx-\mathrm{D}'=0$, or $t=\frac{mx+\mathrm{D}'}{i}$, which follows the time of evanescence of the forces by $\frac{\mathrm{D}'}{i}$. In all cases, therefore, the conspicuous phase which next follows the evanescence of forces is high water.

Coefficient of force supposed variable.

(328.) 5th. Suppose the coefficient of force to be variable and equal to $\mathrm{H}+\mathrm{H}'.\cos i't$, i' being small. Then the force $=(\mathrm{H}+\mathrm{H}'.\cos i't).\sin\overline{it-mx}=\mathrm{H}.\sin\overline{it-mx}+\frac{\mathrm{H}'}{2}\sin\overline{(i+i')t-mx}+\frac{\mathrm{H}'}{2}\sin\overline{(i-i')t-mx}$, and the expression for K is

$$\frac{-km\mathrm{H}}{(i^2-v^2m^2)^2+f^2i^2}\{(i^2-v^2m^2).\cos\overline{it-mx}-fi.\sin\overline{it-mx}\}$$
$$-\frac{km\mathrm{H}'}{\{(i+i')^2-v^2m^2\}^2+f^2.(i+i')^2}.\frac{1}{2}\left\{\{(i+i')^2-v^2m^2\}.\cos\overline{(i+i')t-mx}-f(i+i').\sin\overline{(i+i')t-mx}\right\}$$
$$-\frac{km\mathrm{H}'}{\{(i-i')^2-v^2m^2\}^2+f^2.(i-i')^2}.\frac{1}{2}\left\{\{(i-i')^2-v^2m^2\}.\cos\overline{(i-i')t-mx}-f(i-i')\sin.\overline{(i-i')t-mx}\right\}.$$

Suppose f so small that its square may be neglected. Then K becomes

$$-\frac{km\mathrm{H}}{i^2-v^2m^2}\cos\overline{it-mx}+\frac{kfim\mathrm{H}}{(i^2-v^2m^2)^2}\sin\overline{it-mx}$$
$$-\frac{1}{2}.\frac{km\mathrm{H}'}{\{(i+i')\}^2-v^2m^2}\cos\overline{(i+i')t-mx}+\frac{1}{2}.\frac{kf(i+i')m\mathrm{H}'}{\{(i+i')^2-v^2m^2\}^2}\sin\overline{(i+i')t-mx}$$
$$-\frac{1}{2}.\frac{km\mathrm{H}'}{\{(i-i')\}^2-v^2m^2}\cos\overline{(i-i')t-mx}+\frac{1}{2}.\frac{kf(i-i')m\mathrm{H}'}{\{(i-i')^2-v^2m^2\}^2}\sin\overline{(i-i')t-mx}.$$

Expanding these expressions to the first power of i', and omitting the general multiplier $\frac{km\mathrm{H}}{i^2-v^2m^2}$, the whole may be put in the following form.

$$\left\{-1-\frac{\mathrm{H}'}{\mathrm{H}}\cos i't-f\frac{\mathrm{H}'}{\mathrm{H}}.\frac{i'(3i^2+v^2m^2)}{(i^2-v^2m^2)^2}\sin i't\right\}\cos\overline{it-mx}$$
$$+\left\{-2\frac{\mathrm{H}'}{\mathrm{H}}.\frac{ii'}{i^2-v^2m^2}\sin i't+\frac{fi}{i^2-v^2m^2}+\frac{\mathrm{H}'}{\mathrm{H}}.\frac{fi}{i^2-v^2m^2}\cos i't\right\}\sin\overline{it-mx}.$$

(329.) On any given day (in treating of the tides) $i't$ may be considered nearly constant. Regarding the coefficients of $\cos\overline{it-mx}$ and $\sin\overline{it-mx}$ therefore as constant, the greatest elevation and depression of the water on that day will be expressed by the square root of the sums of their squares. Expanding the squares on the supposition that $\frac{H'}{H}$ is small, and taking only the first power of $\frac{H'}{H}$, the first power of f, the first power of i', and the combination of these first powers (a process which is legitimate for showing the combined effect of friction and variable coefficient, although the square of any one of these quantities is rejected), we have for the square of elevation or depression

$$1+\frac{2H'}{H}\cos i't+2f\frac{H'}{H}\,\frac{i'(3i^2+v^2m^2)}{(i^2-v^2m^2)^2}\sin i't-4f\frac{H'}{H}\cdot\frac{i^2i'}{(i^2-v^2m^2)^2}\sin i't$$

$$=1+\frac{2H'}{H}\cos i't+2f\frac{H'}{H}\cdot\frac{i'(i^2+v^2m^2)}{(i^2-v^2m^2)^2}\sin i't,$$

and the expression for the greatest elevation or depression, restoring the factor, is

$$-\frac{kmH}{i^2-v^2m^2}\left\{1+\frac{H'}{H}\cos i't+f\frac{H'}{H}\cdot\frac{i'(i^2+v^2m^2)}{(i^2-v^2m^2)^2}\sin i't\right\}.$$

The day on which the rise or fall is greatest is determined by making the quantity within the brackets maximum, or making $\cos i't+\frac{fi'(i^2+v^2m^2)}{(i^2-v^2m^2)^2}\sin i't$ maximum. This will be when $\tan i't$ or $i't=\frac{fi'(i^2+v^2m^2)}{(i^2-v^2m^2)^2}$, or when $t=\frac{f(i^2+v^2m^2)}{(i^2-v^2m^2)^2}$. But the variable force is greatest when $t=0$: Therefore the greatest tide follows the greatest force by the time $\frac{f(i^2+v^2m^2)}{(i^2-v^2m^2)^2}$. This appears to us an important result, and one which no other theory has obtained. The equilibrium-theory of tides necessarily makes the tides to be greatest upon the same day on which the force is greatest. Laplace's theory (93.), and the theory of waves in canals without friction (288.), give the same result. But here we find a retardation accounted for by friction; and moreover this retardation is considerable. For the alteration in the time of any high water was found (326.) to be $\frac{D}{i}$, or $\frac{f}{i^2-v^2m^2}$: here the retardation in the time of the greatest tide is $\frac{f(i^2+v^2m^2)}{(i^2-v^2m^2)^2}$, or is equal to the alteration in the time of high water $\times\frac{i^2+v^2m^2}{i^2-v^2m^2}$. When i^2 is not much greater than v^2m^2 or gkm^2, or when the depth is not much less than that in which the free wave would move as rapidly as the forced wave, this multiplier may be considerable, and (for the tides) the retardation may amount to one or several days.

Greatest tide occurs some time later than the greatest force.

(330.) If the term $H=0$, or if the coefficient of force be merely $H'.\cos i't$, the expression for K is

$$\frac{kmH'}{2}\left\{\left(-\frac{1}{(i-i')^2-v^2m^2}-\frac{1}{(i+i')^2-v^2m^2}\right)\cos i't+\left(-\frac{f(i-i')}{\{(i-i')^2-v^2m^2\}^2}+\frac{f(i+i')}{\{(i+i')^2-v^2m^2\}^2}\right)\sin i't\right\}\cos\overline{it-mx}$$

$$+\frac{kmH'}{2}\left\{\left(-\frac{1}{(i-i')^2-v^2m^2}+\frac{1}{(i+i')^2-v^2m^2}\right)\sin i't+\left(\frac{f(i-i')}{\{(i-i')^2-v^2m^2\}^2}+\frac{f(i+i)}{\{(i+i')^2-v^2m^2\}^2}\right)\cos i't\right\}\sin\overline{it-mx}.$$

If i' be small, this is nearly

$$\frac{kmH'}{i^2-v^2m^2}\left\{-\cos i't-f.\frac{i'(3i^2+v^2m^2)}{(i^2-v^2m^2)^2}\sin i't\right\}\cos\overline{it-mx}$$

$$+\frac{kmH'}{i^2-v^2m^2}\left\{\frac{-2ii'}{i^2-v^2m^2}\sin i't+\frac{fi}{i^2-v^2m^2}\cos i't\right\}\sin\overline{it-mx}.$$

The square of the elevation or depression upon any day (regarding $i't$ as constant) is the sum of the squares of the coefficients of $\cos\overline{it-mx}$ and $\sin\overline{it-mx}$; which, omitting the factor $\frac{kmH'}{i^2-v^2m^2}$, and taking only the first power of f, is

$$\cos^2 i't+\frac{4i^2i'^2}{(i^2-v^2m^2)^2}\sin^2 i't+f\left\{\frac{2i'(3i^2+v^2m^2)}{(i^2-v^2m^2)^2}-\frac{4i^2i'}{(i^2-v^2m^2)^2}\right\}\sin i't.\cos i't$$

of which the second term, as depending on the square of i' is to be omitted. Thus the expression becomes

$$\cos^2 i't+f.\frac{2i'(i^2+v^2m^2)}{(i^2-v^2m^2)^2}\sin i't\ \cos i't$$

or

$$\tfrac{1}{2}+\tfrac{1}{2}\cos 2i't+\frac{fi'(i^2+v^2m^2)}{(i^2-v^2m^2)^2}\sin 2i't;$$

whose maximum value occurs when $\tan 2i't$ or $2i't=\frac{2fi'(i^2+v^2m^2)}{(i^2-v^2m^2)^2}$, or $t=\frac{f(i^2+v^2m^2)}{(i^2-v^2m^2)^2}$, as before.

(331.) It is to be remarked that the slower the recurrence of the tide is in proportion to the space which it passes over (that is, the smaller i is in proportion to vm), the greater is the retardation. Thus the lunar tide is more retarded than the solar tide.

We shall now consider some cases in which the limits enter.

Tide propagated up a river, when there is friction.

(332.) Problem.—To find the nature of the tides propagated up a river of indefinite length communicating with a tidal sea, friction being considered, but no tidal forces being supposed to act on the river.

Here we must take the general solution of (321.) on the supposition that the force is 0, and we find for the general expression for X,

$$\varepsilon^{px}\{C.\cos\overline{it+qx}+C'.\sin\overline{it+qx}\}+\varepsilon^{-px}\{C''.\cos\overline{it-qx}-C'''.\sin\overline{it-qx}\}$$

where p^2 and q^2 have the values given in (320.).

As we suppose our wave to be propagated from the sea, and to meet with nothing which reflects it, we must take only those terms which depend on $it-qx$, and therefore X becomes

$$\varepsilon^{-px}\{C''.\cos\overline{it-qx}-C'''.\sin\overline{it-qx}\}.$$

From this,
$$\frac{dX}{dx}=\varepsilon^{-px}\{(-pC''+qC''').\cos\overline{it-qx}+(qC''+pC''').\sin\overline{it-qx}\},$$

and
$$K=-k\frac{dX}{dx}\text{ nearly }=k\varepsilon^{-px}.\{(pC''-qC''').\cos\overline{it-qx}+(-qC''-pC''').\sin\overline{it-qx}\}.$$

At the sea, or where $x=0$, this becomes $k\{(pC''-qC''').\cos it+(-qC''-pC''').\sin it\}$. If we suppose the tidal elevation of the sea to be expressed by $A.\sin nt$, we must have $i=n$, $k(pC''-qC''')=0$, $k(-qC''-pC''')=A$. Substituting these in the general expression for K,

$$K=A\varepsilon^{-px}.\sin\overline{nt-qx},$$

p and q having the values obtained by putting n for i. And $C''=\dfrac{-qA}{k(p^2+q^2)}$, $C'''=\dfrac{-pA}{k(p^2+q^2)}$; therefore

$$X=\frac{A}{k(p^2+q^2)}\varepsilon^{-px}.\{-q.\cos\overline{nt-qx}+p.\sin\overline{nt-qx}\}.$$

Tidal disturbance gradually diminishes in going up the river.

These expressions indicate a wave whose vertical elevation and horizontal motion of particles diminish continually as it travels up the river. The value of $\dfrac{dX}{dt}$ or the velocity of the water is,

$$\frac{nA}{k(p^2+q^2)}.\varepsilon^{-px}.\{q.\sin\overline{nt-qx}+p.\cos\overline{nt-qx}\}.$$

The flow ceases before the water has dropped to mean height.

Now high water occurs when $\sin\overline{nt-qx}$ has its greatest positive value, or $nt-qx=90°$; the next mean elevation will occur then when $nt-qx=180°$; at this time the velocity of the water $=-\dfrac{nA}{k(p^2+q^2)}\varepsilon^{-px}.p$; or the water will be flowing downwards; and therefore the direction of tide-current changes sooner after high water than if there were no friction.

Tide in a river stopped by a barrier, considering friction.

(333.) Problem.—To find the nature of the tides in the river when there is a barrier at a certain distance a from the mouth; other suppositions being as before.

In this case, taking the general solution, we cannot reject the first terms, because there may be a reflected wave. And, moreover, without taking these first terms, we shall not have a sufficient number of arbitrary constants for our conditions. These conditions are, that when $x=0$, K must $=A\sin nt$, and when $x=a$, X must $=0$; for all values of t. Assume then

$$X=\varepsilon^{px}\{C.\cos\overline{it+qx}+C'.\sin\overline{it+qx}\}+\varepsilon^{-px}.\{C''.\cos\overline{it-qx}-C'''.\sin\overline{it-qx}\}$$
$$K=-k\frac{dX}{dx}=-k\varepsilon^{px}\{(pC+qC').\cos\overline{it+qx}+(-qC+pC').\sin\overline{it+qx}\}$$
$$-k\varepsilon^{-px}\{(-pC''+qC''').\cos\overline{it-qx}+(qC''+pC''').\sin\overline{it-qx}\}.$$

When $x=0$, K becomes

$$-k\{(pC+qC').\cos it+(-qC+pC').\sin it\}-k\{(-pC''+qC''').\cos it+(qC''+pC''').\sin it\}.$$

The first condition therefore requires

$$i=n$$
$$pC+qC'-pC''+qC'''=0$$
$$-k\{-qC+pC'+qC''+pC'''\}=A.$$

The second condition requires

$$\varepsilon^{pa}.\{\quad C.\cos qa+C'.\sin qa\}+\varepsilon^{-pa}.\{C''.\cos qa+C'''.\sin qa\}=0$$
$$\varepsilon^{pa}\ \{-C.\sin qa+C'.\cos qa\}+\varepsilon^{-pa}.\{C''.\sin qa-C'''\ \cos qa\}=0.$$

Determining from the last four equations the values of C, C′, C″, C‴, and substituting them in the expressions for X and K, we find

$$K=\frac{A}{\sqrt{\{\varepsilon^{2pa}+\varepsilon^{-2pa}+2\cos 2qa\}}}\times\{\varepsilon^{px-pa}.\sin\overline{it+qx-E}+\varepsilon^{pa-px}.\sin\overline{it-qx+F}\}$$

where $\tan E=\frac{\sin 2qa}{\varepsilon^{-2pa}+\cos 2qa}$, $\tan F=\frac{\sin 2qa}{\varepsilon^{2pa}+\cos 2qa}$, and therefore $E+F=2qa$.

Putting the quantity within the brackets under the form,

$$\cos it\times\{\varepsilon^{px-pa}.\sin\overline{qx-E}-\varepsilon^{pa-px}.\sin\overline{qx-F}\}+\sin it\times\{\varepsilon^{px-pa}.\cos\overline{qx-E}+\varepsilon^{pa-px}.\cos\overline{qx-F}\}$$

$$=P.\cos it+Q.\sin it=\sqrt{P^2+Q^2}.\left\{\frac{P}{\sqrt{(P^2+Q^2)}}\cos it+\frac{Q}{\sqrt{(P^2+Q^2)}}\sin it\right\},$$

and making $\frac{Q}{P}=\tan D$, this becomes

$$\sqrt{P^2+Q^2}.\cos\overline{it-D};$$

and, substituting for P and Q,

$$K=A\sqrt{\frac{\varepsilon^{2px-2pa}+\varepsilon^{2pa-2px}+2\cos\overline{2qa-2qx}}{\varepsilon^{2pa}+\varepsilon^{-2pa}+2\cos 2qa}}\times\cos\overline{it-D}.$$

(334.) At any given point of the river, the greatest elevation or depression of the water is the coefficient of $\cos\overline{it-D}$. This coefficient cannot, with any values of x and a, be infinite; and in this respect the result now found differs from that found in (307.) without friction. The numerator of K increases as x increases, only when $4q.\sin\overline{2qa-2qx}$ is greater than $2p\ (\varepsilon^{2pa-2px}-\varepsilon^{2px-2pa})$; which differs from the result of (307.). The time t' of high water at any place will be determined by making $t'=\frac{D}{i}$, and the reciprocal of the velocity with which the phase of high water travels up the river will be $\frac{1}{i}.\frac{dD}{dx}$. Since $\tan D=\frac{Q}{P}$, $\frac{dD}{dx}=\frac{P\frac{dQ}{dx}-Q\frac{dP}{dx}}{P^2+Q^2}$. Putting for P and Q their values, we find for the reciprocal of the velocity of the phase of high water,

$$\frac{1}{i}.\frac{q(\varepsilon^{2pa-2px}-\varepsilon^{2px-2pa})+2p.\sin\overline{2qa-2qx}}{\varepsilon^{2pa-2px}+\varepsilon^{2px-2pa}+2\cos\overline{2qa-2qx}}.$$

Wave travels up the river.

This quantity is always positive $\left(\text{for even when } 2qa-2qx=\frac{3\pi}{2}\text{, which gives the second term its greatest negative value } -2p\text{, the two first terms } =q\left(\varepsilon^{\frac{3\pi p}{2q}}-\varepsilon^{\frac{-3\pi p}{2q}}\right)=3\pi p+\&c.\right)$. Thus, in all cases, there is a wave rolling up the river. This result is different from that of (307.), as found without supposing friction.

(335.) The value of X, found in the same manner, is

$$\frac{A}{k\sqrt{(p^2+q^2)}\sqrt{(\varepsilon^{2pa}+\varepsilon^{-2pa}+2\cos 2qa)}}+\{\varepsilon^{px-pa}.\cos\overline{it+qx-G}-\varepsilon^{pa-px}.\cos\overline{it-qx-H}\},$$

when $\tan G=\frac{-p-p\varepsilon^{2pa}.\cos 2qa+q\varepsilon^{2pa}.\sin 2qa}{q+p\varepsilon^{2pa}.\sin 2qa+q\varepsilon^{2pa}.\cos 2qa}$, $\tan H=\frac{p\varepsilon^{4pa}+p\varepsilon^{2pa}.\cos 2qa+q\varepsilon^{2pa}.\sin 2qa}{-q\varepsilon^{4pa}+p\varepsilon^{2pa}.\sin 2qa-q\varepsilon^{2pa}.\cos 2qa}$.

Putting the quantity within the brackets, or

$$\cos it\times(\varepsilon^{px-pa}.\cos\overline{qx-G}-\varepsilon^{pa-px}.\cos\overline{qx+H})-\sin it\times(\varepsilon^{px-pa}.\sin\overline{qx-G}+\varepsilon^{pa-px}.\sin\overline{qx+H}),$$

into the form

$$P'.\cos it-Q'.\sin it=\sqrt{P'^2+Q'^2}.\cos\overline{it+D'},\ \text{where } \tan D'=\frac{Q'}{P'},$$

and remarking that $H-G=-2qa$, the expression for X becomes

$$\frac{A}{k}\sqrt{\frac{\varepsilon^{2pa-2px}+\varepsilon^{2px-2pa}-2\cos\overline{2qa-2qx}}{(p^2+q^2)(\varepsilon^{2pa}+\varepsilon^{-2pa}+2\cos 2qa)}}\times\cos\overline{it+D'}.$$

The time at which, for any given place, the water has its greatest horizontal displacement up the river (or the time when the flow ceases and the ebb commences) is therefore $-\frac{D'}{i}$. But we have found for the time of high water $\frac{D}{i}$. Therefore the end of flow follows high water by $-\frac{1}{i}(D'+D)$.

Now
$$\tan(D'+D)=\frac{P'Q+PQ'}{PP'-QQ'}=\frac{-(\varepsilon^{2pa-2px}-\varepsilon^{2px-2pa})+2\sin\overline{2qa-2qx}.\tan\overline{E-G}}{(\varepsilon^{2pa-2px}-\varepsilon^{2px-2pa})\tan\overline{E-G}+2\sin\overline{2qa-2qx}}.$$

Putting for tan E and tan G their values, it is easily found that $\tan\overline{E-G}=\frac{p}{q}$; therefore
$$\tan(-D'-D)=\frac{q(\varepsilon^{2pa-2px}-\varepsilon^{2px-2pa})-2p.\sin\overline{2qa-2qx}}{p(\varepsilon^{2pa-2px}-\varepsilon^{2px-2pa})+2q.\sin\overline{2qa-2qx}}.$$

End of flow follows high water very soon.

Both numerator and denominator of this expression are positive, and therefore the end of flow *follows* high water. But near the mouth of the river $\varepsilon^{2pa-2px}-\varepsilon^{2px-2pa}$ is reduced to $\varepsilon^{2pa}-\varepsilon^{-2pa}$ nearly, which is large, and the numerator is therefore large, or the end of flow follows high water by a considerable time. Near the barrier, $\varepsilon^{2pa-2px}-\varepsilon^{2px-2pa}$ becomes $4(pa-px)$ nearly, and $\sin\overline{2qa-2qx}$ becomes $2qa-2qx$ nearly, and the numerator is therefore very small, or the end of flow follows the high water very closely.

Tides in a canal bounded at both ends, considering friction.

(336.) Problem.—The external force $H.\sin\overline{it-mx}$ acts upon the waters of a canal which is bounded at both ends: to find the motion of the water, taking friction into account.

Here we must use the general solution of (321). It gives
$$X=L.\cos\overline{it-mx}+M.\sin\overline{it-mx}+\varepsilon^{px}\{C.\cos\overline{it-qx}+C'.\sin\overline{it+qx}\}+\varepsilon^{-px}\{C''.\cos\overline{it-qx}-C'''.\sin\overline{it-qx}\};$$
where L, M, p, q, are the constants whose values are to be found in (320.), and where C, C′, C″, C‴, are arbitrary. Let α and β be the two values of x at the boundaries of the canal. Then the conditions by which the values of C, C′, C″, C‴, are to be determined are that, for all values of t, $X=0$ when $x=\alpha$, and when $x=\beta$.

(337.) The elimination presents no difficulty, and leads to the following expression. Let $\varepsilon^{2p\alpha-2p\beta}-2\cos\overline{2q\alpha-2q\beta}+\varepsilon^{2p\beta-2p\alpha}=B$; then X=
$$\begin{aligned}
&L\cos\overline{it-mx}+M\sin\overline{it-mx}\\
&+\frac{L}{B}(-\varepsilon^{px+p\alpha-2p\beta}.\cos\overline{it+qx-m\alpha-q\alpha}+\varepsilon^{px-p\beta}.\cos\overline{it+qx-m\beta+q\beta-2q\alpha}+\varepsilon^{px-p\alpha}.\cos\overline{it+qx-m\alpha+q\alpha-2q\beta}\\
&\qquad-\varepsilon^{px-2p\alpha+p\beta}\cos\overline{it+qx-m\beta-q\beta})\\
&+\frac{M}{B}(-\varepsilon^{px+p\alpha-2p\beta}.\sin\overline{it+qx-m\alpha-q\alpha}+\varepsilon^{px-p\beta}.\sin\overline{it+qx-2q\alpha-m\beta+q\beta}+\varepsilon^{px-p\alpha}.\sin\overline{it+qx-m\alpha+q\alpha-2q\beta}\\
&\qquad-\varepsilon^{px-2p\alpha+p\beta}.\sin\overline{it+qx-m\beta-q\beta})\\
&+\frac{L}{B}(-\varepsilon^{-px-p\alpha+2p\beta}.\cos\overline{it-qx-m\alpha+q\alpha}+\varepsilon^{-px+p\beta}.\cos\overline{it-qx+2q\alpha-m\beta-q\beta}+\varepsilon^{-px+p\alpha}.\cos\overline{it-qx-m\alpha-q\alpha+2q\beta}\\
&\qquad-\varepsilon^{-px+2p\alpha-p\beta}.\cos\overline{it-qx-m\beta+q\beta})\\
&+\frac{M}{B}(-\varepsilon^{-px-p\alpha+2p\beta}.\sin\overline{it-qx-m\alpha+q\alpha}+\varepsilon^{-px+p\beta}.\sin\overline{it-qx+2q\alpha-m\beta-q\beta}+\varepsilon^{-px+p\alpha}.\sin\overline{it-qx-m\alpha-q\alpha+2q\beta}\\
&\qquad-\varepsilon^{-px+2p\alpha-p\beta}.\sin\overline{it-qx-m\beta+q\beta})
\end{aligned}$$
from which the expression for K will readily be inferred by observing that $K=-k\frac{dX}{dx}$; and that
$$-k\frac{d}{dx}(\varepsilon^{px+a}.\cos\overline{b+qx})=-k.\varepsilon^{px+a}.(p\cos\overline{b+qx}-q\sin\overline{b+qx})=-k\sqrt{p^2+q^2}.\varepsilon^{px+a}.\cos\overline{b+qx+c},\text{ where }\tan c=\frac{q}{p}.$$
The application of c is the same throughout (since $-p$ is accompanied by $-q$); but for $-p$, the sign of the multiplier $\sqrt{p^2+q^2}$ must be changed.

(338.) The purport of this expression will be best understood by examining the state of motion of the water at the middle of the canal and at one end, its length being supposed considerable. Suppose $\alpha>\beta$; the value of the divisor B will be nearly $\varepsilon^{2p\alpha-2p\beta}$. First suppose $x=\frac{\alpha+\beta}{2}$; then $\varepsilon^{px+p\alpha-2p\beta}=\varepsilon^{\frac{3p}{2}(\alpha-\beta)}$; when divided by B the quotient will be $\varepsilon^{-\frac{p}{2}(\alpha-\beta)}$; and as $\alpha-\beta$ is large, this term will be small. In like manner all the other terms will be small; and thus, near the middle of the canal, the expressions will be reduced to their first terms,
$$X=L.\cos\overline{it-mx}+M.\sin\overline{it-mx},\qquad K=-kmL.\sin\overline{it-mx}+kmM.\cos\overline{it-mx},$$
which are the same as if the canal were indefinitely long. Secondly, suppose $x=\alpha$; then $\varepsilon^{px+p\alpha-2p\beta}=\varepsilon^{2p\alpha-2p\beta}$; when divided by B the quotient is 1; this term therefore is sensible; but no other term is in the same predicament. Hence, near the end of the canal, we have only to consider the following terms in X;

The tidal motion is greater at the ends than in the middle.

$$L.\cos\overline{it-mx}+M.\sin\overline{it-mx}-\frac{L}{B}\varepsilon^{px+p\alpha-2p\beta}.\cos\overline{it+qx-m\alpha-q\alpha}-\frac{M}{B}\varepsilon^{px+p\alpha-2p\beta}.\sin\overline{it+qx-m\alpha-q\alpha};$$
from which (remarking that p is small and q is not small),

$$K=-k\frac{dX}{dx}=-kmL.\sin\overline{it-mx}+kmM.\cos\overline{it-mx}-\frac{kqL}{B}\varepsilon^{px+p\alpha-2p\beta}.\sin\overline{it+qx-m\alpha-q\alpha}$$
$$+\frac{kqM}{B}\varepsilon^{px+p\alpha-2p\beta}.\cos\overline{it+qx-m\alpha-q\alpha}.$$

Putting α for x and $\varepsilon^{2p\alpha-2p\beta}$ for B, this becomes

$$K=-kL\,(m+q).\sin\overline{it-m\alpha}+kM\,(m+q).\cos\overline{it-m\alpha},$$

or the vertical tide at the end of the canal is greater than that in the middle in the proportion of $m+q : m$.

A different form of arbitrary function sometimes necessary

(339.) The solution which applied to the several Problems which we have just terminated was founded essentially upon the assumption that the motions of the water recur with the same magnitude when it has changed by 2π. But it may happen that, even if there are oscillations, they may not recur with the same magnitude, but may continually decrease. This assumption will not affect that part of the solution in (321.) which depends on $\sin\overline{it-mx}$ and $\cos\overline{it-mx}$; but it will affect the terms which are multiplied by arbitrary constants. We shall now undertake this investigation. To find whether the equation $\frac{d^2X}{dt^2}=-f\frac{dX}{dt}+v^2\frac{d^2X}{dx^2}$ can be satisfied by the assumption $X=C.\varepsilon^{rt+sx}.\cos\overline{ut+wx+C'}$.

(340.) Differentiating, we have

$$\frac{dX}{dt}=C.\varepsilon^{rt+sx}\left(r.\cos\overline{ut+wx+C'}-u.\sin\overline{ut+wx+C'}\right)$$
$$\frac{d^2X}{dt^2}=C.\varepsilon^{rt+sx}\left((r^2-u^2).\cos\overline{ut+wx+C'}-2ru.\sin\overline{ut+wx+C'}\right)$$
$$\frac{d^2X}{dx^2}=C.\varepsilon^{rt+sx}\left((s^2-w^2).\cos\overline{ut+wx+C'}-2sw.\sin\overline{ut+wx+C'}\right)$$

Substituting in the equation,

$$(r^2-u^2).\cos\overline{ut+wx+C'}-2ru.\sin\overline{ut+wx+C'}=$$
$$-fr.\cos\overline{ut+wx+C'}+fu.\sin\overline{ut+wx+C'}+v^2(s^2-w^2).\cos\overline{ut+wx+C'}-2v^2sw.\sin\overline{ut+wx+C'}.$$

As this is to be true for all values of t and of x, it must hold for the separated coefficients of the sine and cosine; or

$$r^2-u^2=-fr+v^2(s^2-w^2);\qquad -2ru=fu-2v^2sw,$$

leaving C and C′ indeterminate. When the values of two of the quantities r, s, v, w, are fixed by the conditions of any Problem, the values of the other two can be found from these equations.

Tides on a current river, considering friction.

(341.) Problem.—A river of indefinite length runs on a declivity towards a tidal sea: to investigate the motion of its waters; its mean depth being uniform, and friction being taken into account.

Take for the axis of x a line drawn along the bottom of the river. It will be inclined to the horizon by a very small angle α. Resolve the force of gravity into one part perpendicular to the bottom of the river and one part parallel to it. The former will not sensibly differ from g; the latter will $=g\sin\alpha$. And (measuring x, as in all other cases, up the river) this force tends to diminish x, or is $=-g\sin\alpha$. Hence the general equation becomes

$$\frac{d^2X}{dt^2}=-g\sin\alpha-f\frac{dX}{dt}+v^2\frac{d^2X}{dx^2}.$$

A solution of this is, $X=-\frac{g\sin\alpha}{f}t$, which we will call $-bt$. (It is evident that this term alone denotes that the water will run towards the sea with a uniform velocity.) The most general solution then, which is adapted to our purposes, is

$$X=-bt+\text{ the general solution of the equation }\frac{d^2X}{dt^2}=-f\frac{dX}{dt}+v^2\frac{d^2X}{dx^2},$$

or $$X=-bt+C\varepsilon^{rt+sx}.\cos(ut+wx+C'),$$

where $$r^2-u^2=-fr+v^2(s^2-w^2),\qquad -2ru=fu-2v^2sw;$$

from which $$K=-k\frac{dX}{dx}=-k.C.\varepsilon^{rt+sx}.(s.\cos\overline{ut+wx+C'}-w.\sin\overline{ut+wx+C'}).$$

(342.) Let x' be the ordinate of any place upon the bank of the river, to which the situation of a particle of water corresponds at any instant. Then $x'=x+X$ nearly, or $x=x'-X$; and, as the only term of X which becomes large is $-bt$, we may take $x=x'+bt$. This makes $rt+sx=(r+bs)\,t+sx'$, $ut+wx=(u+bw)\,t+wx'$; and the expression for K corresponding to the place x' on the river bank is

$$K=-k.C.\varepsilon^{(r+bs)t+sx'}\left(s.\cos\overline{(u+bw)\,t+wx'+C'}-w.\sin\overline{(u+bw)\,t+wx'+C'}\right).$$

At the mouth of the river, $x'=0$, and this expression becomes

$$-kC.\varepsilon^{(r+bs)t}.\left(s.\cos\overline{(u+bw)\,t+C'}-w.\sin\overline{(u+bw)\,t+C'}\right).$$

But the law of the rise of the sea is assumed to be A. sin $\overline{nt+B}$. Making these expressions coincide, we have

$$r+bs=0, \qquad u+bw=n,$$

$$-kCs.\cos(C'-B)+kwC.\sin(C'-B)=0, \qquad kCs.\sin(C'-B)+kCw.\cos(C'-B)=A.$$

The two last equations give only the values of C and C′. Combining the two preceding them with the two found in (341.) we have four equations for the four quantities r, s, u, w; and eliminating r, u, w, we obtain

$$-(v^2-b^2)s^2+(v^2-b^2)\left(\frac{fn-2bns}{2(v^2-b^2)s+fb}\right)^2-fbs+\frac{2bfn^2-4b^2n^2s}{2(v^2-b^2)s+fb}-n^2=0;$$

a biquadratic equation for s. Then $w=\frac{fn-2bns}{2(v^2-b^2)\,s+fb}$. Without going through the solution, we will only remark, that when b is small, a solution may be obtained which will allow a negative value $-s'=\frac{-f}{2v-2b}$ to be taken for s; that then w has a negative value $-w'=\frac{-1}{v-b}$; and that the elevation of the water is then expressed by

$$A.\varepsilon^{-s'x'}.\sin\overline{nt-w'x'+B}.$$

This elevation is above the mean level of the river at that point. But the mean level there is higher than that of the sea by $x'.\sin\alpha$. Therefore the surface of the river is higher than the mean level of the sea by

$$x'\sin\alpha+A.\varepsilon^{-s'x'}.\sin\overline{nt-w'x'+B}.$$

Low water in the river may be higher than high water in the sea.

(343.) At low water at any place, $\sin\overline{nt-w'x+B}=-1$, and therefore the elevation of low water at any place, above the mean level of the sea, is $x'\sin\alpha-A.\varepsilon^{-s'x'}$. The elevation of the high tide of the sea above its mean level is $+A$. The low water then at a point up the river will be higher than the high water of the sea if $x'\sin\alpha-A\varepsilon^{-s'x'}$ be greater than A. As, by increasing x', $x'\sin\alpha$ may be made as great as we please, and $A\varepsilon^{-s'x'}$ as little as we please, it is evident that a point may be found where this condition is satisfied. The circumstance that low water on a tidal river may be higher than high water on the sea, paradoxical as it may appear, is therefore a simple consequence of theory.

(344.) We shall conclude with the following Problem. The water being in the state of undulation represented by $X=L.\cos\overline{it-mx}$, the forces which have maintained it in that state suddenly cease when $t=\alpha$: to find the subsequent motion of the water.

Motion of water supposing the tidal forces to cease.

(345.) It is evident that there can be no such multiplier as ε^{sx} in the expression for X, since there is none such when $t=\alpha$. Let therefore

$$X=\Sigma.C.\varepsilon^{rt}.\cos(ut+wx)+\Sigma.C'.\varepsilon^{rt}.\sin(ut+wx).$$

It is plain that w must $=\pm m$. This restricts the assumption to

$$X=C.\varepsilon^{rt}.\cos(ut+mx)+E.\varepsilon^{rt}.\cos(ut-mx)+C'.\varepsilon^{rt}.\sin(ut+mx)+E'.\varepsilon^{rt}.\sin(ut-mx).$$

We have first to find r and u. The general equations become $r^2-u^2=-fr-v^2m^2$; $-2ru=fu$. From the second, $r=-\frac{f}{2}$. Substituting in the first, $\frac{f^2}{4}-\frac{f^2}{2}+v^2m^2=u^2$, or $u=\sqrt{\left(v^2m^2-\frac{f^2}{4}\right)}$. Then the special conditions to be satisfied are, that, when $t=\alpha$, X must $=L.\cos it.\cos mx+L.\sin it.\sin mx$, and $\frac{dX}{dt}$ must $=-iL.\sin it.\cos mx+iL.\cos it.\sin mx$; or X must then $=L\cos i\alpha.\cos mx+L\sin i\alpha.\sin mx$, and $\frac{dX}{dt}$ must then $=-iL.\sin i\alpha.\cos mx+iL\cos i\alpha.\sin mx$. Comparing these with the quantities deduced from the assumed expression, we have

$$\varepsilon^{r\alpha}\cos u\alpha\,(C+E)+\varepsilon^{r\alpha}\sin u\alpha\,(C'+E')=L\cos i\alpha$$

$$\varepsilon^{r\alpha}\sin u\alpha\,(E-C)+\varepsilon^{r\alpha}\cos u\alpha\,(C'-E')=L\sin i\alpha$$

$$\varepsilon^{r\alpha}(r\cos u\alpha-u\sin u\alpha).(C+E)+\varepsilon^{r\alpha}(r\sin u\alpha+u\cos u\alpha).(C'+E')=-iL\sin i\alpha$$

$$\varepsilon^{r\alpha}(r\sin u\alpha+u\cos u\alpha).(E-C)+\varepsilon^{r\alpha}(r\cos u\alpha-u\sin u\alpha).(C'-E')=\quad iL\cos i\alpha.$$

From the first and third, C + E and C′ + E′ are found; from the second and fourth, E − C and C′ − E′ are found; and from these C, E, C′, E′, are found. Then the expression for X is

The motions will diminish rapidly.

$$\varepsilon^{-\frac{ft}{2}}.\left\{C.\cos\overline{ut+mx}+E.\cos\overline{ut-mx}+C'.\sin\overline{ut+mx}+E'.\sin\overline{ut-mx}\right\}.$$

The multiplier $\varepsilon^{-\frac{ft}{2}}$ shows that the oscillations will diminish rapidly and will therefore soon become insensible.

Tides and Waves.

(346.) The functions $\varepsilon^{\pm pt}.\overset{\sin}{\underset{\cos}{}}qx$, $\varepsilon^{rt}\overset{\sin}{\underset{\cos}{}}(ut\pm mx)$, $\varepsilon^{rt+sx}.\overset{\cos}{\underset{\sin}{}}(ut+wx)$, are in their meaning and application exactly analogous to the simpler expressions which we have used to represent the free tide-wave in (291.) and the articles which follow it.

Subsection 7.—Theory of Waves upon Open Seas.

Equations for water of three dimensions.

(347.) We shall now point out the form which the investigation assumes when the motion of water in space of three dimensions is considered.

Let z be the original horizontal co-ordinate of any particle measured at right angles to x, and Z the displacement of that particle in the direction of z at the time t, y being the vertical ordinate as before. Then, nearly as in (145.), we shall find the following equation of continuity:

$$\mathrm{Y}=\Xi\frac{d\eta}{dx}+\zeta\frac{d\eta}{dz}-\int_y\left(\frac{d\mathrm{X}}{dx}+\frac{d\mathrm{Z}}{dz}\right)(\text{from }\eta\text{ to }y),$$

where ζ is the value of Z corresponding to the bottom.

And, nearly as in (147.), we shall find the two following equations of equal pressure (no external force being supposed to act):

$$\frac{d^2\mathrm{X}}{dt^2}=\frac{d}{dx}\left\{-g\mathrm{K}+\int_y\frac{d^2\mathrm{Y}}{dt^2}\ (\text{from }k\text{ to }y)\right\},$$

$$\frac{d^2\mathrm{Z}}{dt^2}=\frac{d}{dz}\left\{-g\mathrm{K}+\int_y\frac{d^2\mathrm{Y}}{dt^2}\ (\text{from }k\text{ to }y)\right\}.$$

We shall not attempt to solve these equations, except in the case where the depth is uniform, and where the oscillations are of uniform period (as in all the preceding investigations). And, even with these limitations, we shall find our solution exceedingly restricted.

(348.) Assuming, then, the same function of y as that which has occurred in the preceding investigations, (the propriety of which will be proved by its satisfying the equation so as to make the solution possible as regards the other co-ordinates, with the utmost generality,) and assuming the same relation between m and n, and making our expressions multiply $\cos nt$. (the same investigation applying in all respects to $\sin nt$,) let us suppose

$$\mathrm{X}=\mathrm{U}.(\varepsilon^{my}+\varepsilon^{-my}).\cos nt,$$
$$\mathrm{Z}=\mathrm{V}.(\varepsilon^{my}+\varepsilon^{-my}).\cos nt,$$

U and V being functions of x and z only.

Then $$\mathrm{Y}=-\int_y\left(\frac{d\mathrm{U}}{dx}+\frac{d\mathrm{V}}{dz}\right).(\varepsilon^{my}+\varepsilon^{-my}).\cos nt=\frac{1}{m}.\left(\frac{d\mathrm{U}}{dx}+\frac{d\mathrm{V}}{dz}\right).(-\varepsilon^{my}+\varepsilon^{-my}).\cos nt.$$

And $$\frac{d^2\mathrm{Y}}{dt^2}=\frac{n^2}{m}.\left(\frac{d\mathrm{U}}{dx}+\frac{d\mathrm{V}}{dz}\right).(\varepsilon^{my}-\varepsilon^{-my}).\cos nt:$$

therefore $$-\int_y\frac{d^2\mathrm{Y}}{dt^2}(y\text{ to }k)=\frac{n^2}{m^2}\left(\frac{d\mathrm{U}}{dx}+\frac{d\mathrm{V}}{dz}\right).(-\varepsilon^{mk}-\varepsilon^{-mk}+\varepsilon^{my}+\varepsilon^{-my}).\cos nt.$$

Also $$-g\mathrm{K}=\frac{g}{m}\left(\frac{d\mathrm{U}}{dx}+\frac{d\mathrm{V}}{dz}\right)(\varepsilon^{mk}-\varepsilon^{-mk}).\cos nt.$$

Therefore $-g\mathrm{K}-\int_y\frac{d^2\mathrm{Y}}{dt^2}(y\text{ to }k)$, having regard to the equation $n^2(\varepsilon^{mk}+\varepsilon^{-mk})=gm(\varepsilon^{mk}-\varepsilon^{-mk})$, becomes

$$\frac{n^2}{m^2}\left(\frac{d\mathrm{U}}{dx}+\frac{d\mathrm{V}}{dz}\right)(\varepsilon\ \ +\varepsilon^{-my}).\cos nt.$$

Also $$\frac{d^2\mathrm{X}}{dt^2}=-n^2\mathrm{U}.(\varepsilon^{my}+\varepsilon^{-my}).\cos nt,\qquad\frac{d^2\mathrm{Z}}{dt^2}=-n^2\mathrm{V}.(\varepsilon^{my}+\varepsilon^{-my}).\cos nt.$$

Hence the equations of equal pressure become

$$-n^2\mathrm{U}.(\varepsilon^{my}+\varepsilon^{-my}).\cos nt=\frac{n^2}{m^2}.\frac{d}{dx}\left(\frac{d\mathrm{U}}{dx}+\frac{d\mathrm{V}}{dz}\right).(\varepsilon^{my}+\varepsilon^{-my}).\cos nt,$$

$$-n^2\mathrm{V}.(\varepsilon^{my}+\varepsilon^{-my}).\cos nt=\frac{n^2}{m^2}.\frac{d}{dz}\left(\frac{d\mathrm{U}}{dx}+\frac{d\mathrm{V}}{dz}\right)(\varepsilon^{my}+\varepsilon^{-my}).\cos nt,$$

or

$$m^2\mathrm{U}+\frac{d}{dx}\left(\frac{d\mathrm{U}}{dx}+\frac{d\mathrm{V}}{dz}\right)=0$$

$$m^2V+\frac{d}{dz}\left(\frac{dU}{dx}+\frac{dV}{dz}\right)=0;$$

equations which are of the most general kind for the determination of U and V, and which are cleared of y and t.

Partial differential equation whose solution is necessary.

(349.) If we differentiate the first of these equations with regard to x, and the second with regard to z, and then add them together, and if we put W for $\frac{dU}{dx}+\frac{dV}{dz}$, we find

$$m^2W+\frac{d^2W}{dx^2}+\frac{d^2W}{dz^2}=0.$$

It will be remarked that W is proportional to the factor of cos nt in the expression for K, so that, if we could solve this equation, we should at once obtain the expression for the elevation of the wave (supposed stationary) at every point. And as $m^2U=-\frac{dW}{dx}$, $m^2V=-\frac{dW}{dz}$, all the circumstances of the motion of the water would be completely known.

Form of solution which would be desirable.

(350.) There are, however, great difficulties in the solution of this equation. The most convenient form for our purposes would be $W=P\cos Q$, P and Q being functions of x and z. If we could obtain this, we could also obtain another $W'=P\sin Q$; and combining the former of these as factor with cos nt and the latter with sin nt, we should have for the value of K

$$-\frac{1}{m}(\varepsilon^{mk}-\varepsilon^{-mk})\,P\,(\cos Q\,.\,\cos nt+\sin Q\,.\,\sin nt)$$
$$=-\frac{1}{m}\,(\varepsilon^{mk}-\varepsilon^{-mk})\,.P.\cos\overline{nt-Q},$$

and the equation determining the position of the ridge of wave at any time t would be

$$Q=\text{constant}.$$

But the general solution of the equation in this form does not appear practicable.

(351.) There are two limited solutions (and perhaps others) which may be easily shown to satisfy the equation. The first may be interpreted partially; the second completely.

1st. Let $W=\phi(r)$, where $r=\sqrt{\{(x-a)^2+(z-b)^2\}}$. Then $\frac{dW}{dx}=\frac{dW}{dr}\,.\,\frac{dr}{dx}=\phi'(r)\,.\,\frac{x-a}{r}$: $\frac{d^2W}{dx^2}=\frac{\phi'(r)}{r}+\overline{x-a}\,.\left(\frac{\phi''(r)}{r}-\frac{\phi'(r)}{r^2}\right).\frac{dr}{dx}=\frac{\phi'(r)}{r}+\left(\phi''(r)-\frac{\phi'(r)}{r}\right)\frac{(x-a)^2}{r^2}$. Similarly $\frac{d^2W}{dz^2}=\frac{\phi'(r)}{r}+\left(\phi''(r)-\frac{\phi'(r)}{r}\right)\frac{(z-b)^2}{r^2}$. Substituting in the equation $m^2W+\frac{d^2W}{dx^2}+\frac{d^2W}{dz^2}=0$, we obtain

$$m^2\phi(r)+\frac{\phi'(r)}{r}+\phi''(r)=0.$$

Solution expressing annular waves.

The solution of this equation is the following, in which the letter S is put to denote the definite integral between the limits 0 and π:

$$\phi(r)=C.S_v\cos(mr\cos v)+C'.S_v\{\cos(mr\cos v).\log(r\sin^2 v)\}$$

where v is a new variable, introduced solely for the purpose of forming a function which is to be integrated, and disappearing entirely from the result, which is the sum of two integrals between definite limits. But the values of the two definite integrals cannot be expressed by means of any usually tabulated quantities, and must be computed numerically. (A table of the values of the first integral, to a small extent, will be found in the *Philosophical Magazine* for January, 1841, page 7.) Putting S′ and S″ for the two integrals, corresponding to a given value of r, the most general form for W or $\phi(r)$ will be

$$E'.S'.\cos(nt+F')+E''.S''.\sin(nt+F''),$$

E′, E″, F′, and F″, being arbitrary constants. It is evident that this form of W expresses a series of circular waves converging to or diverging from the point whose co-ordinates are a, b.

(352.) The equation determining W will also be satisfied by the sum of any number of functions $\phi_{,}(r_{,})$, $\phi_{,,}(r_{,,})$, &c., where $r_{,}=\sqrt{\{(x-a_{,})^2+(z-b_{,})^2\}}$, $r_{,,}=\sqrt{\{(x-a_{,,})^2+(z-b_{,,})^2\}}$, &c., and where each of the functions $\phi_{,}$, $\phi_{,,}$ &c. satisfies the equation $m^2\phi(r)+\frac{\phi'(r)}{r}+\phi''(r)=0$. That is, there may be any number of systems of such circular waves, each system converging to or diverging from an arbitrary centre.

Solution expressing parallel waves.

(353.) 2d. Let $W=A.\cos(ax+bz)$: on substituting we obtain $m^2-a^2-b^2=0$ as the only condition. The same holds if we assume $W'=A.\sin(ax+bz)$: combining the former as factor with cos nt and the latter with sin nt, we find for the elevation of any part of the water

$$-\frac{1}{m}(\varepsilon^{mk}-\varepsilon^{-mk})\,\mathrm{A}.\cos(nt-ax-bz).$$

The positions of the ridges of waves at the time t are determined by making $ax+bz=nt\pm\pi$, or $=nt\pm3\pi$, or $=nt\pm5\pi$, &c. The ridges, therefore, are all parallel to the line whose equation is $ax+bz=0$. If from the origin of co-ordinates we draw a perpendicular upon one of the ridges, its length is found to be $\frac{nt\pm\pi}{\sqrt{a^2+b^2}}$, or $\frac{nt\pm3\pi}{\sqrt{a^2+b^2}}$, &c., that is $\frac{nt\pm\pi}{m}$, $\frac{nt\pm3\pi}{m}$, &c. The distance, therefore, from one ridge to the next is $\frac{2\pi}{m}$: and the velocity with which each ridge travels on is $\frac{n}{m}$.

(354.) The equation determining W will also be satisfied by the sum of any number of expressions $\mathrm{A}_{,}\cos(nt-a_{,}x-b_{,}z)$, $\mathrm{A}_{,,}\cos(nt-a_{,,}x-b_{,,}z)$, &c., provided that $a_{,}^2+b_{,}^2=m^2$: $a_{,,}^2+b_{,,}^2=m^2$, &c. Each of these denotes a series of parallel waves with the interval $\frac{2\pi}{n}$ between one wave and the next, the waves being parallel to any arbitrary line. And the circumstance of the equation being satisfied by the algebraic sum of the different solutions indicates that the elevation of the water at the intersection of any ridges will be the algebraic sum of the elevations corresponding to each ridge. The same remark applies to the sum of the solutions representing circular waves, or to the sum of any number of solutions of both these kinds or of any other kinds.

Reflexion of parallel waves from a straight boundary.

(355.) Now suppose the water to be terminated on one side by a straight boundary: let the co-ordinates be so taken that the boundary may be parallel to z; let the corresponding value of x be c; then, whatever be the value of z while $x=c$, the motion of the particles of water in the direction of x must at all times be 0. For, all the particles which are once in contact with the boundary, that is, all those for which $x=c$, must remain in contact with the boundary; that is, they must always have $x=c$; and, therefore, X must $=0$. It is plain that this condition cannot be satisfied if we confine the expression for the elevation to the single term $-\frac{1}{m}(\varepsilon^{mk}-\varepsilon^{-mk})\,\mathrm{A}.\cos(nt-ax-bz)$. For then $\mathrm{W}=\mathrm{A}.\cos(ax+bz)$, $\mathrm{W}'=\mathrm{A}.\sin(ax+bz)$: $\mathrm{U}=-\frac{1}{m^2}.\frac{d\mathrm{W}}{dx}$ $=\frac{a}{m^2}\mathrm{A}.\sin(ax+bz)$, $\mathrm{U}'=\frac{-a}{m^2}\mathrm{A}.\cos(ax+bz)$; and the complete value of $\mathrm{X}=\mathrm{U}.\cos nt+\mathrm{U}'.\sin nt=$ $-\frac{a\mathrm{A}}{m^2}\sin(nt-ax-bz)$; which is not generally $=0$ when $x=c$. But it may be made to satisfy the required condition by adding another term which itself satisfies the original equation $m^2\mathrm{W}+\frac{d^2\mathrm{W}}{dx^2}+\frac{d^2\mathrm{W}}{dz^2}=0$. For let the values, as increased by the new terms, be

$$\mathrm{W}=\mathrm{A}\cos(ax+bz)+\mathrm{A}\cos(2ac-ax+bz),$$
$$\mathrm{W}'=\mathrm{A}\sin(ax+bz)+\mathrm{A}\sin(2ac-ax+bz);$$

then the new value of U or $-\frac{1}{m^2}\frac{d\mathrm{W}}{dx}$ is

$$\frac{a\mathrm{A}}{m^2}\sin(ax+bz)-\frac{a\mathrm{A}}{m^2}\sin(2ac-ax+bz);$$

and that of U′ is

$$-\frac{a\mathrm{A}}{m^2}\cos(ax+bz)+\frac{a\mathrm{A}}{m^2}\cos(2ac-ax+bz):$$

and, therefore, the new value of X or $\mathrm{U}.\cos nt+\mathrm{U}'.\sin nt$ is

$$-\frac{a\mathrm{A}}{m^2}\sin(nt-ax-bz)+\frac{a\mathrm{A}}{m^2}\sin(nt-2ac+ax-bz);$$

and upon making $x=c$ this expression becomes

$$-\frac{a\mathrm{A}}{m^2}\sin(nt-ac-bz)+\frac{a\mathrm{A}}{m^2}\sin(nt-ac-bz)$$

which $=0$ whatever be the values of x and t. Thus we find that the existence of one series of waves and the assumption of a rectilinear boundary imply the existence of another system of waves, whose elevation will be represented by substituting in the expression for K the additional terms of W and W′, and will therefore be

$$-\frac{1}{m}(\varepsilon^{mk}-\varepsilon^{-mk}).\mathrm{A}\,\{\cos(2ac-ax+bz)\cos nt+\sin(2ac-ax+bz).\sin nt\}$$
$$=-\frac{1}{m}(\varepsilon^{mk}-\varepsilon^{-mk}).\mathrm{A}.\cos(nt-2ac+ax-bz).$$

This expression, examined in the same manner as before, represents a series of parallel waves, in which the equation to the ridge of every one is $-ax+bz=nt-2ac\pm\pi$, &c., and which are all parallel to the line whose equation is $-ax+bz=0$. The ridges of the former waves were found to be parallel to the line whose equation is $ax+bz=0$. Hence the inclinations of the ridges of the two sets of waves to the boundary are equal, but they are inclined opposite ways. This is the mathematical explanation of the reflexion of waves from a straight boundary.

(356.) The whole elevation of the waves is

$$-\frac{1}{m}(\varepsilon^{mk}-\varepsilon^{-mk})\,\mathrm{A}\,(\cos\overline{nt-ax-bz}+\cos\overline{nt-2ac+ax-bz});$$

which, when $x=c$, becomes

$$-\frac{2}{m}(\varepsilon^{mk}-\varepsilon^{-mk})\,\mathrm{A}.\cos\overline{nt-ac-bz}.$$

The coefficient, therefore, for the undulation at contact with the boundary, is twice as great as that of an unreflected wave.

Reflexion of waves of any kind from a straight boundary.

(357.) In the same manner, if we take the expression for W in its most general state, putting it in the form $\phi(x,z)$, we may add to it another term $\phi(\overline{2c-x},z)$, which will satisfy the equation $m^2\mathrm{W}+\frac{d^2\mathrm{W}}{dx^2}+\frac{d^2\mathrm{W}}{dz^2}=0$ equally well, and which in the expression for X adds the new term $+\phi'(\overline{2c-x},z)$ to the former term $-\phi'(x,z)$, the sum of which is 0 when $x=c$. And, as above, the expression for K is

$$-\frac{1}{m}(\varepsilon^{mk}-\varepsilon^{-mk})\{\phi(x,z)+\phi(\overline{2c-x},z)\},$$

which, when $x=c$, becomes $-\frac{2}{m}(\varepsilon^{mk}-\varepsilon^{-mk}).\phi(c,z)$, or is double that at the same point in an unreflected wave. The additional term for W being $\phi(c+\overline{c-x},z)$, and the original term being $\phi(c+\overline{x-c},z)$, it is evident that the system of waves represented by one expression depends on $x-c$, in the same manner in which the other depends on $c-x$, and is, therefore, a reflected system whose form is exactly similar to the form in which the original system would have proceeded if not stopped by the boundary.

(358.) Leaving for the present the consideration of the motion of the waves as determined by the differential equations, we shall consider one case in which we seem to derive some assistance from general reasoning.

Form of the crest of the wave in broad channels which are shallow near the sides.

(359.) Suppose that a tide-wave is travelling along a canal of large dimensions, and of variable depth in its cross section, the depth diminishing gradually to both shores. (We may suppose the dimensions to be such as those of the English Channel, or any similar arm of the sea.) It is evident that the investigation of (218.) does not apply here: for, on account of the shallowness of the water at the sides, the velocity of flow towards both sides to produce the elevation of water there must be comparable with, perhaps equal to, the velocity of flow at mid-channel in the direction of the canal's length. Moreover, as the slope of the bottom is exceedingly small, the waves in every part of the channel will be travelling in nearly the same manner as if the extent of sea of the same depth were infinitely great, and will therefore travel with the velocity due to that depth: and, therefore, the ridge of wave cannot possibly stretch transversely to the channel, and travel along with uniform velocity lengthways of the channel. The state of things, then, will be this: the central part of the wave will advance rapidly (171.) along the middle of the channel; the lateral parts will not advance so rapidly; and the whole ridge will assume a curved shape, its convex side preceding. When this form is once acquired, it may perhaps proceed with little alteration; for if, as in figure 18, we suppose two such curves exactly similar, but one a little in advance of the other, the space which separates the wings of the two curves, measured perpendicularly to the curves, (the direction in which that part of the wave must really travel,) is much less than the space which separates the centres of the curves, and by proper inclination may be less in any proportion; and, therefore, may represent exactly the space travelled over by the wave at that depth while the wave at the greater depth travels over the greater space. That part of the ridge of the wave which is nearest to the coast will, therefore, assume a position nearly parallel to the line of coast.

(360.) Now the wave whose ridge is nearly parallel to the coast, or which advances almost directly towards the coast, will be a wave of the same character as that treated of in (307.). For the slope of the beach adds to the surface of the sea a very insignificant quantity, as compared with the breadth of the tide-wave, and the general effect is the same as if a perpendicular cliff terminated the sea on that side. Therefore, for those parts of the sea which are near to the coasts the law of (307.) holds; namely, the greatest horizontal displacement of the particles occurs at the same time as the greatest vertical displacement; and, therefore, when the sea is rising, the water is, for some distance from the coast, flowing towards the coast, and when it is falling, the water is flowing from the coast.

(361.) In mid-channel, the motion of the water will be such as is described in (184.), &c.; that is, the water will be flowing most rapidly up the channel at the time of high water, and its motion upwards will cease when the water has dropped to its mean height.

(362.) From this there follows a curious consequence with regard to the currents at an intermediate distance from the shore, where the effects of these two motions may be conceived to be combined.

At high water the water is not flowing to or from the shore, but is flowing up the channel.

When the water has dropped to its mean elevation, the water is ebbing from the shore, but is stationary with regard to motion up or down the channel.

At low water, the water is not flowing to or from the shore, but is running down the channel.

When the water has risen to its mean height, the water is flowing to the shore, but is stationary with regard to motion up or down the channel.

Revolving motion of the tide near the shore.

(363.) Consequently, in the course of one complete tide, the direction of the current will have changed through 360°, the water never having been stationary. And the direction of the change of current will be of such a kind that, if we suppose ourselves sailing up the mid-channel, the tide-current will turn, in those parts which are on the *left* hand, in the *same* direction as the hands of a watch; and in those parts which are on the *right* hand, in the direction *opposite* to that of the hands of a watch.

(364.) Beyond this we can add little to the Theory of Waves upon a sea extended in both dimensions. But the following remarks will be found important with reference to the method of determining from observations some of the phenomena of tides.

Cotidal lines on open seas.

(365.) In tracing the progress of the tide across an extended sea, we cannot observe the different waves as we can those upon a small piece of water. We can do nothing but make observations of the time of the rise and fall of the sea at many different points along the shores of the bounding continents, or at islands in different parts of the sea: and when we have thus ascertained the absolute time of high water at many different points, if they are sufficiently numerous, we may draw lines over the surface of the sea passing through all the points at which high water takes place at the same absolute instant. These lines (adopting the word introduced into general use by the highest authority on the discussion of tide-observations) we shall call *cotidal lines*. The tracing out the cotidal lines in different seas is the greatest advance that has yet been made in the discussion of the phenomena of the tides in open seas.

The relation between the cotidal lines and the waves from which they originate is very obscure.

(366.) Now when the series of waves is single, the cotidal lines correspond exactly with the lines marking the position of the ridge of the wave at different times. But when the series of waves is compound, it may happen that the form of the cotidal lines will not present to the eye the smallest analogy with the forms of the ridges of the mingled waves. This will be seen in a simple instance.

(367.) Suppose that there are two systems of parallel waves rolling across the sea at the same time, the ridges of all the waves of one series being parallel to x, and the ridges of all the waves of the other being parallel to z. The forms of the ridges, as they might be seen by an eye placed at a sufficient distance, would be the intersecting lines represented in figure 19. The elevation of water caused by the former at the time t will be represented by $b.\cos\overline{nt-mz}$: that caused by the latter will be represented by $a.\cos\overline{nt-px}$. We have taken the same coefficient for t in both these expressions, because the recurrence of tide-waves, whether forced waves, or free waves introduced in the integration for satisfying the limiting conditions, must be periodical as the exciting cause. But the coefficients of x and z may be different: thus, for instance, one of these waves may be a forced tide-wave, and the other may be a free tide-wave, in which case the coefficients (292.) will not necessarily be the same: this is, however, immaterial to the present investigation.

(368.) The whole elevation, then, of the water at any point will be

$$a.\cos\overline{nt-px}+b.\cos\overline{nt-mz}$$

$$=(a\cos px+b\cos mz)\cos nt+(a\sin px+b\sin mz)\sin nt,$$

which has its maximum value for that point when

$$\tan nt=\frac{a\sin px+b\sin mz}{a\cos px+b\cos mz}.$$

This expression for t determines the time of high water at that place; and, therefore, the line connecting all the points at which it is high water at the same instant will be determined by making $\frac{a\sin px+b\sin mz}{a\cos px+b\cos mz}$ equal to the same quantity $\tan nt$. Giving a definite value C to the quantity nt, we have for the equation to a certain cotidal line,

$$\frac{a\sin px+b\sin mz}{a\cos px+b\cos mz}=\tan \mathrm{C},$$

from which

$$\sin\overline{mz-\mathrm{C}}=-\frac{a}{b}\sin\overline{px-\mathrm{C}}.$$

(369.) If $a=b$, this equation becomes $\sin\overline{mz-\mathrm{C}}=-\sin\overline{px-\mathrm{C}}$; whence $mz-\mathrm{C}=-px+\mathrm{C}$, or $=-px+\mathrm{C}\pm 2\pi$, or $=-px+\mathrm{C}\pm 4\pi$, &c., or $mz-\mathrm{C}=px-\mathrm{C}\pm\pi$, or $=px-\mathrm{C}\pm 3\pi$, &c. These expressions evidently represent two series of straight lines, making equal angles with the co-ordinates: one of them is stationary, (as C or nt disappears from the equation,) and its deduction from the investigation above denotes that there is no sensible tide along those lines: the other is the real system of cotidal lines. The former is represented in figure 20 by the double lines, the latter by the single lines. In drawing the latter, we have supposed C to vary successively by $\frac{\pi}{2}$ at each step.

(370.) If $a<b$, the first expression for $mz-\mathrm{C}$ is included between the arc whose sine is $\frac{a}{b}$, and the arc

whose sine is $-\frac{a}{b}$, which values $mx - C$ attains when $px - C$ is $\frac{\pi}{2} \pm 2n\pi$ and $-\frac{\pi}{2} \pm 2n\pi$. The corresponding curves for values of C varying successively by $\frac{\pi}{2}$ are represented in figure 21.

(371.) If $a > b$, the curves will be such as those represented in figure 22.

(372.) It is evident that the contemplation of these curves (more especially if a small part only of each can be traced) will not easily enable us to discover the nature of the simple interfering systems of waves from which they originate. If either system were complicated, as in (308.), the difficulty would be still greater.

SECTION V.—ACCOUNT OF EXPERIMENTS ON WAVES.

(373.) Our theory of waves, as we have remarked in the Introduction, is not the most complete that could be devised. It embraces (as we believe) every case of general interest to which mathematics are at present applicable, but it does not comprehend those special cases which have been treated at so great length by Poisson (*Mémoires de l'Institut*) and Cauchy (*Savans Etrangers*). With respect to these we may express here an opinion, borrowed from other writers, but in which we join, that as regards their physical results these elaborate treatises are entirely uninteresting; although they rank among the leading works of the present century in regard to the improvement of pure mathematics. We shall not therefore trouble ourselves with detailing the few imperfect experiments of Biot (*Mémoires de l'Institut*) and Bidone (*Turin Memoirs*) which have been made in verification of these theories.

(374.) One of the most important works that has been published, in regard to experiments as well as to the theory of Waves, is that by the two brothers Weber, entitled "*Wellenlehre auf Experimente gegründet.*" This work contains an abstract of all the theories and all the principal experiments of preceding writers that the authors had been able to collect. The points however to which we shall allude here are the experiments made by the Webers themselves. These were made with an apparatus which they call *Wellenrinne*. It is a very narrow trough with glass sides. In one instance it was 5 ft. 4 in. long, (Paris measure,) about 8 inches deep, and about ½ an inch wide; in another instance it was 6 feet long, 2½ feet deep, and a little more than an inch wide. The glass sides were properly supported by pieces of wood connected with the bottom; in the smaller, the glass sides were continuous; in the larger, the glass only occupied 6 openings in different parts of the sides, the other parts being of wood. Some experiments were made with quicksilver, and some with brandy; but the principal part were made with water containing a great number of floating particles of the same specific gravity as the water; by observing the movements of these through the glass sides, sometimes with the naked eye and sometimes with a microscope, the motions of the particles of water, even to the bottom, were easily examined. The waves of experiment were generated by plunging a glass tube into the fluid, raising the fluid into the tube by suction, and then allowing it suddenly to drop.

Weber's *Wellenrinne*.

Motion of particles floating in the water observed.

Method of determining the form of the wave.

(375.) The form of the wave was determined by immerging into the liquid with its plane vertical a slate sprinkled with flour, and suddenly withdrawing it. In this way it appears that a satisfactory trace of the front of the wave was obtained; the liquid removing the flour from every part which it touched. In a nearly similar manner the form of the back of the wave was obtained; the slate being in this case suddenly plunged into the fluid; these determinations are however confessedly much less satisfactory than the former. The experimenters, however, were able to ascertain that, when the height of the wave was large in proportion to its depth, its front was much steeper than its back, as our theory of (203.) gives it.

(376.) The wave was sometimes observed when it had run to one end of the trough and was reflected there, (a method carried to great perfection in Mr. Russell's experiments, to be described hereafter.) But generally the observations were made soon after the wave was formed. We have no doubt that some irregularities in the results were entirely due to the mixture of waves of various lengths which always occurs at first, and that they would have been avoided if the actual observation had been deferred till the principal wave had cleared itself of the small waves.

(377.) By inspection of the motion of the particles, the Webers discovered the following general rules. When a wave-ridge is followed by an equal wave-hollow, every particle moves in an ellipse, (or a curve as near to an ellipse as the eye can judge,) whose major axis is horizontal; the motion of the particle when in the highest part of the ellipse being in the same direction as the motion of the wave, and in the opposite direction when at the lowest part of the ellipse. (Fig. 23 is copied from Weber's figure.) When a small wave-hollow follows a large wave-ridge, the motion is such as is represented in fig. 24; and when a large wave-hollow follows a small wave-ridge, the motion is such as is represented in fig. 25. These motions are all in general conformity with the results of our theory in (182.); it being remarked that, by the theory of (226.), &c., the same may (with certain combinations) apply to a single wave. At different depths the motion was different; the horizontal motion being diminished in some degree for the deeper particles, and the vertical motion being very much diminished, so that, on approaching the bottom, the ellipse became nearly a horizontal line, as shown in figure 26. These results agree with those of (177.), &c. It was also found that different particles in the same vertical line described corresponding parts of their courses at the same instant of time, as we have found in (162.).

(378.) From contemplation of these experimental circumstances, the Webers constructed figure 27 to represent the motion of particles at the surface of a progressive wave followed by other waves. We need scarcely point out to the reader that these motions coincide exactly with those which we have found in (182.).

(379.) Some discordances were found in the results, depending on the manner in which the wave was produced, and which it would be extremely difficult to compare with theory. Thus when the suction-tube was plunged deep in the fluid, it was sometimes found that the horizontal motion of particles near the bottom was greater than that of particles at about half the depth. The form of the waves was varied by plunging the suction-tube to different depths. When it was very deep, the wave produced was long and flat; when it only touched the surface, the wave was short and high. In the latter case it was found that each particle performed its elliptical revolution in a shorter time than in the former; as the theory of (169.) gives.

(380.) In some experiments it was found that the time occupied by particles near the bottom in describing their elliptic courses was less than that occupied by particles near the surface. It is plain that some complicated system of waves was here produced by some peculiarity in the primary disturbance, of which we can give no further account.

(381.) Each particle described its second course in a shorter time than the first. This is evidently caused by a small wave following a large one.

(382.) In regard to the general velocity of the wave, the Webers found that it was increased by increasing the depth of the fluid in the trough, but they did not ascertain the law. They also found that it was independent of the specific gravity of the fluid. They found that a bulky wave travels more quickly than a small one, as appears from (208.).

(383.) Observations were also made of the motion of the particles when two equal waves meet each other. It was found here that the motion of each particle was backwards and forwards in a straight line, as is represented in fig. 28, which is copied from Weber's figure. We need scarcely to point out that this is precisely the same kind of motion as that which we have found from theory in (189.), &c.

(384.) Other observations were made by the Webers, but none which seem to bear closely upon our theory.

(385.) In regard to the experiments that we have abstracted, we may give our opinion as follows:—The contrivance of using a vessel with glass sides and observing the motions of floating particles is one so admirably adapted to overcome the greatest of all the difficulties attending the comparison of a wave-theory with experiment, namely, that of ascertaining the laws of movement of individual particles, that we think it gives these experiments a claim for superiority above all others. In other respects we think causes of uncertainty may be pointed out. The narrowness of the troughs used makes the effect of any irregularity of the sides great. The rapidity of the observation throws great doubt on the measures of time. However much the Webers might be inclined to trust to their "Tertien-Uhr," (a watch with which the $\frac{1}{60}$ part of a second of time could be observed,) we have little confidence in the use of it. The same cause—namely, the observation of the waves as soon as they were formed—has introduced great complexity into the facts of experiment, which would not have existed if the slower process used by Mr. Russell had been adopted. Although a *complete* theory ought to explain the *most complicated* experiments, yet, under all the difficulties of wave-mathematics, we must confine ourselves to simple cases if we wish to have valid comparisons of theory and observation. We would however point out to any future observer the use of Weber's *Wellenrinne* with several of Russell's methods of observation as likely to give better results than any yet obtained.

(386.) No allusion is made to theory, in the course of the Webers' experiments; and though they have stated the leading points of several theories, (in another part of their book,) they do not appear to have the power of familiarly applying them. We look upon their experiments therefore as quite free from theory, and for that reason we consider their coincidences with theory as peculiarly valuable.

Russell's experiments.

(387.) Mr. Russell's experiments on Waves are contained in the Report of the Seventh Meeting of the British Association, p. 417—496. They constitute, upon the whole, the most important body of experimental information in regard to the motion of Waves which we possess. We shall endeavour here to epitomize the principal contents of that paper, (omitting, for the present, all that relates to the tide-wave;) it will be necessary, however, to make some remarks upon Mr. Russell's references to theory, because we believe that any one who should derive his first knowledge of the nature of waves from that paper would receive from it a most erroneous notion of the extent of the Theory of Waves at the date of those experiments.

Apparatus for creating a wave.

(388.) We shall commence with the experiments made with apparatus arranged expressly for this purpose. A rectangular trough or cistern was constructed, 20 feet long, 1 foot broad, and more than 7 inches deep. At one end, an additional length of 7·3 inches was left, so that in fact the trough really was an uninterrupted trough, whose length was 20 feet 7·3 inches. Only 20 feet, however, was used in the experiments, the remaining part being used for the generation of a wave, in one of the following manners. A sluice being placed at the distance 7·3 inches from the end, water was poured into the small part of the trough behind the sluice, to a known height above the surface of the water in the trough; then, upon raising the sluice, that portion of this water which was higher than the general level (and whose volume therefore was known) rushed into the trough, forming a swell there which was immediately propagated as a wave along the surface of the water in the trough; and the sluice, being depressed, formed a smooth end to the trough in that part from which the wave began. Or, a vertical rectangular trunk, occupying the whole or a part of the small portion at the end of the horizontal trough was filled with water to a certain height, and, by lifting the trunk, that water was allowed to gush out below its lower edge. Or, the sluice of which we have spoken was used to form a wave by merely agitating it with the hand. And in some experiments the disturbance was given by pressing a solid into the water, and in others by withdrawing a solid from the water.

Mode of increasing the range of a wave.

(389.) The method used for measuring the velocities of the waves is extremely ingenious. The length of 20 feet was far too small to permit of any accurate determination of velocity. But Mr. Russell remarked that the wave, upon meeting one of the vertical ends of the trough, was reflected without alteration of form, and therefore could be observed in its reflected course as well as if the trough had been prolonged; and, as the same remark applied to every reflection at each end of the trough, the trough might be used as a channel of indefinite length. (The theory of (355.) and (357.) shows that the reflection from the plane end will in all cases produce a wave of exactly the same kind as that which comes in contact with the end, whatever that kind may be.) Thus the wave was sometimes observed after it had been reflected 60 times, or after it had really described a length of 1200 feet. Moreover, the progress of the wave was observed without difficulty at a great number of points in its course,—for instance, in the experiment just cited, at three points in each length of 20 feet, or in 180 points in the length of 1200 feet. The first observations were usually made after the wave had run the length of the trough once or twice; this allowed many small waves (such as apparently have injured Weber's experiments) to separate themselves and disappear.

Mode of observing the passage of a wave.

(390.) The method of observing the time at which the crest of a wave passed a given point was most happy. The flame of a candle, placed above the trough and at a small horizontal distance from it, was reflected by a mirror in an inclined position downwards to the water, then by the surface of the water it was reflected upwards, and being received upon another inclined mirror was reflected to the eye of an observer, who viewed it through an eye-tube, furnished with an internal wire and a more distant mark for directing the observer's eye. When the water was at rest, or when the horizontal surface at the top of the wave was passing under the mirror, the candle was seen in the centre of the eye-tube; when an inclined part of the wave (either the anterior or the posterior) was passing, the candle was seen on one or other side of the eye-tube. In this manner the passage of the highest part of a wave whose length was three feet, and whose height was only one-tenth of an inch, could be observed with accuracy.

Mode of observing the length and height of a wave.

(391.) The length of the wave was observed by adjusting two fine conical points, which nearly touched the quiescent surface, so that the anterior part of the wave would touch one and the posterior part would leave the other at the same instant. The height of the wave was observed by noting the elevation of the water in small pipes passing from the side of the trough and turning upwards at its outside. We doubt the accuracy of these determinations; they are, however, less important than the determination of velocity; yet we shall presently find that fuller information regarding them would have been valuable.

Species of wave observed by Russell.

(392.) Mr. Russell's researches, in these experiments, were directed entirely to the examination of what he denominates "The great primary wave," and which he describes as "differing in its origin, its phænomena, and its laws, from the undulatory and oscillatory waves which alone had been investigated previous to the researches of Mr. Russell." We are not disposed to recognize this wave as deserving the epithets "great" or "primary," (the wave being the solitary wave whose theory is discussed in (226.) &c.,) and we conceive that, ever since it was known that the theory of shallow waves of great length was contained in the equation $\frac{d^2X}{dt^2} = gk\frac{d^2X}{dx^2}$ (195.), with limitations similar to those in (226.), the theory of the solitary wave has been perfectly well known. Leaving this, however, we may state that Mr. Russell's experiments were all made upon a single wave of considerable length, similar to that discussed in (230.) and (232.), in which a particle is actually moved a certain distance by the wave and then remains at rest in a position differing from its original position. The result in (234.) shows that such a wave may travel, without any force to maintain its motion, provided it be long in proportion to the depth of the fluid; and provided that its velocity be $\sqrt{gk}$, k being the depth; or in other words, that it can, when moving freely, have no other velocity than $\sqrt{gk}$. We are not able to state fully how far Mr. Russell's experiments satisfy the former condition: for Mr. Russell was not aware of the influence of the length of the wave in any case, and therefore has not given it here. Supposing, however, (as his incidental remarks imply,) that the length was 3 feet, this length may correspond to a in the second or principal term in the expression of (232.), and as a has the same place there which λ has in (165.), &c., we may consider $\lambda = 3$ feet. Therefore, when the depth was 6 inches, $\frac{\lambda}{k} = 6$; when the depth was 4 inches, $\frac{\lambda}{k} = 9$, &c. The velocity is therefore (see the table in (170.)) sensibly not the same as if the wave were infinitely long. The wave, therefore, (in conformity with the remarks in (235.),) would tend to split into several waves, each of which would move with its own velocity; and this appears to have happened in some instances (rejected in Mr. Russell's table of results). But the difference of velocities would be small, and probably the elevation observed would be that of the first part, which corresponds to $\lambda = 3$ feet.

Section Account Experi-ments o Waves.

Influen of the length the wa upon t velocit neglec by Mr Russel

Inf of th heig the w upon veloc

(393.) There is, however, another point to be considered, namely, that the height of the wave, in many of the experiments, bears a sensible proportion to the depth. According to the theory of (208.), supposing the succession of waves continuous, the top of the wave would travel with a velocity greater than that due to the undisturbed depth, and even greater than that due to the disturbed depth, and expressed by $\sqrt{gk} \times (1+3b)$, where $b = \frac{\text{height of wave}}{\text{depth of water}}$. But if, as in continuous waves, we refer our first calculation not to the undisturbed depth but to the mean depth; then instead of k we must put $k\left(1+\frac{b}{2}\right)$, the mean depth; and instead of $3bk$ we must put $\frac{3bk}{2}$, the greatest elevation above the mean being $\frac{bk}{2}$. Thus the last formula becomes

$$\sqrt{gk\left(1+\frac{b}{2}\right)\left(1+\frac{3b}{2}\right)} = \sqrt{gk}(1+2b).$$

(394.) To examine, then, the general coincidence of Mr. Russell's results with the theory, we have proceeded thus:—We have taken the abstract in pp. 440, 441, 442, of the *Report of the British Association*, having corrected a few errors in it, and have divided the experiments into groups in which the depth of the water and the height of the wave are nearly equal. We have assumed that the mean of the observed velocities corresponds to the mean of the depths, &c., an assumption which is not rigorously true, but probably much nearer to truth than any one experiment. We have then computed the theoretical velocity for the undisturbed depth by the formula of (169.), &c., supposing $\lambda = 36$ inches; and in other columns we have altered this velocity in the proportion of $1 : \sqrt{1+b}$, $1 : \sqrt{1+3b}$, and $1 : \sqrt{1+2b}$.

(395.) The experiments which are most favourable for determining the influence of the height of the wave are those of the second group. If we compare the column of "Velocity computed for undisturbed depth" with the column "Observed velocities," we find that *all* the computed velocities are too small. If we compare the "Computed velocity $\times\sqrt{1+b}$," which is the same as that due to the depth measured from the crest of the wave to the bottom of the trough, we find that 9 are too small and 3 too great. If we compare the "Computed velocity $\times\sqrt{1+2b}$," which is that deduced from our theory of (208.), we find that 5 are too small and 7 too great. If we compare the "Computed velocity $\times\sqrt{1+3b}$," we find that 3 are too small and 9 too great. The comparison of the first group leads to nearly the same result; the numbers in the corresponding columns being — all too small — 6 too small, 2 too great — 4 too small, 4 too great — 4 too small, 4 too great. On the whole, therefore, we think ourselves fully entitled to conclude from these experiments that the theory of (208.) is entirely supported; and that the velocity is correctly calculated by supposing it to be that due to the mean depth increased by three times the semi-oscillation in depth, or the whole depth from the crest of the wave increased by the whole oscillation in depth.

(396.) The reader will, however, remark that the *excesses* of our computed quantities are for the most part in the *small* depths of water, and the *defects* in the *great* depths. We think it most likely that this is due to the difference in the lengths of the waves. It is not unlikely that λ was less than 36 inches in the small depths, and greater than 36 inches in the great depths. If we had calculated with such numbers, we should have found smaller computed velocities for the small depths, and greater for the great depths; and the agreement with the observed velocities would have been extremely close.

the length of the waves.

Experiments of a general character.

(397.) Other experiments of Mr. Russell's were directed to the inquiry, whether the mode of producing the wave (in other words, the form of the wave) influenced its velocity; it was found that no difference of velocity was perceptible with waves produced in different ways. This is in accordance with (234.). Experiments were also made, (of which no details are given,) which showed that the motion of the particles from the surface to the bottom of the channel is the same, and that particles once in a vertical plane continue in a vertical plane. These results agree with those of (180.).

Negative wave produced by the paddles of a steam-boat.

(398.) Some experiments were made by Mr. Russell on what he calls a *negative* wave—that is, a wave which is in reality a progressive hollow or depression. But (we know not why) he appears not to have been satisfied with these experiments, and has omitted them in his abstract. All the theories of our IVth Section, without exception, apply to these as well as to *positive* waves, the sign of the coefficient only being changed. We may remark, as a matter which may be observed (in some localities) in daily experience, that the phænomenon of a negative wave is given in great perfection by the paddles of a steam-boat: the first wave which passes away from it being a hollow of considerable depth. We were first made aware of this by observation of the traces made by Mr. Bunt's excellent self-registering tide-gauge on the banks of the Avon, at a short distance below Bristol; but we have since frequently remarked it in the waves caused by steam-boats in other places, merely by watching the fall and rise of the water on the river banks.

Experiments in triangular and trapezoidal channels.

(399.) Experiments were also made by Mr. Russell as to the velocity of transmission of a wave in a channel whose section is a triangle. In some channels which he used the breadth was $\frac{3}{2}\times$ the depth, in others it was $3\times$ the depth; and one side in all cases was vertical. This construction, in conformity with the remark of (222.), could not be expected to give exactly the velocity determined by the formula of (220.). And it is expressly remarked by Mr. Russell that the wave did not stretch across the channel, but travelled in the manner described in (359.). We should therefore expect the experimental velocity of the leading part of the wave (or that corresponding to the deep side) to approach more nearly than the formula of (220.) gives to that of a rectangular channel of the same depth. This is what appears in some degree from the experiments, although their results are irregular. We select a few in which the height of the wave is small. With these we shall give some observations made in trapezoidal channels. In computing all these we shall use the following process. We shall take the undisturbed depth of the water from Mr. Russell's numbers. From this we shall compute the equivalent depth in a rectangular channel, by dividing the area of section by the breadth of the surface (220.). To this we shall add double the height of the wave, as in (395.), and with this sum we shall compute the velocity.

Tabular abstract of experiments.

Triangular Channel H, breadth $= \frac{3}{2} \times$ depth; both sides above the surface of the water being vertical.

Undisturbed Depth in Inches.	Depth of Equivalent Rectangular Channel.	Height of Wave.	Computed Velocity in Feet.	Observed Velocity.

6·01	4·01	0·40	3·22	3·08
6·01	4·01	0·86	3·40	3·50

The general agreement with our theory is at least as close as the agreement of the observations among themselves. The mean of all the triangular results, and that of each of the trapezoidal results, agree closely with the theory.

(400.) A series of experiments was made in a channel of uniform depth, whose sides were vertical and met in a vertical line, the horizontal plan of the channel being a triangle with one acute angle. Observations of the height of the wave were made at three stations, at which the breadths of the channel were in the proportion of 4, 2, 1. According to the theory of (254.) and (263.), the heights at these points ought to be in the proportion of $\frac{1}{2}$, $\frac{1}{\sqrt{2}}$, 1. And this proportion very well represents those observed; the inequality being sometimes greater and sometimes less. Thus, comparing the first and third, which ought to be as $\frac{1}{2}$: 1, they are found to be (in the different observations)

1·5 : 3·5
2·0 : 3·3
2·0 : 3·6
1·25 : 2·5
1·5 : 3·25
2·0 : 3·3
1·0 : 2·0
0·25 : 0·4

The velocity cannot be easily calculated, the height of the wave being great in the narrow part of the channel; but it appears, on a general view, to agree well with that in a rectangular channel of the same depth.

(401.) It was always found that the wave broke when its elevation above the general level became equal or nearly so to the general depth. The application of mathematics to this circumstance is so difficult, that we confine ourselves to the mention of the observed fact.

(402.) Observations were also made in a channel (we presume of uniform breadth) whose depth diminished gradually, the bottom being inclined at a slope of 1 in 51. The height of the wave here, in conformity with the theory of (247.) and (264.), ought to be inversely as the fourth root of the depth. The results are irregular, but it is easy to see that this proportion agrees well with the general mean, and that other proportions (for instance, inversely as the depth or as the square root of the depth) would not at all agree with it. Here too it was remarked that the wave broke when its height above the general level was equal to the depth of the water at that place.

(403.) In confirmation of the last remark, observations were made on the surf of the sea, a series of rods being fixed in the sand, by which the height of the wave at the instant of breaking could be observed. The general result was that the wave broke when its height above the antecedent hollow was equal to the depth of the water. Mr. Russell, however, has not stated whether this depth was measured from the mean level of the surface, or from the bottom of the hollow.

(404.) Before dismissing these experiments, however, we must allude to a very remarkable practical fact which led to the whole investigation. It had been accidentally discovered that the navigation of certain canals of small depth, on which boats are drawn by horses, could be greatly facilitated by increasing the speed of the boats; the resistance when the velocity was great being considerably less than when the velocity was small. The whole of the circumstances affecting this result are most ably analyzed by Mr. Russell in a paper in the *Edinburgh Transactions*, vol. xiv. The following general statement will put the reader in possession of the principal facts. There is one particular velocity (that defined by the equation $v^2=gk$) at which a free wave will travel along a canal of given depth k. Nevertheless a boat travelling along a canal, at whatever speed, will be accompanied by a wave travelling with the same speed as the boat, whose motion at that particular speed is maintained by the horizontal pressure of the boat upon the water. These two kinds of waves are in all respects analogous to the free-tide-wave and the forced-tide-wave, of which we have spoken frequently in Section IV., and may with propriety be called the *free-canal-wave* and the *forced-canal-wave*. Now the general fact is this. If the boat moves more slowly than the free wave, the forced wave precedes the middle of the boat, and the force necessary to keep up the speed of the boat is (in proportion to its velocity) considerable. If the boat moves more rapidly than the free wave, the forced wave follows the middle of the boat, and the force necessary to keep up the speed is (in proportion to its velocity) less than in the former case. But if the boat moves with a velocity equal to, or rather slightly exceeding, the velocity of the free wave, then the boat rides with its middle on the top of the wave, and is drawn with a force much less (in proportion to its velocity) than at lower speeds, and even absolutely less. And these are the facts to be explained by our theory.

(405.) The theory of (229.), &c., is sufficient for this purpose. Suppose, as in (232.), the value of X to be 0 when $vt-x$ is <0; and to be $\frac{2b}{3\pi}\left\{\frac{3}{2}\cdot\frac{\pi(vt-x)}{a}-\sin\frac{2\pi(vt-x)}{a}+\frac{1}{8}\sin\frac{4\pi(vt-x)}{a}\right\}$ when $vt-x$ is >0, $<a$: and to be b when $vt-x$ is $>a$: (in which expressions v is not necessarily $=\sqrt{gk}$, but may be any quantity whatever). Since, by (194.), $k+\text{K}=\frac{k}{1+\frac{d\text{X}}{dx}}=k-k\frac{d\text{X}}{dx}$ nearly, we have $\text{K}=-k\frac{d\text{X}}{dx}=\frac{8kb}{3a}\sin^4\frac{\pi(vt-x)}{a}$. This is the elevation of the surface of the water; and, since it applies only from $vt-x=0$ to $vt-x=a$, it shows that through that extent the water will be elevated, its elevation decreasing very gradually at both extremities of the wave. Now in the expressions of (233.) and (234.), suppose a the length of the wave to be so large that the terms depending on $\frac{1}{a^4}$ may be neglected: then the expression for F, the force which is necessary to maintain the motion of the wave with the velocity v, will be found to be

$$\frac{32\,\pi b}{3a^2}(v^2-gk)\,.\,\sin^3\frac{\pi(vt-x)}{a}.\cos\frac{\pi(vt-x)}{a}.$$

Position of the wave with regard to the boat, explained from theory.

(406.) Suppose now the velocity to be less than that of a free wave, or v^2 to be $<gk$. The form of the expression for the necessary force is then $-\text{C}.\sin^3\frac{\pi(vt-x)}{a}.\cos\frac{\pi(vt-x)}{a}$. The changes of sign of this expression depend only on the last term [$\sin\frac{\pi(vt-x)}{a}$ being always positive when $vt-x$ is >0, $<a$]. For the front of the wave, as far as its middle, $vt-x$ is $<\frac{a}{2}$, $\frac{\pi(vt-x)}{a}$ is $<\frac{\pi}{2}$, and F is negative. For the back of the wave, $vt-x$ is $>\frac{a}{2}$, $\frac{\pi(vt-x)}{a}$ is $>\frac{\pi}{2}$, and F is positive. It appears, then, that the wave may be retained at this slow speed if there be a force resisting its front and a force urging forward its back. And it will therefore easily be conceived that (with perhaps a trifling change in the wave's form) a portion of the effect will be produced by only a force urging forward its back. As the motion of a boat can produce no force except forwards, it is readily seen that the boat can produce the force requisite only by following the wave. Thus when the velocity is less than that of a free wave, the wave will precede the boat.

(407.) If the velocity were greater than that of a free wave, or $v^2>gk$, the form of the expression for the force would be $+\text{C}.\sin^3\frac{\pi(vt-x)}{a}.\cos\frac{\pi(vt-x)}{a}$, which would be found to be positive for the front of the wave, and negative for its back. The force therefore to maintain a rapid wave ought to tend to accelerate its front and to retard its back. As before, the boat can produce only the accelerative part, and therefore must be upon the front of the wave, or must be followed by the crest of the wave.

(408.) If $v^2=gk$, no force is requisite. But as we have found in the preceding instances that an accelerating force on the front and a retarding force on the back produce the same effect, we may infer that the combination of an accelerating force in front and an accelerating force on the back will produce no effect, or will produce the same effect as no force, or will make $v^2=gk$. If, then, the head and the stern of the canal-boat equally urged the water, the boat must ride on the top of the wave to maintain this velocity.

(409.) But as the head of the boat urges the water more than the stern does, the velocity of the wave must be such as requires a greater accelerating pressure on the front than on the back, or such as requires a pressure similar to that treated of in (407.), or must be a little greater than the velocity of the free wave, in order that the boat may ride evenly on the crest of the wave. This is true in practice.

Theory of long wave maintained by a force, in its general form.

(410.) There is no difficulty in determining the exact form of the wave which a given force exerted by the boat would produce, provided we suppose it to act equally on all the particles in the same vertical, the wave being long. The equation of (236.), omitting the product of $\frac{d\text{X}}{dx}$ and $\frac{d^2\text{X}}{dx^2}$, becomes $\frac{d^2\text{X}}{dt^2}-gk\frac{d^2\text{X}}{dx^2}=\text{F}$. If we make $gk=v'^2$, v' is the velocity of a free wave. And as F depends upon the position of the boat, and upon the position of any particle of water with respect to the boat, F may be expressed by $\chi''(vt-x)$. Thus the equation becomes

$$\frac{d^2X}{dt^2} - v'^2\frac{d^2X}{dx^2} = \chi''(vt-x).$$

Making $v't-x=u$, $v't+x=w$, as in (197.), we have

$$4v'^2 \cdot \frac{d^2X}{du\,dw} = \chi''\left\{\frac{v+v'}{2v'}u + \frac{v-v'}{2v'}w\right\}.$$

Integrating this with respect to u and w, as in (198.), we have

$$4v'^2X = \phi(u) + \psi(w) + \frac{4v'^2}{v^2-v'^2}\chi\left\{\frac{v+v'}{2v'}u + \frac{v-v'}{2,'}w\right\}$$

or $4v'^2X = \phi(v't-x) + \psi(v't+x) + \frac{4v'^2}{v^2-v'^2}\chi(vt-x)$.

Omitting the two first terms, which express free waves,

$$X = \frac{1}{v^2-v'^2}\chi(vt-x).$$

And $K = -k\frac{dX}{dx} = \frac{k}{v^2-v'^2}\chi'(vt-x)$; or $F = \chi''(vt-x) = \frac{v'^2-v^2}{k} \cdot \frac{dK}{dx}$.

We leave the discussion of this equation to the reader, conceiving that the process which we have used in the last articles is better adapted to the general explanation of the observed facts. We may remark, however, that the breaking of the waves attending the boat, in certain cases, appears to be owing to this circumstance, that the form of the function χ'' is such that the function χ does not satisfy the equations of (229.), and therefore at some point there is an infinite force on the particles of water.

Explanation from theory of the diminution of the resistance to the boat.

(411.) We have not yet, however, alluded to the algebraical circumstances on which the diminution of resistance to the boat depends. For this purpose we will consider the velocities of the individual particles of water. For any particle this is expressed by

$$\frac{dX}{dt} = \frac{2b}{3\pi}\left\{\frac{3\pi}{2a}v - \frac{2\pi v}{a}\cos\frac{2\pi(vt-x)}{a} + \frac{\pi v}{2a}\cos\frac{4\pi(vt-x)}{a}\right\}.$$

When $vt-x=a$ or 0, that is at the beginning or end of the wave, this velocity is

$$\frac{2b}{3\pi}\left\{\frac{3\pi}{2a}v - \frac{2\pi v}{a} + \frac{\pi v}{2a}\right\} = 0.$$

When $vt-x=\frac{a}{2}$, that is at the middle of the wave, this velocity is

$$\frac{2b}{3\pi}\left\{\frac{3\pi}{2a}v + \frac{2\pi v}{a} + \frac{\pi v}{2a}\right\} = \frac{8bv}{3a}.$$

The boat, riding on the top of the wave, has its head and stern almost free of the water, while its middle is immersed in water which is travelling in the same direction as itself with the velocity $\frac{8bv}{3a}$. Consequently the velocity through the water, upon which the resistance depends, is not v but $v-\frac{8bv}{3a}$; and the resistance is therefore diminished in the proportion of $1 : \left(1-\frac{8b}{3a}\right)^2$. To this is owing the great facility of drawing the boat at the high speed, provided it ride on the top of the wave. Perhaps it may be assisted by the circumstance that the head being raised above the water, or rather being left by the water, presents less of bluff resistance than usual. Neither of these circumstances (the rapid motion of the water in the same direction as the boat, and the elevation of the boat's head above the water) presents itself when the boat either precedes or follows the wave.

Section V Account Experiments on Waves.

(412.) It was remarked that at low velocities the boat is followed by a breaking wave, but that at the advantageous velocity there is no broken wave. We cannot undertake to put the explanation of this fact in detail into a mathematical form.

Observations of waves o canals.

(413.) Observations were made by Mr. Russell on the velocity of waves in navigable canals. Their results agree generally with theory; but as the circumstances are never so perfectly known as in artificial canals, we do not think them worthy of the detailed notice which we have given to the others in (392.), &c.

Observations of waves o the sea.

(414.) Mr. Russell also made some observations on the motion of waves of the sea. These observations completely failed. Mr. Russell was not aware that the velocity of waves depends on their lengths, and, in deep water, depends sensibly on nothing else; and was therefore baffled by obtaining the most discordant results. His observations, too, are useless to any other person, as no attempt was made to measure the length of the waves. Observations were, however, made (by immersing a glass tube to a considerable depth in the water) to determine whether the agitation of the water produces a sensible effect at great depths. It was found that where the depth was 12 feet, waves 4 or 5 feet long produce no sensible motion near the bottom; waves 30 or 40 feet long produce a very inconsiderable effect. The reader will see that these results agree perfectly with those of (177.), &c.

(415.) We shall allude hereafter to some of Mr. Russell's observations of tides. Meantime we shall repeat our opinion of the great value of the experiments which we have abstracted, but we must warn the reader against attaching any importance to the theoretical expressions which are mingled with them in the original account.

Gene facts sea-w are n torio

(416.) The general phænomena of waves of the sea, to which we have incidentally alluded in several parts of Section IV., are so notorious that it would be useless and indeed difficult to produce authorities. They are, the great velocity of large waves as compared with that of small ones (168.); the crossing of any number of systems of waves without obliterating each other, (352.) and (354.); the power of the wind to raise the waves, and their broken character during the raising, (271.); the power of the wind to maintain the waves in increasing height from the windward shore, and their smooth character, (267.); the reflection of waves, unbroken, from a vertical wall, (357.); the breaking of the waves on the edge of a shoal, (158.) and (248.); the breaking of the surf on a sloping beach, (249.); and some others.

Spec treat on w of th

We may, however, remark that some treatises have been written expressly on the motion of the waves of the sea, embodying the results of considerable thought and extensive observation, and in some respects worthy of the reader's attention. Among these we may particularly specify those of De la Coudraye, Bremontier, and Emy. The theories of these writers are throughout of very little value, (as will always hold with theories of waves which are not based upon the mathematical expressions of the general properties of fluids:) their observations are, in a great measure, directed to the prac-

Section V. Account of Experiments on Waves.

tical effect of waves, upon sea beaches and erections in the sea. Among those which have a bearing on our theory, we may mention that the horizontal motion of the particles of water next to the bottom, produced in shallow water by long waves (180.), is proved to be sensible by the disturbance of the stones and sand at the bottom; and that the breaking over the edge of a shoal (248.) is stated as occurring on the edge of the bank of Newfoundland when the waves in general are high, although the depth on the shallow side is 500 feet, (that on the deep side being much greater.) We may mention, on the authority of the best charts, that a similar breaking is observed about the line of "no soundings," (that is, where the water suddenly becomes deeper than 600 feet,) which at some distance borders the British Isles. We defer the mention of the bore and other tidal phænomena (to which these authors allude) to our last Section.

Height of waves of the sea.

(417.) The estimations of the height of the greatest waves raised by the wind (272.), which are scattered through the works of different writers, are very unsatisfactory. We are, however, inclined to think that in no circumstances does the height of an unbroken wave exceed 30 or 40 feet.

SECTION VI.—INVESTIGATION OF THE MATHEMATICAL EXPRESSIONS FOR THE TIDES PRODUCED BY THE SUN AND MOON, CONSIDERED AS WAVES IN CANALS.

(418.) In our last section we quitted for a time the main object of this Essay, in order to show that the results of our Theory of Waves are supported by experiment, as far as experiments on the small scale can be found which admit of comparison with them. We now return to our principal object, (to which the remainder of the Essay will be devoted,) and shall employ the present Section in investigating the nature of the tides which would occur if the water were confined in a channel of uniform section and of simple form. The theorems of Section IV., as will appear from the following proposition, will be applicable to this inquiry, as soon as the magnitude of the disturbing forces shall be determined.

(419.) Proposition.—In investigating the motion of the sea in a narrow canal, it is unnecessary to consider the forces arising from the rotation of the Earth.

The general equations for the motion of the waters on the surface of the Earth, whether limited by fixed boundaries or not, are those of (84.), omitting the second for the reasons given in (87.). They are, therefore,

Laplace's equations, applicable to fluids in canals as well as to fluids covering the whole spheroid.

$$\frac{dp'''}{d\theta} = -r^2\frac{d^2u}{dt^2} + 2nr^2.\sin\theta.\cos\theta.\frac{dv}{dt}$$

$$\frac{dp'''}{d\varpi} = -2nr^2.\sin\theta.\cos\theta.\frac{du}{dt} - r^2\sin^2\theta.\frac{d^2v}{dt^2}$$

$$w = -\frac{d}{d\theta}(u\gamma) - u\gamma.\text{cotan}\,\theta - \gamma\frac{dv}{d\varpi}$$

$$= \mathrm{I} + \frac{3\mathrm{Sb}^2}{2\mathrm{D}^3}\left\{(\sin\sigma.\cos\theta + \cos\sigma.\sin\theta.\cos\overline{nt+\varpi-s})^2 - \frac{1}{3}\right\} - gw + p''',$$

where ϖ is the terrestrial longitude (measured from a certain fixed meridian carried by the Earth) of the original or mean place of a particle of water, $\varpi+v$ its longitude as disturbed by tide at the time t; θ is the original angular distance from the north pole, $\theta+u$ the same angle as disturbed by tide at the time t; γ the depth of the water, w its tidal elevation at the time t; n the earth's angular velocity of rotation; p''' that part of the pressure of the particles which depends upon their motion; and the other quantities as in (22.) and (82.). Now it is our object to show that, when these equations are transformed into that shape which applies to the motion of water in a narrow canal, the symbol n will disappear. As this latter is found only in the two first, it will be sufficient for us to show that it disappears from the combination of the two first.

(420.) Now, in investigating the motion of water longitudinally in a narrow canal, putting l for the length of the canal as measured from a fixed point to any particle of water under consideration, we want to find $\frac{dp'''}{dl}$, to be used in the same manner as in (149.) or (195.) To do this by means of the equations above, we must put $\frac{dp'''}{dl} = \frac{dp'''}{d\theta}.\frac{d\theta}{dl} + \frac{dp'''}{d\varpi}.\frac{d\varpi}{dl}$. In figure 29, let BT$=l$, BT$'=l+\delta l$, T and T$'$ being two particles upon a line parallel to the axis of the canal; and let θ, ϖ, and $\theta+\delta\theta$, $\varpi+\delta\varpi$, correspond to the same two particles. Then it is evident that TU$=\mathrm{b}\delta\theta$, UT$'=\mathrm{b}\delta\varpi\times\sin\theta$. Putting T, therefore, for the acute angle at T, we have, $\sin\mathrm{T} = \frac{\mathrm{UT}'}{\mathrm{TT}'} = \frac{\mathrm{b}\delta\varpi\times\sin\theta}{\delta l}$; $\cos\mathrm{T} = \frac{\mathrm{TU}}{\mathrm{TT}'} = \frac{\mathrm{b}\delta\theta}{\delta l}$: or $\frac{\delta\varpi}{\delta l} = \frac{\sin\mathrm{T}}{\mathrm{b}.\sin\theta}$, $\frac{\delta\theta}{\delta l} = \frac{\cos\mathrm{T}}{\mathrm{b}}$. Using these as the values of $\frac{d\varpi}{dl}$ and $\frac{d\theta}{dl}$ in the expression for $\frac{dp'''}{dl}$, we have

$$\frac{dp'''}{dl} = \frac{dp'''}{d\theta}.\frac{d\theta}{dl} + \frac{dp'''}{d\varpi}.\frac{d\varpi}{dl}$$

$$= -\frac{r^2}{\mathrm{b}}\left(\cos\mathrm{T}.\frac{d^2u}{dt^2} + \sin\mathrm{T}.\sin\theta.\frac{d^2v}{dt^2}\right) + \frac{2nr^2}{\mathrm{b}}\left(\cos\mathrm{T}.\sin\theta.\cos\theta.\frac{dv}{dt} - \sin\mathrm{T}.\cos\theta.\frac{du}{dt}\right).$$

Now considering the motion of the water produced by the tide to be only in the direction of the canal's length, and putting L for the displacement of the particle in that direction, it is seen in figure 30 that $\mathrm{b}v.\sin\theta=\mathrm{L}.\sin\mathrm{T}$, or $v=\frac{\mathrm{L}.\sin\mathrm{T}}{\mathrm{b}.\sin\theta}$; and, therefore, $\frac{dv}{dt}=\frac{\sin\mathrm{T}}{\mathrm{b}.\sin\theta}.\frac{d\mathrm{L}}{dt}$, and $\frac{d^2v}{dt^2}=\frac{\sin\mathrm{T}}{\mathrm{b}.\sin\theta}.\frac{d^2\mathrm{L}}{dt^2}$ (omitting, in the differentiation, the terms depending on the differentials of θ and T, because they would introduce the squares of small quantities.) Similarly, $\mathrm{b}u=\mathrm{L}.\cos\mathrm{T}$, or $u=\frac{\mathrm{L}.\cos\mathrm{T}}{\mathrm{b}}$, and $\frac{du}{dt}=\frac{\cos\mathrm{T}}{\mathrm{b}}.\frac{d\mathrm{L}}{dt}$, and $\frac{d^2u}{dt^2}=\frac{\cos\mathrm{T}}{\mathrm{b}}.\frac{d^2\mathrm{L}}{dt^2}$. Substituting these quantities,

$$\frac{dp'''}{dl}=-\frac{r^2}{\mathrm{b}^2}.\frac{d^2\mathrm{L}}{dt^2}=-\frac{d^2\mathrm{L}}{dt^2} \text{ (since b and } r \text{ are sensibly equal).}$$

When the equations are applied to canals, the centrifugal force does not enter.

This equation does not contain n, and, therefore, is unaffected by the Earth's rotation: or, in other words, it is indifferent whether we consider the relative change of place between the point on the Earth and the disturbing luminary to arise, partly from the motion of the Earth and partly from the motion of the luminary, or entirely from the motion of the luminary. (This does not hold when we consider the Earth as covered, in whole or in part, by extensive sheets of water.) The equation, moreover, is exactly the same as if the canal were straight.

(421.) Having established this point, we shall desert this method of investigation, and shall proceed to ascertain the value and effects of the acting forces, as if the Earth were fixed, and the Sun and Moon revolved in diurnal movement round it.

(422.) Problem.—The form of a canal is a small circle upon the Earth, of any diameter, and in any position: the luminary being in any position, it is required to find its force upon the waters at each point, in the direction of the canal's length.

(423.) In figure 31, let He be the small circle, e the point at which the force is to be ascertained, S the place of the luminary: take KF the great circle parallel to the small circle, and therefore passing through E the centre of the sphere: draw SN perpendicular to its plane produced, meeting that plane in N; join EN by the line EFN; take G the centre of the small circle, and draw GH parallel to EF. Since GE is perpendicular to the planes of the circles, or parallel to SN, it is evident that G, E, H, F, S, N, are all in the same plane perpendicular to the plane of the circles. Draw es, en, parallel to ES, EN; join Ee, Se. Let the radius of the small circle, expressed by the angle corresponding to the distance in arc between its pole and its circumference, be α: let the linear radius of the sphere be b; then $\mathrm{GH}=\mathrm{b}.\sin\alpha$, $\mathrm{EG}=\mathrm{b}.\cos\alpha$. Also let ES=D, $\angle\mathrm{GES}=\beta$; then $\mathrm{EN}=\mathrm{D}.\sin\beta$, $\mathrm{SN}=\mathrm{D}.\cos\beta$. And let $\angle\mathrm{HG}e=\theta$. Then, conceiving x to be measured parallel to EN, y perpendicular to it in the plane of the great circle, z parallel to EG, and E to be the origin of co-ordinates, the values of those co-ordinates respectively are as follows:

For S;	$\mathrm{D}.\sin\beta$,	0,	$\mathrm{D}.\cos\beta$.
For e;	$\mathrm{b}.\sin\alpha.\cos\theta$,	$\mathrm{b}.\sin\alpha.\sin\theta$,	$\mathrm{b}.\cos\alpha$;

and, therefore,

$$\begin{aligned}(\mathrm{S}e)^2&=(\mathrm{D}.\sin\beta-\mathrm{b}.\sin\alpha.\cos\theta)^2+(\mathrm{b}.\sin\alpha.\sin\theta)^2+(\mathrm{D}.\cos\beta-\mathrm{b}.\cos\alpha)^2\\&=\mathrm{D}^2-2\mathrm{Db}\,(\cos\beta.\cos\alpha+\sin\beta.\sin\alpha.\cos\theta)+\mathrm{b}^2.\end{aligned}$$

(424.) Now the force which the luminary exerts upon the solid part of the sphere is the same as if the whole matter of the sphere were collected at E, and may, therefore, be represented by $\frac{\mathrm{S}}{(\mathrm{S\,E})^2}$ or $\frac{\mathrm{S}}{\mathrm{D}^2}$ in the direction ES. The force of the luminary upon the particle at e may be represented by $\frac{\mathrm{S}}{(\mathrm{S}e)^2}$ in the direction eS; or by $\frac{\mathrm{S}.e\mathrm{E}}{(\mathrm{S}e)^3}$ in the direction eE, and $\frac{\mathrm{S}.\mathrm{ES}}{(\mathrm{S}e)^3}$ in the direction es parallel to ES. The former of these, by (279.), produces no sensible effect, and may, therefore, be put out of consideration. Hence we have

$$\text{Force upon the solid sphere parallel to ES}\quad=\frac{\mathrm{S}}{\mathrm{D}^2}.$$

$$\text{Force upon the particle at } e \text{ parallel to ES}\quad=\frac{\mathrm{S}.\mathrm{D}}{(\mathrm{S}e)^3}.$$

Excess of the latter above the former, which is the true relative disturbing force upon the particle at e,

$$=\mathrm{S}\left(\frac{\mathrm{D}}{(\mathrm{S}e)^3}-\frac{1}{\mathrm{D}^2}\right).$$

(425.) This, however, is the disturbing force in the direction es. If we resolve it into two parts, one parallel to en and one perpendicular to it, or parallel to eg, the latter will be entirely transverse to the direction of the canal at that point, and will, therefore, in our investigation be rejected: the former will be found by multiplying the force in the direction es by $\cos sen$ or $\sin\beta$. Thus we have

$$\text{Disturbing force in the direction } en\quad=\mathrm{S}\left(\frac{\mathrm{D}}{(\mathrm{S}e)^3}-\frac{1}{\mathrm{D}^2}\right)\sin\beta.$$

Tides and Waves.

(426.) Finally, resolving this force into two, one parallel to Ge, and the other perpendicular to it, or tangential to the small circle (and, therefore, urging the water along the canal), we find for the latter,

Expression for the disturbing force produced by the Sun or Moon on the water of a canal.

$$\text{Disturbing force in the direction of the canal at } e = \mathrm{S}\left(\frac{\mathrm{D}}{(\mathrm{S}e)^3} - \frac{1}{\mathrm{D}^2}\right)\sin\beta.\sin\theta.$$

Putting for $\frac{1}{(\mathrm{S}e)^3}$ the expression $\left\{\mathrm{D}^2 - 2\mathrm{Db}(\cos\beta.\cos\alpha + \sin\beta.\sin\alpha.\cos\theta) + \mathrm{b}^2\right\}^{-\frac{3}{2}}$, and expanding to the second power of b, the expression becomes

$$\mathrm{S}.\sin\beta.\sin\theta\left\{\frac{3\mathrm{b}}{\mathrm{D}^3}(\cos\beta.\cos\alpha + \sin\beta.\sin\alpha.\cos\theta) - \frac{3}{2}.\frac{\mathrm{b}^2}{\mathrm{D}^4} + \frac{15}{2}.\frac{\mathrm{b}^2}{\mathrm{D}^4}(\cos\beta.\cos\alpha + \sin\beta.\sin\alpha.\cos\theta)^2\right\}.$$

This force acts to urge the water in the direction eH. We shall, however, conceive the length of the canal to be measured positively in the same direction in which θ is measured positively, that is, from H towards e: and this gives for the proper expression for the disturbing force,

$$\mathrm{S}.\sin\beta.\sin\theta\left\{-\frac{3\mathrm{b}}{\mathrm{D}^3}(\cos\beta.\cos\alpha + \sin\beta.\sin\alpha.\cos\theta) + \frac{3}{2}.\frac{\mathrm{b}^2}{\mathrm{D}^4} - \frac{15}{2}.\frac{\mathrm{b}^2}{\mathrm{D}^4}(\cos\beta.\cos\alpha + \sin\beta.\sin\alpha.\cos\theta)^2\right\}.$$

(427.) Problem.—To find the expression for the force as varying with the time, the luminary being supposed to revolve uniformly in a small circle.

Let Ppo, figure 32, be a sphere whose centre is the centre of the earth, and whose circumference passes through the circle oS in which the luminary revolves: let P be the pole of the circle oS (it will, therefore, in fact be the point corresponding to the pole of the earth): and let p be the point corresponding to the pole of the canal; let P, p, o, O, E, G, be in the same plane; and let p, S, H, E, G, be in the same plane; let O be the origin of the angle or arc for the canal Oe; and let o be the origin of the angle or arc for the small circle oS. The spherical angle opS is evidently equal to OGH. Let OGe=ϕ: this angle is independent of the position of S, and may, therefore, be properly used for defining the point e. The angle θ in the investigation above is HGe, or ϕ−OGH, or $\phi - op$S, figures 32 and 33; β or GES is represented on the sphere by pS; α is here a constant. We will put 90°−σ for Po or PS (σ is then the declination of the luminary); and δ for Pp; and nt for the angle oPS, which is proportional to the time.

(428.) Now our expressions above depend on $\sin\beta.\sin\theta$, $\cos\beta$, and $\sin\beta.\cos\theta$; and these we must endeavour to express so as to contain no variable but nt.

First,
$$\sin\beta.\sin\theta = \sin p\mathrm{S}.\sin(\phi - op\mathrm{S})$$
$$= \sin\phi.\sin p\mathrm{S}.\cos op\mathrm{S} - \cos\phi.\sin p\mathrm{S}.\sin op\mathrm{S}.$$

Now
$$\cos op\mathrm{S} = -\cos \mathrm{P}p\mathrm{S} = \frac{\cos\beta.\cos\delta - \sin\sigma}{\sin\beta.\sin\delta} \text{ (figure 33.)};$$

therefore
$$\sin p\mathrm{S}.\cos op\mathrm{S} = \frac{\cos\beta.\cos\delta - \sin\sigma}{\sin\delta} = \frac{\cos\delta(\sin\sigma.\cos\delta + \cos\sigma.\sin\delta.\cos nt) - \sin\sigma}{\sin\delta}$$
$$= \cos\sigma.\cos\delta.\cos nt - \sin\sigma.\sin\delta.$$

And
$$\sin p\mathrm{S}.\sin op\mathrm{S} = \sin\mathrm{PS}.\sin o\mathrm{PS} = \cos\sigma.\sin nt;$$

therefore
$$\sin\beta.\sin\theta = -\sin\sigma.\sin\delta.\sin\phi + \cos\sigma.\cos\delta.\sin\phi.\cos nt - \cos\sigma.\cos\phi.\sin nt.$$

Second,
$$\cos\beta = \sin\sigma.\cos\delta + \cos\sigma.\sin\delta.\cos nt.$$

Third,
$$\sin\beta.\cos\theta = \sin p\mathrm{S}.\cos(\phi - op\mathrm{S}) = \cos\phi.\sin p\mathrm{S}.\cos op\mathrm{S} + \sin\phi.\sin p\mathrm{S}.\sin op\mathrm{S}$$
$$= -\sin\sigma.\sin\delta.\cos\phi + \cos\sigma.\cos\delta.\cos\phi.\cos nt + \cos\sigma.\sin\phi.\sin nt.$$

Fourth. By means of the two last we obtain $\cos\alpha.\cos\beta + \sin\alpha.\sin\beta.\cos\theta =$
$$\cos\alpha.\sin\sigma.\cos\delta - \sin\alpha.\sin\sigma.\sin\delta.\cos\phi + \cos\alpha.\cos\sigma.\sin\delta.\cos nt + \sin\alpha.\cos\sigma.\cos\delta.\cos\phi.\cos nt$$
$$+ \sin\alpha.\cos\sigma.\sin\phi.\sin nt.$$

Expressions which must be multiplied to give the disturbing force in terms of the time.

And the first and fourth are now to be substituted in the expression at the end of (426.).

It is evident that this would lead to results of great complexity; and we shall content ourselves, therefore, with applying it to a few special cases.

(429.) (I.) Suppose the luminary in the equator, or $\sigma = o$.

Disturbing body supposed to be in the equator, the canal forming any small circle.

In this case
$$\sin\beta.\sin\theta = \cos\delta.\sin\phi.\cos nt - \cos\phi.\sin nt.$$
$$\cos\alpha.\cos\beta + \sin\alpha.\sin\beta.\cos\theta = \cos\alpha.\sin\delta.\cos nt + \sin\alpha.\cos\delta.\cos\phi.\cos nt + \sin\alpha.\sin\phi.\sin nt.$$

The product of these two expressions, with sign changed, which represents the principal part of the disturbing force, is

$$-\frac{1}{2}\cos\alpha.\sin\delta.\cos\delta.\sin\phi.(1 + \cos 2nt) - \frac{1}{2}\sin\alpha.\cos^2\delta.\sin\phi.\cos\phi(1 + \cos 2nt)$$

$$-\frac{1}{2}\sin\alpha.\cos\delta.\sin^2\phi.\sin 2nt+\frac{1}{2}\cos\alpha.\sin\delta.\cos\phi.\sin 2nt+\frac{1}{2}\sin\alpha.\cos\delta.\cos^2\phi.\sin 2nt$$
$$+\frac{1}{2}\sin\alpha.\sin\phi.\cos\phi.(1-\cos 2nt).$$

This expression consists of three distinct classes of terms:

Disturbance of mean level.

(430.) The first or $-\frac{1}{2}\cos\alpha.\sin\delta.\cos\delta.\sin\phi+\frac{1}{2}\sin\alpha.\sin^2\delta.\sin\phi.\cos\phi$, does not depend on nt, and therefore does not give rise to any oscillation, or any state of waters varying with the time. But as it depends on ϕ, it shows, (152.) and (283.), that the relative mean level in different parts of the canal is not the same as if the luminary did not exist.

(431.) The second, or $-\frac{1}{2}\cos\alpha.\sin\delta.\cos\delta.\sin\phi.\cos 2nt+\frac{1}{2}\cos\alpha.\sin\delta.\cos\phi.\sin 2nt$, depends on ϕ and $2nt$. Putting it in the form $A.\sin\overline{2nt+\phi}+B.\sin\overline{2nt-\phi}$, or $(A+B)\sin 2nt.\cos\phi+(A-B)\cos 2nt.\sin\phi$, we easily find for its equivalent

$$\cos\alpha.\sin^3\frac{\delta}{2}.\cos\frac{\delta}{2}.\sin\overline{2nt+\phi}+\cos\alpha.\sin\frac{\delta}{2}.\cos^3\frac{\delta}{2}.\sin\overline{2nt-\phi}.$$

If x be the length of the canal measured from the same origin as ϕ, $\phi=\frac{x}{b\sin\alpha}$, and this expression becomes

$$\cos\alpha.\sin^3\frac{\delta}{2}.\cos\frac{\delta}{2}.\sin\overline{2nt+\frac{x}{b\sin\alpha}}+\cos\alpha.\sin\frac{\delta}{2}.\cos^3\frac{\delta}{2}.\sin\overline{2nt-\frac{x}{b\sin\alpha}}.$$

Each of these two terms is of the same form as those considered in (274.), putting H for the multiplier here, nt for $2nt$, and mx for $\pm\frac{x}{b\sin\alpha}$; and each will give rise to a wave, one of which will roll in one direction and the other in the opposite direction. If we examine the expression for Y at the surface, or K, in (279.), and (284.), and remark that for these two waves m has different signs, we shall see that the two coefficients above will be multiplied by equal factors with opposite signs; the absolute sign of either depending upon the depth of the water. The whole elevation of the water then, produced by these two waves, will be represented by

$$\frac{kb\sin\alpha.\cos\alpha.\sin\delta}{8n^2b^2\sin^2\alpha-2gk}\times\left\{\sin^2\frac{\delta}{2}.\cos\overline{2nt+\frac{x}{b\sin\alpha}}-\cos^2\frac{\delta}{2}.\cos\overline{2nt-\frac{x}{b\sin\alpha}}\right\},$$

or
$$\frac{kb.\sin\alpha.\cos\alpha.\sin\delta}{8n^2b^2\sin^2\alpha-2gk}\times\{-\cos\delta.\cos\phi.\cos 2nt-\sin\phi.\sin 2nt\}.$$

If we make $\tan\psi=\frac{\tan\phi}{\cos\delta}$, this becomes

$$-\frac{kb.\sin\alpha.\cos\alpha.\sin\delta}{8n^2b^2\sin^2\alpha-2gk}\times\sqrt{\cos^2\delta.\cos^2\phi+\sin^2\phi}.\cos\overline{2nt-\psi},$$

where it must be remembered that k is the depth of the water, and that the multiplier $\frac{3Sb}{D^3}$ has been omitted.

First semidiurnal tide.

This expression shows, 1st, that *for the same place* the oscillation goes through all its phases while $2nt$ changes by 2π, and therefore the oscillation goes twice through all its phases while $2nt$ changes by 4π, or while nt changes by 2π, or while the luminary performs its revolution; that is, the tide is semidiurnal. 2nd, that *for the same time* the oscillation has all its different phases for values of ψ extending through 2π, that is for values of ϕ extending through 2π (for ϕ and ψ have the values $0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}, 2\pi$, together), that is, for the whole extent of the canal and for no smaller extent; therefore there is but one wave on the canal, which passes round it with an irregular motion twice in a tidal day. 3rd, that the magnitude of the fluctuation is different at different places.

But as the expression contains the factors $\cos\alpha.\sin\delta$, this wave has no existence unless the canal is a small circle whose pole does not coincide with the pole of the earth.

(432.) The third class of terms, or $-\frac{1}{4}\sin\alpha(1+\cos^2\delta)\sin 2\phi.\cos 2nt+\frac{1}{2}\sin\alpha.\cos\delta.\cos 2\phi.\sin 2nt$, depends upon 2ϕ and $2nt$. Putting it in the form $A.\sin\overline{2nt+2\phi}+B.\sin\overline{2nt-2\phi}$, it becomes

$$-\frac{1}{2}\sin\alpha.\sin^4\frac{\delta}{2}.\sin\overline{2nt+2\phi}+\frac{1}{2}\sin\alpha.\cos^4\frac{\delta}{2}.\sin\overline{2nt-2\phi};$$

which, as above, will produce an elevation of waters represented by

$$-\frac{1}{4}.\frac{kb.\sin^2\alpha}{n^2b^2\sin^2\alpha-gk}\left\{\sin^4\frac{\delta}{2}.\cos\overline{2nt+2\phi}+\cos^4\frac{\delta}{2}.\cos\overline{2nt-2\phi}\right\},$$

or
$$-\frac{1}{4}.\frac{kb\sin^2\alpha}{n^2b^2\sin^2\alpha-gk}\left\{\left(\frac{1}{2}+\frac{1}{2}\cos^2\delta\right)\cos 2\phi.\cos 2nt+\cos\delta.\sin 2\phi.\sin 2nt\right\}.$$

If $\tan\chi = \frac{2\cos\delta}{1+\cos^2\delta}\tan 2\phi$, this becomes

$$-\frac{1}{4}\cdot\frac{kb\sin^2\alpha}{n^2b^2\sin^2\alpha - gk}\times\sqrt{\left(\frac{1}{2}+\frac{1}{2}\cos^2\delta\right)^2.\cos^2 2\phi + \cos^2\delta.\sin^2 2\phi}.\cos\overline{2nt-\chi},$$

to which the multiplier $\frac{3Sb}{D^3}$ is yet to be supplied.

Second semi-diurnal tide.

This expression shows, 1st, that *for the same place* the oscillation goes through all its phases while $2nt$ changes by 2π, or is semidiurnal; 2nd, that *for the same time* the oscillation has all its different phases for values of χ extending through 2π, that is, for values of 2ϕ extending through 2π; or it has all its different phases twice repeated for values of χ extending through 4π, that is for values of ϕ extending through 2π; therefore there is a double wave on the canal which passes round it with an irregular motion once in a tidal day; 3rd, that the magnitude of the fluctuation is different in different places.

These two are compounded into one semi-diurnal tide at every place.

(433.) The two waves which we have found will produce only one apparent semidiurnal wave at each place. For the expressions $L.\cos\overline{2nt-\psi} + M.\cos\overline{2nt-\chi}$ or $(L\cos\psi + M\cos\chi)\cos 2nt + (L\sin\psi + M\sin\chi)\sin 2nt$ may be represented by $N.\cos\overline{2nt-O}$ where $N = \sqrt{\{(L\cos\psi + M\cos\chi)^2 + (L\sin\psi + M\sin\chi)^2\}}$ and $\tan O = \frac{L\sin\psi + M\sin\chi}{L\cos\psi + M\cos\chi}$; which, as estimated at the place, presents the appearance of a single semidiurnal tide-fluctuation. As the relation of the coefficients of the two waves, and even the similarity or opposition of their signs, will depend on the depth of the canal and other special circumstances, we cannot proceed further in the investigation.

(434.) There is no term depending on nt, and therefore no diurnal wave.

The canal supposed to be a great circle in any position, and the disturbing body in any position.

(435.) (II.) Suppose the canal to be a great circle, or $\alpha = 90°$; the position of the great circle and the declination of the luminary being any whatever. (We shall, for convenience, assume this case in all our succeeding investigations.)

In this case $\sin\beta.\sin\theta = -\sin\sigma.\sin\delta.\sin\phi + \cos\sigma.\cos\delta.\sin\phi.\cos nt - \cos\sigma.\cos\phi.\sin nt$;

and $\cos\alpha.\cos\beta + \sin\alpha.\sin\beta.\cos\theta = -\sin\sigma.\sin\delta.\cos\phi + \cos\sigma.\cos\delta.\cos\phi.\cos nt + \cos\sigma.\sin\phi.\sin nt$.

If we multiply these terms with sign changed, we find in the result the following classes of terms.

Disturbance of mean level.

(436.) First, the terms $\left(-\sin^2\sigma + \frac{1}{2}\cos^2\sigma\right)\sin^2\delta.\sin\phi.\cos\phi$ independent of nt. These, as before, do not indicate an oscillation, but they show that the mean elevation of the water at each place is modified by the attraction of the luminary. And as the extent of this modification depends on σ, there will be a slow change in the mean elevation of the water depending on the slow changes of σ. The elevation will however be the same for equal values of σ with opposite signs. Introducing the factor $S.\frac{3b}{D^3}$, putting $\left(\frac{1}{2} - \frac{3}{2}\sin^2\sigma\right)$ for $-\sin^2\sigma + \frac{1}{2}\cos^2\sigma$, and observing that $\phi = \frac{x}{b}$, x being the length of the canal, the actual elevation, by (152.) is

$$+\frac{3Sb}{2gD^3}\left(\frac{1}{2} - \frac{3}{2}\sin^2\sigma\right)\sin^2\delta\int_x \sin 2\phi$$

or

$$+\frac{3Sb^2}{2gD^3}\left(\frac{1}{2} - \frac{3}{2}\sin^2\sigma\right)\sin^2\delta\int_\phi \sin 2\phi,$$

or

$$-\frac{3Sb^2}{4gD^3}\left(\frac{1}{2} - \frac{3}{2}\sin^2\sigma\right)\sin^2\delta.\cos 2\phi.$$

The part which depends on σ is $+\frac{9Sb^2}{8gD^3}\sin^2\sigma.\sin^2\delta.\cos 2\phi$. Now $\sin\sigma =$ sine of declination of luminary; and ϕ is 0 or 180°, or $\cos 2\phi = 1$, for those parts of the canal which have the greatest geographical latitude; consequently at those parts the mean level of the water rises when the declination of the luminary is greatest; it falls by the same amount at the equator.

Computation in feet.

(437.) To estimate it in feet we may remark, that this coefficient for the Sun is $\frac{9}{4}$ of the coefficient computed in (31.), or $\frac{9}{4}\times 0{\cdot}2710$ foot, or 0·61 foot. Therefore when the Sun's declination is σ, the elevation of the water depending on these terms, produced by the Sun, is 0·61 foot $\times \sin^2\sigma.\sin^2\delta.\cos 2\phi$. If the canal pass through the pole, $\sin\delta = 1$, and the expression is 0·61 foot $\times \sin^2\sigma.\cos 2\phi$. As ϕ in this case is measured from the pole, the expression shows that the water is raised at the poles by 0·61 foot $\times \sin^2\sigma$, and is lowered at the equator by the same quantity.

(438.) If we put M for the mass of the Moon, D′ for her distance, and μ for her declination, the corresponding quantity for the effect of the Moon's action will be $\frac{9\text{M}\text{b}^2}{8g\text{D}'^3}\sin^2\mu.\sin^2\delta.\cos 2\phi$. Observing that (if the Moon's mass be supposed $\frac{1}{80}$ of the Earth's) this coefficient is $\frac{9}{4}$ of that computed in (35.), the numerical coefficient is $\frac{9}{4}\times 0\cdot 5959$ foot or $1\cdot 34$ foot; and the elevation of the water is $1\cdot 34$ foot $\times \sin^2\mu.\sin^2\delta.\cos 2\phi$.

(439.) Secondly, there are the following terms depending on nt and 2ϕ

$$\sin\sigma.\cos\sigma.\sin\delta.(\cos\delta.\sin 2\phi.\cos nt-\cos 2\phi.\sin nt)$$

or

$$-\sin\sigma.\cos\sigma.\sin\delta.\left(\sin^2\frac{\delta}{2}.\sin\overline{nt+\frac{2x}{\text{b}}}+\cos^2\frac{\delta}{2}.\sin\overline{nt-\frac{2x}{\text{b}}}\right).$$

As before, the effects of these two terms will be represented by two waves, one moving in one direction and the other in the opposite direction; and the elevation produced by both will be represented by

$$\frac{2k\text{b}.\sin\sigma.\cos\sigma.\sin\delta}{n^2\text{b}^2-4gk}\left(-\sin^2\frac{\delta}{2}.\cos\overline{nt+\frac{2x}{\text{b}}}+\cos^2\frac{\delta}{2}.\cos\overline{nt-\frac{2x}{\text{b}}}\right)$$

or by

$$\frac{2k\text{b}.\sin\sigma.\cos\sigma.\sin\delta}{n^2\text{b}^2-4gk}.(\cos\delta.\cos nt.\cos 2\phi+\sin nt.\sin 2\phi).$$

Let $\tan\psi=\frac{\tan 2\phi}{\cos\delta}$; then the expression for the elevation becomes

$$\frac{2k\text{b}.\sin\sigma.\cos\sigma.\sin\delta}{n^2\text{b}^2-4gk}\times\sqrt{\cos^2\delta.\cos^2 2\phi+\sin^2 2\phi}\times\cos\overline{nt-\psi}$$

which is to be multiplied by $\frac{3\text{Sb}}{\text{D}^3}$.

Diurnal tide; it depends on the declination of the disturbing body, and disappears if the body is in the equator.

From this expression it appears, 1st, that *for the same place* the oscillation of the water goes through all its phases while nt increases by 2π, or while the luminary goes round the earth; it is therefore a diurnal tide; 2nd, that *for the same time* the wave is in all its different stages for the extent through which ψ varies by 2π, or through which 2ϕ varies by 2π, and is therefore to be found twice in all its different stages for the extent through which ϕ varies by 2π; or there are two complete waves upon the canal, going round it once in two days, with an irregular motion; 3rd, that the amount of oscillation is different at different places; 4th, that, other circumstances being the same, the extent of the oscillation is proportional to the sine of twice the luminary's declination, and changes sign when the declination changes from north to south, and vanishes when the luminary is in the equator.

When the canal is equatorial there is no diurnal tide.

(440.) There are two cases that deserve distinct notice.

1st. If the canal is equatorial, $\delta=0$, and the whole expression vanishes; or, whatever be the declination of the luminary, there is no diurnal tide.

2nd. If the canal passes through the poles of the earth, $\delta=90°$, and the expression is reduced to

$$\frac{2k\text{b}.\sin\sigma.\cos\sigma}{n^2\text{b}^2-4gk}\sin nt.\sin 2\phi$$

When the canal passes through the poles, the tide-wave is a stationary wave.

or the wave is a stationary wave, such as is treated of in (187.). Its period is diurnal; there are two waves always existing at the same time. The origin of ϕ is, in this case, at the pole; and there will therefore be no vertical oscillation at the poles, (where $2\phi=0$ or $360°$,) and none at the equator, (where $2\phi=180°$ or $540°$,) but there will be a large oscillation at latitude $\pm 45°$ (where $2\phi=90°$, $270°$, $450°$, or $630°$). An elevation in north latitude occurs at the same time as a depression in south latitude. The origin of nt is the plane which passes through the axis of the earth and the axis of the canal; and the water is therefore in its mean state, as depends on this diurnal wave, when the luminary is six hours from the meridian, and in its most elevated or depressed state when the luminary is on the meridian. The elevation or depression depends on the sign of $\sin\sigma$ or sine of declination; it depends also on the sign of $n^2\text{b}^2-4gk$, which will vary as the canal is deep or shallow.

(441.) Thirdly, there are terms depending on $2nt$ and 2ϕ, namely,

$$\frac{1}{2}\cos^2\sigma.\cos\delta.\cos 2\phi.\sin 2nt-\frac{1}{4}\cos^2\sigma.(1+\cos^2\delta).\sin 2\phi.\cos 2nt,$$

or

$$-\frac{1}{2}\cos^2\sigma.\sin^4\frac{\delta}{2}.\sin\overline{2nt+2\phi}+\frac{1}{2}\cos^2\sigma.\cos^4\frac{\delta}{2}.\sin\overline{2nt-2\phi},$$

Semi-diurnal tide, different in different parts of the canal.

which produce two waves travelling in opposite directions, the sum of the corresponding elevations fo which will be represented by

$$-\frac{1}{4}.\frac{k\text{b}.\cos^2\sigma}{n^2\text{b}^2-gk}\left\{\sin^4\frac{\delta}{2}.\cos\overline{2nt+2\phi}+\cos^4\frac{\delta}{2}.\cos\overline{2nt-2\phi}\right\}$$

or by

$$-\frac{1}{4}.\frac{kb.\cos^2\sigma}{n^2b^2-gk}\left\{\left(\frac{1}{2}+\frac{1}{2}\cos^2\delta\right).\cos 2nt.\cos 2\phi+\cos\delta.\sin 2nt.\sin 2\phi\right\}.$$

ect. VI. xpres- ns for Tides idered Waves Canals.

Making $\tan\chi=\frac{2\cos\delta}{1+\cos^2\delta}\tan 2\phi$, this becomes

$$-\frac{1}{4}.\frac{kb.\cos^2\sigma}{n^2b^2-gk}\sqrt{\left(\frac{1}{2}+\frac{1}{2}\cos^2\delta\right)^2.\cos^2 2\phi+\cos^2\delta.\sin^2 2\phi}.\cos\overline{2nt-\chi}$$

which is to be multiplied by $\frac{3Sb}{D^3}$.

From this it is readily seen; 1st, that the tide is semidiurnal; 2nd, that there are two waves on the canal at the same time, revolving irregularly in a day; 3rd, that the extent of oscillation is different in different parts of the canal; 4th, that it is in all proportional to the square of the cosine of the luminary's declination.

If the canal is equatorial, the tide is equal in all parts.

(442.) If the canal is equatorial, $\delta=0$, $\cos\delta=1$, and the expression becomes

$$-\frac{3Sb}{4D^3}.\frac{kb\cos^2\sigma}{n^2b^2-gk}\cos\overline{2nt-2\phi},$$

or the extent of oscillation is everywhere the same, and the water is high or low on the meridian under the luminary according as gk is greater or less than n^2b^2.

If the canal passes through the poles, the wave is a stationary wave.

(443.) If the canal pass through the pole, $\delta=90^\circ$, $\cos\delta=0$, and the expression is reduced to

$$-\frac{3Sb}{8D^3}.\frac{kb\cos^2\sigma}{n^2b^2-gk}\cos 2\phi.\cos 2nt,$$

which shows that there is a stationary wave at each pole and at each intersection with the equator, the high water at the pole corresponding to the low water at the equator. The extreme phases of the oscillation occur when the luminary is on the meridian of the canal, and when it is in the meridian six hours from that of the canal; if n^2b^2 be greater than gk, it is high water at the equator and low water at the poles in the former of the cases, and low water at the equator and high water at the poles in the latter case.

Relation of the sign of the expressions to the depth of the sea.

(444.) The reader will remark that gk is less than n^2b^2 if $\frac{k}{b}$ is less than $\frac{n^2b}{g}$, or if $\frac{\text{depth of sea}}{\text{earth's radius}}$ is less than $\frac{\text{equatorial centrifugal force}}{\text{gravity}}$, or less than $\frac{1}{289}$; or if the depth of the sea is less than 14 miles. And $4gk$ is less than n^2b^2 if $\frac{k}{b}$ is less than $\frac{n^2b}{4g}$, or if the depth of the sea is less than $3\frac{1}{2}$ miles. In this calculation we suppose n the apparent angular velocity of the luminary to be not sensibly different from the real angular velocity of the earth; this applies very nearly to the sun and nearly enough to the moon.

(445.) In the expression for the force urging the water along the canal, we have preserved the terms depending on $\frac{b^2}{D^4}$. We do not however think that the examination of the effects of substituting in these expressions the values found in (428.) or (429.) or (435.) would repay us for the trouble. The additional factor $\frac{b}{D}$ is about $\frac{1}{60}$, and the terms multiplied by this factor are of the same order as those already discussed, so that the new terms may be considered as of magnitude corresponding to $\frac{1}{60}$ part of those already found (more or less). The terms depending on nt and $2nt$ are nearly similar to those already found; the only novelty is, that there are terms depending on $3nt$. But as these terms are evidently small, and as observation has not yet given reason to suppose that there is a sensible sea-tide occurring three times every day, we shall not further consider these terms.

(446.) Now it must be remarked, that the coefficient of each of the terms which we have discussed is slowly variable. The coefficient of the term examined in (439.) depends on $\frac{\sin\sigma.\cos\sigma}{D^3}$; that of the term in (441.) depends on $\frac{\cos^2\sigma}{D^3}$; where σ is the declination of the sun (or moon), and D its distance; two elements which are continually varying. The elements, however, and the combinations of them which we have just set down, may be expanded (by the usual astronomical developments) in such series as $H+H'\cos i't+$ &c., where, for $\frac{\sin\sigma.\cos\sigma}{D^3}$, H is 0; and, for $\frac{\cos^2\sigma}{D^3}$, H is much larger than H'. In the latter of these cases, which applies to the semidiurnal tide, supposing the force only to vary, the coefficient of elevation or depression, by (288.), Variation of the disturbing body's distance and of its angular velocity considered.

would not sensibly differ from $\frac{km}{i^2-gkm^2}(\mathrm{H}+\mathrm{H}'\cos i't)$, which is the same as that corresponding to the position of the luminary at the time of the tide, supposing the elevation or depression computed from that position as if it remained constant; but the time of high or low water would be sensibly different. But in reality, when the force varies from change of the attracting body's distance from perigee and of declination, its angular motion varies at the same time: it will be convenient, then, to consider the effect of these two causes together. Now the reader will perceive that in (427.) and all the articles following it, we have used nt merely to denote the hour-angle of the attracting body; and, therefore, upon supposing that angle to increase irregularly, we must, in (427.) &c., put a new symbol. Thus we shall put $-\frac{3}{2}\cdot\frac{\mathrm{Sb}\cos^2\sigma}{\mathrm{D}^3}\cdot\sin^4\frac{\delta}{2}\cdot\sin\overline{2\text{ hour-angle}+2\phi}$ for the first term in (441.); or $-\frac{3}{2}\cdot\frac{\mathrm{Sb}\cos^2\sigma}{\mathrm{D}^3}\sin^4\frac{\delta}{2}\cdot\sin\overline{2\text{ hour-angle}+2\frac{x}{\mathrm{b}}}$. Now let e be the eccentricity of the orbit in which the body moves round the earth, ht its mean anomaly, ω the inclination of its orbit to the earth's equator, lt its mean distance from the intersection of its orbit with the equator. Then, as its true right ascension may be expressed very nearly by the formula,

$$\text{mean right ascension}+2e\sin ht-\frac{\omega^2}{4}\sin 2lt,$$

its true hour-angle may be expressed very nearly by

$$nt-2e\sin ht+\frac{\omega^2}{4}\sin 2lt;$$

and the expression above becomes

$$-\frac{3}{2}.\mathrm{Sb}.\sin^4\frac{\delta}{2}\times\frac{\cos^2\sigma}{\mathrm{D}^3}.\sin\overline{2nt+\frac{2x}{\mathrm{b}}-4e\sin ht+\frac{\omega^2}{2}\sin 2lt}.$$

Expanding the sine, and remarking that, when z is small, $\sin\overline{2nt+\frac{2x}{\mathrm{b}}+z}$ is expressed with sufficient accuracy by

$$\sin\left(2nt+\frac{2x}{\mathrm{b}}\right)+z.\cos\left(2nt+\frac{2x}{\mathrm{b}}\right),$$

the expression becomes

$$-\frac{3}{2}\mathrm{Sb}\sin^4\frac{\delta}{2}\times\frac{\cos^2\sigma}{\mathrm{D}^3}\times\left\{\sin\left(2nt+\frac{2x}{\mathrm{b}}\right)-2e.\sin\left(2nt+ht+\frac{2x}{\mathrm{b}}\right)+2e.\sin\left(2nt-ht+\frac{2x}{\mathrm{b}}\right)\right.$$
$$\left.+\frac{\omega^2}{4}\sin\left(2nt+2lt+\frac{2x}{\mathrm{b}}\right)-\frac{\omega^2}{4}\sin\left(2nt-2lt+\frac{2x}{\mathrm{b}}\right)\right\}.$$

(447.) Now $\cos^2\sigma=1-\sin^2\sigma=1-\omega^2.\sin^2 lt$ nearly $=1-\frac{\omega^2}{2}+\frac{\omega^2}{2}\cos 2lt$. And, putting D_m for the mean distance, as in (22.), $\mathrm{D}=\mathrm{D}_m(1-e.\cos ht)$ nearly, or $\frac{1}{\mathrm{D}^3}=\frac{1}{\mathrm{D}_m^3}(1+3e.\cos ht)$ nearly; therefore $\frac{\cos^2\sigma}{\mathrm{D}^3}=\frac{1-\frac{\omega^2}{2}}{\mathrm{D}_m^3}\times\left(1+3e.\cos ht+\frac{\omega^2}{2}\cos 2lt\right)$ nearly. Substituting this, the expression above becomes

$$-\frac{3}{2}\left(1-\frac{\omega^2}{2}\right).\frac{\mathrm{Sb}}{\mathrm{D}_m^3}.\sin^4\frac{\delta}{2}\times\left\{\sin\overline{2nt+\frac{2x}{\mathrm{b}}}-\frac{e}{2}\sin\overline{2nt+ht+\frac{2x}{\mathrm{b}}}+\frac{7e}{2}\sin\overline{2nt-ht+\frac{2x}{\mathrm{b}}}+\frac{\omega^2}{2}\sin\overline{2nt+2lt+\frac{2x}{\mathrm{b}}}\right\};$$

and the corresponding expression for the elevation of the water, omitting the constant factor $-3\left(1-\frac{\omega^2}{2}\right).\frac{\mathrm{Sb}^2k}{\mathrm{D}_m^3}\sin^4\frac{\delta}{2}$, is

$$\frac{1}{4n^2\mathrm{b}^2-4gk}\cos\overline{2nt+\frac{2x}{\mathrm{b}}}-\frac{1}{(2n+h)^2\mathrm{b}^2-4gk}.\frac{e}{2}\cos\overline{2nt+ht+\frac{2x}{\mathrm{b}}}+\frac{1}{(2n-h)^2\mathrm{b}^2-4gk}.\frac{7e}{2}.\cos\overline{2nt-ht+\frac{2x}{\mathrm{b}}}$$
$$+\frac{1}{(2n+2l)^2\mathrm{b}^2-4gk}.\frac{\omega^2}{2}.\cos\overline{2nt+2lt+\frac{2x}{\mathrm{b}}}.$$

Expression for the elevation of the tide, with force and angular velocity variable.

(448.) Expanding this expression to the first power of h and l, and omitting the constant factor $\frac{1}{4n^2\mathrm{b}^2-4gk}$, it may be put in the form $\mathrm{P}.\cos\overline{2nt+\frac{2x}{\mathrm{b}}}+\mathrm{Q}.\sin\overline{2nt+\frac{2x}{\mathrm{b}}}$, where

$$\mathrm{P}=1+\left(3+\frac{16n\mathrm{b}^2h}{4n^2\mathrm{b}^2-4gk}\right)e.\cos ht+\left(\frac{1}{2}-\frac{4n\mathrm{b}^2l}{4n^2\mathrm{b}^2-4gk}\right)\omega^2.\cos 2lt$$

$$Q=\left(4+\frac{12n\mathrm{b}^2h}{4n^2\mathrm{b}^2-4gk}\right)e.\sin ht+\left(-\frac{1}{2}+\frac{4n\mathrm{b}^2l}{4n^2\mathrm{b}^2-4gk}\right)\omega^2.\sin 2lt\,;$$

and this may be put in the form $R.\cos\overline{2nt+\frac{2x}{\mathrm{b}}-T}$, or $R.\cos\overline{2nt+2\phi-T}$, wher $R=\sqrt{P^2+Q^2}=P$ nearly, and $T=4e.\sin ht-\frac{\omega^2}{2}\sin 2lt$ nearly.

(449.) If the magnitude of the wave had been computed on the supposition that the force was constant and equal to that given by the values of D and σ for the time of computation, the expression would have been merely $\left(1+3e\cos ht+\frac{\omega^2}{2}\cos 2lt\right)\times\cos\overline{2nt+\frac{2x}{\mathrm{b}}}$. It appears, therefore, that one effect of introducing the motions which we have considered is, to increase the term (in the coefficient of elevation of tides) which depends on the eccentricity of the orbit, or to make the tide proportional to a higher power than the cube of the parallax (supposing the depth of the sea less than 14 miles); another effect is, to diminish the term depending on the declination, or to make the tide proportional to a lower power than the square of the cosine of declination (on the same supposition): a third effect is, to make the phase of tide depend on $\overline{2nt-4e\sin ht+\frac{\omega^2}{2}\sin 2lt+2\phi}$ nearly, or on $\overline{2\text{ true hour-angle }+2\phi}$. The hour-angle, however, is to be computed with an increased value of ellipticity of the moon's orbit, and a diminished obliquity. The same remarks apply, in all respects, to the term depending on $\overline{2nt-2\phi}$, and therefore to their combination.

Modifications to be made in the computation proceeding on the supposition of constant force.

The terms in the moon's longitude and distance depending on the evection (which is but a slowly varying eccentricity of the moon's orbit) follow the same law as those depending on the eccentricity, so nearly that the same investigations may be held to apply to them, without farther examination. The law of the inequality called *Variation* is a little different. If the inequality in the moon's distance depending on variation be called $-D_m.p.\cos qt$, that in longitude will be $+\frac{11}{8}p.\sin qt$, or that in hour-angle will be $-\frac{11}{8}.p.\sin qt$. Treating these terms in the same manner as those above, it will be found that there is added to P the term $\left(3+\frac{11n\mathrm{b}^2q}{4n^2\mathrm{b}^2-4gk}\right)p.\cos qt$, and to Q the term $\left(\frac{11}{4}+\frac{12n\mathrm{b}^2q}{4n^2\mathrm{b}^2-4gk}\right)p.\sin qt$. The second term within each of these brackets bears to the first a proportion which is not exactly the same as that for the terms depending on e, but is not very different from it; and, as the numerical value of Variation is small, there will be no sensible error in assuming that it is exactly the same. Thus, the remarks which we have made regarding the term depending on the eccentricity apply also to the evection and variation: the term depending on the obliquity following a different law. There is no other inequality in the moon's motion worthy of notice.

(450.) To examine the effect of friction, we will neglect the square of f in the expression of (325.); and putting i successively $=2n$, $2n+h$, $2n-h$, and $2n+2l$; $v^2=gk$, $m=\frac{2}{\mathrm{b}}$, and omitting the same constant factor as in (447.), we have the following terms to add to those at the end of (447.):

Friction taken into account.

$$-\frac{f\mathrm{b}^2 2n}{(4n^2\mathrm{b}^2-4gk)^2}\sin\overline{2nt+\frac{2x}{\mathrm{b}}}+\frac{f\mathrm{b}^2(2n+h)}{((2n+h)^2.\mathrm{b}^2-4gk)^2}.\frac{e}{2}\sin\overline{2nt+ht+\frac{2x}{\mathrm{b}}}$$

$$-\frac{f\mathrm{b}^2(2n-h)}{((2n-h)^2\mathrm{b}^2-4gk)^2}.\frac{7e}{2}.\sin\overline{2nt-ht+\frac{2x}{\mathrm{b}}}-\frac{f\mathrm{b}^2(2n+2l)}{((2n+2l)^2\mathrm{b}^2-4gk)^2}.\frac{\omega^2}{2}.\sin\overline{2nt+2lt+\frac{2x}{\mathrm{b}}}\,;$$

which, if expanded to the first power of h and l, may be put in the form $P'.\sin\overline{2nt+\frac{2x}{\mathrm{b}}}+Q'.\cos\overline{2nt+\frac{2x}{\mathrm{b}}}$, where

$$P'=\frac{f\mathrm{b}^2}{4n^2\mathrm{b}^2-4gk}\left\{-2n-\left(6n+4h\,\frac{12n^2\mathrm{b}^2+4gk}{4n^2\mathrm{b}^2-4gk}\right)e.\cos ht-\left(n-2l\,\frac{6n^2\mathrm{b}^2+2gk}{4n^2\mathrm{b}^2-4gk}\right)\omega^2.\cos 2lt\right\}$$

$$Q'=\frac{f\mathrm{b}^2}{4n^2\mathrm{b}^2-4gk}\left\{\left(8n+h\,\frac{36n^2\mathrm{b}^2+12gk}{4n^2\mathrm{b}^2-4gk}\right)e.\sin ht+\left(-n+l\,\frac{12n^2\mathrm{b}^2+4gk}{4n^2\mathrm{b}^2-4gk}\right)\omega^2.\sin 2lt\right\};$$

the additional factor $\frac{1}{4n^2\mathrm{b}^2-4gk}$ being omitted, as in (448.). It is easily seen that

$$P'=-P\times\frac{2nf\mathrm{b}^2}{4n^2\mathrm{b}^2-4gk}-f\mathrm{b}^2h\,.\,\frac{16n^2\mathrm{b}^2+16gk}{(4n^2\mathrm{b}^2-4gk)^2}e.\cos ht+f\mathrm{b}^2l\,\frac{4n^2\mathrm{b}^2+4gk}{(4n^2\mathrm{b}^2-4gk)^2}\omega^2.\cos 2lt$$

$$Q'=Q\times\frac{2nf\mathrm{b}^2}{4n^2\mathrm{b}^2-4gk}+f\mathrm{b}^2h\,.\,\frac{12n^2\mathrm{b}^2+12gk}{(4n^2\mathrm{b}^2-4gk)^2}e.\sin hl+f\mathrm{b}^2l\,\frac{4n^2\mathrm{b}^2+4gk}{(4n^2\mathrm{b}^2-4gk)^2}\omega^2.\sin 2lt.$$

(451.) If we combine these terms with those of (448.), introducing some terms of the order f^2eh and $f^2\omega^2l$ (which are perfectly insensible), and if we make $\frac{f\mathrm{b}^2}{4n^2\mathrm{b}^2-4gk}=\rho$, $\frac{f\mathrm{b}^2(4n^2\mathrm{b}^2+4gk)}{(4n^2\mathrm{b}^2-4gk)^2}=\rho_{\prime}$, it will be found that the complete expression for the height of the water at any instant, omitting the factors $-3\left(1-\frac{\omega^2}{2}\right)\frac{\mathrm{Sb}^2k}{\mathrm{D}_m^3}\sin^4\frac{\delta}{2}\frac{1}{4n^2\mathrm{b}^2-4gh}$, is

Alteration which it produces in the last expression.

$$\{\cos(2nt+2\phi)-2n\rho\,.\sin(2nt+2\phi)\}\times\left\{1+\left(3+\frac{16n\mathrm{b}^2h}{4n^2\mathrm{b}^2-4gk}\right)e\,(\cos ht+h\rho_{\prime}.\sin ht)\right.$$
$$\left.+\left(\frac{1}{2}-\frac{4n\mathrm{b}^2l}{4n^2\mathrm{b}^2-4gk}\right)\omega^2(\cos 2lt+2l\rho_{\prime}.\sin 2lt)\right\}$$
$$+\{\sin(2nt+2\phi)+2n\rho\,.\cos(2nt+2\phi)\}\times\left\{\left(4+\frac{12n\mathrm{b}^2h}{4n^2\mathrm{b}^2-4gk}\right)e\,(\sin ht-h\rho_{\prime}.\cos ht)\right.$$
$$\left.+\left(-\frac{1}{2}+\frac{4n\mathrm{b}^2l}{4n^2\mathrm{b}^2-4gk}\right)\omega^2(\sin 2lt-2l\rho_{\prime}.\cos 2lt)\right\};$$

or

$$\cos\overline{2n(t+\rho)+2\phi}\times\left\{1+\left(3+\frac{16n\mathrm{b}^2h}{4n^2\mathrm{b}^2-4gk}\right)e.\cos\overline{h(t-\rho_{\prime})}+\left(\frac{1}{2}-\frac{4n\mathrm{b}^2l}{4n^2\mathrm{b}^2-4gk}\right)\omega^2.\cos\overline{2l(t-\rho_{\prime})}\right\}$$
$$+\sin\overline{2n(t+\rho)+2\phi}\times\left\{\left(4+\frac{12n\mathrm{b}^2h}{4n^2\mathrm{b}^2-4gk}\right)e.\sin\overline{h(t-\rho_{\prime})}+\left(-\frac{1}{2}+\frac{4n\mathrm{b}^2l}{4n^2\mathrm{b}^2-4gk}\right)\omega^2.\sin\overline{2l(t-\rho_{\prime})}\right\}.$$

May be represented by using the elements of an earlier epoch, and then adding a constant to the phase of the tide.

(452.) The interpretation of this expression is as follows:

The tides, as affected by friction, may still be computed by the formula of (449.), provided that first we take the co-ordinates of the attracting body's place, not for the time for which the calculation is made, but for a time anterior to it by $\rho_{\prime}$; and, secondly, that, having thus computed the time of any phase of the tide (high water, for instance), we adopt a time earlier than the time so found, by ρ.

(453.) In the case of the diurnal tide, for which the coefficient has the form $\mathrm{H}'.\cos i't$, and in which the phases of tide depend on $it\pm mx$ where $i=n$ and $m=\frac{2}{\mathrm{b}}$ (439.), we think it is desirable to call the reader's attention to the circumstance that the approximate expressions in (286.), (287.), and (289.), may not apply. For, these expressions suppose that i^2-gkm^2 or $n^2-\frac{4gk}{\mathrm{b}^2}$ is large, or that $\frac{n^2\mathrm{b}}{g}-\frac{4k}{\mathrm{b}}$ is large. Now we have seen that this quantity vanishes if the depth of the sea is $3\frac{1}{2}$ miles, and changes sign if the depth is still greater. Our knowledge of the depth of the sea is extremely imperfect, but, such as it is, it entitles us to suppose that the depth may equal or exceed $3\frac{1}{2}$ miles. In this case it will be necessary to resort to the expressions at the end of (289.), and it will be found that it may happen that the greatest diurnal tide will occur on the day when the force which causes it is smallest. We think it unnecessary to remark on the time at which the high or low diurnal tide occurs, because that time has not been a subject of accurate observation.

Effects of two bodies considered.

(454.) We shall now consider the tides in a canal caused by the simultaneous action of two bodies, as the sun and the moon. We shall consider all the symbols of the present Section, up to this point, as applying to the sun, and (as in Section II.) shall put M for the mass of the moon, μ for its declination, and D' for its distance. And, n being the apparent angular motion of the sun round the earth in its diurnal motion, we shall find n' for the apparent angular motion of the moon round the earth, where $\frac{n'}{n}=\frac{29}{30}$ nearly, and $\left(\frac{n'}{n}\right)^2=\frac{14}{15}$ nearly. It will be convenient to compare our conclusions with those of the equilibrium-theory.

(455.) First, in regard to the ordinary semidiurnal tide. The coefficient of solar tide is $-\frac{3}{4}.\frac{\mathrm{S}k\mathrm{b}^2\cos^2\sigma}{\mathrm{D}^3(n^2\mathrm{b}^2-gk)}$, (441.), omitting those factors which depend only on the position of the canal and of the place of observation upon it; the coefficient of lunar tide is $-\frac{3}{4}.\frac{\mathrm{M}k\mathrm{b}^2\cos^2\mu}{\mathrm{D}'^3(n'^2\mathrm{b}^2-gk)}$. Hence,

$$\text{the lunar coefficient} = \text{solar coefficient} \times \frac{\mathrm{M}\cos^2\mu}{\mathrm{D}'^3}\times\frac{\mathrm{D}^3}{\mathrm{S}\cos^2\sigma}\times\frac{n^2\mathrm{b}^2-gk}{n'^2\mathrm{b}^2-gk}.$$

But by the equilibrium-theory (44.), the lunar coefficient = solar coefficient $\times\frac{\mathrm{M}'}{\mathrm{S}'}\left(\frac{\mathrm{P}'}{\mathrm{P}'_m}\right)^2.\left(\frac{\mathrm{P}_m}{\mathrm{P}}\right)^3.\frac{\cos^2\mu}{\cos^2\sigma}$, which upon substituting from the articles preceding (44.) becomes

$$\text{lunar coefficient} = \text{solar coefficient} \times \frac{\mathrm{M}\cos^2\mu}{\mathrm{D}^3}\times\frac{\mathrm{D}^3}{\mathrm{S}\cos^2\sigma}:$$

Consequently the proportion of the lunar coefficient to the solar coefficient given by the wave-theory is greater than that given by the equilibrium-theory in the ratio of $n^2 \mathrm{b}^2 - gk$ to $n'^2 \mathrm{b}^2 - gk$, or in the ratio of $\frac{n^2 \mathrm{b}}{g} - \frac{k}{\mathrm{b}}$ to $\left(\frac{n'}{n}\right)^2 \cdot \frac{n^2 \mathrm{b}}{g} - \frac{k}{\mathrm{b}}$, or in the ratio of $\cdot 00346 - \frac{k}{\mathrm{b}}$ to $\cdot 00323 - \frac{k}{\mathrm{b}}$. Any probable supposition that we may make in regard to the depth of the sea will give for this ratio a value sensibly different from that of equality. Suppose, for instance, the sea were 4 miles deep; then $\frac{k}{\mathrm{b}} = \cdot 001$ nearly, and the ratio is $\cdot 00246 : \cdot 00223$, or $11 : 10$ nearly. The mass of the moon, therefore, as inferred from the tides with a sea 4 miles deep would be too great by $\frac{1}{10}$ part. If the sea were 8 miles deep, the ratio would be $\cdot 00146 : \cdot 00123$, or $13 : 11$ nearly, and the inferred mass of the moon would be too great by $\frac{1}{6}$ part. Thus we find,

The solar and lunar tides are not proportional to to the solar and lunar force: the lunar tide being too great.

1st. If the depth of the sea is less than 14 miles, the mass of the moon inferred from the tides is inevitably too great.

2d. The error will be different (or the moon's mass will appear different) in canals of different depths.

The excess different in canals of different depth.

(456.) In regard to the variations of these coefficients as produced by the variations of distance and declination, the equilibrium-theory requires that those coefficients be used which correspond to the actual distance, &c., of the sun and moon at the moment: the wave-theory with friction requires that coefficients be used which correspond to an earlier time, preceding the tide by $\frac{f}{4} \cdot \frac{\frac{n^2 \mathrm{b}^2}{g^2} + \frac{k}{g}}{\left(\frac{n^2 \mathrm{b}}{g} - \frac{k}{\mathrm{b}}\right)^2}$. This applies at present to the coefficients only.

(457.) In regard to the mode of combining these coefficients, the equilibrium-theory, (44.) and (49.), putting M_2 and S_2 for the coefficients, gives for the height of tide at any instant $\mathrm{M}_2 . \cos 2 . \overline{l - m} + \mathrm{S}_2 . \cos 2 . \overline{l - s}$, or

$$\sqrt{\{\mathrm{M}_2^2 + 2 \mathrm{M}_2 \mathrm{S}_2 . \cos 2 . \overline{m - s} + \mathrm{S}_2^2\}} \times \cos \overline{2 (l - m)} + \mathrm{F},$$

$$\text{where } \tan \mathrm{F} = \frac{\mathrm{S}_2 . \sin 2 . \overline{m - s}}{\mathrm{M}_2 + \mathrm{S}_2 . \cos 2 . \overline{m - s}},$$

$l - m$ being the moon's hour angle, $l - s$ the sun's hour angle, and therefore $m - s$ being the excess of the sun's hour angle above the moon's at the instant of computation for tide. The wave-theory gives in the first instance (441.) for the sun $\mathrm{S}_2 . \cos \overline{2 nt - \chi}$, for the moon $\mathrm{M}_2 . \cos \overline{2 n' t - \chi}$: but these receive some modifications. Both forces are variable, but (on account of the extreme slowness of the variations for the sun) it will be sufficient to consider those of the moon. Both tides are affected by friction, and this must be taken into account for both. Referring then to the expressions at the end of (451.), to the explanation in (452.), and to the formula of (449.), it will be seen that we have to combine two such expressions as the following:

For the Sun $\quad \mathrm{S}_2 . \cos \overline{2nt + 2n\rho - \chi}$.

For the Moon $\quad \mathrm{M}_2 . \cos \overline{2n't + 2n'\rho' - \mathrm{T} - \chi}$,

S_2, M_2, and T, being certain functions of the bodies' co-ordinates at a time anterior by $\rho_{\prime} = \frac{f \mathrm{b}^2 (4n^2 \mathrm{b}^2 + 4gk)}{(4n^2 \mathrm{b}^2 - 4gk)^2}$; and ρ being $= \frac{f \mathrm{b}^2}{4n^2 \mathrm{b}^2 - 4gk}$, and $\rho' = \frac{f \mathrm{b}^2}{4n'^2 \mathrm{b}^2 - 4gk}$.

Combining these as in (49.), an expression will be found exactly similar to that of (49.) cited above, but in which the angle entering in the second term of the coefficient, and in the expression for F, instead of $2 . \overline{m - s}$, is

$$(2n - 2n') \, t + \frac{2nf}{4n^2 - gk \frac{4}{\mathrm{b}^2}} - \frac{2n'f}{4n'^2 - gk \frac{4}{\mathrm{b}^2}} + \mathrm{T}.$$

(458.) If we expand the third term by putting $n' = n + (n' - n)$, and retain only the first power of $(n' - n)$, the expression for the angle becomes

$$(2n - 2n') \, t - \frac{f}{4} \cdot \frac{\frac{n^2 \mathrm{b}^2}{g^2} + \frac{k}{g}}{\left(\frac{n^2 \mathrm{b}}{g} - \frac{k}{\mathrm{b}}\right)^2} (2n - 2n') + \mathrm{T},$$

$$\text{or} \qquad (2n - 2n') \times \left\{ t - \frac{f}{4} \cdot \frac{\frac{n^2 \mathrm{b}^2}{g^2} + \frac{k}{g}}{\left(\frac{n^2 \mathrm{b}}{g} - \frac{k}{\mathrm{b}}\right)^2} + \frac{\mathrm{T}}{2n - 2n'} \right\}.$$

Since $2nt$ is the sun's mean hour angle from a certain plane at the time t, and $2n't$ is the moon's mean hour angle from the same plane, $(2n-2n')\,t$ is the difference of their mean hour angles or the difference of their mean right ascensions at the time t. Consequently the angle above is the difference of mean right ascensions of the sun and moon, not at the time t, but at the time

$$t-\frac{f}{4}\cdot\frac{\frac{n^2 b^2}{g^2}+\frac{k}{g}}{\left(\frac{n^2 b}{g}-\frac{k}{b}\right)^2}+\frac{T}{2n-2n'},$$

or it is the difference of *true* right ascensions at the time $t'=t-\frac{f}{4}\cdot\frac{\frac{n^2 b^2}{g^2}+\frac{k}{g}}{\left(\frac{n^2 b}{g}-\frac{k}{b}\right)^2}$.

The relative positions of the two bodies at an anterior time are to be used in the calculation of tide as affected by friction.

(459.) The second term shows as the effect of friction that we may calculate the height and time of high water on the equilibrium-theory, (the constant χ excepted,) provided we consider the Sun and Moon to have the relative position which they really had at the time preceding the time of tide by $\frac{f}{4}\cdot\frac{\frac{n^2 b^2}{g^2}+\frac{k}{g}}{\left(\frac{n^2 b}{g}-\frac{k}{b}\right)^2}$, or $\rho_{\prime}$. It is singular that this quantity (although found by a very different process) should be exactly the same as the quantity found in (452.) for the retroposition of time for which the coefficients are to be computed. The combination of results shows that both the coefficients and the relative positions are to be used which correspond to a time anterior by a certain quantity.

(460.) With regard to the diurnal tide, we leave the reader to make similar remarks. We will only observe that as the coefficients of the diurnal and of the semidiurnal tide depend in very different ways on the depth of the sea, it is impossible, without a precise knowledge of the depth, to assign any proportion between the coefficients as depending on the proportion of the forces.

Effect of propagation of tide up a river considered.

(461.) Suppose now that a shallow river, or even a shoaly sea of considerable length, communicates with such a canal as we have supposed. The insignificance of such a river will prevent it from altering the tides of the sea in the smallest sensible degree; and we may consider the sole effect of their communication to be, that the sea will always maintain at the mouth of the river the height given by the preceding theory, and that it will always supply or receive the water necessary for the propagation up the river of such waves as are consistent with the circumstances of the river. The only points to which we shall now allude are, the time and height of the tides during the different parts of a lunation.

The relation of the height of the river-tide to the height of the sea-tide always the same.

(462.) With regard to the height of the tide: the highest tide at the station on the river will always be that which is propagated from the highest tide of the sea. The tide occupies always the same time in passing from the sea to the river station (with a small inequality, perhaps of a few minutes, which, although important in the next article, is quite unimportant for our present purpose). The effect of this is only to require a greater retroposition of the places of the sun and moon by which the magnitude of the tide is computed. Thus, suppose that for the sea-tide it is necessary to compute for places of the sun and moon earlier by forty-four hours, and suppose that the tide-wave occupies three hours in passing up the river: then the height of high water at the inland station must be computed from the positions of the sun and moon forty-seven hours earlier than the time of high water at the inland station; because that time is forty-four hours earlier than the time of high water in the sea-tide by which the river-tide is produced.

The relation of the time of the river-tide to the time of the sea-tide not always the same.

(463.) But for the calculation of the time of high water a different rule is necessary. It will be seen by (206.) that the time of high water at the inland station, as measured from a certain fixed phase of the tide at the shore, is $\frac{3\pi}{2mv}+\frac{x'}{v}-\frac{3x'}{2v}b$, or $C-\frac{3x'}{2v}b$, where b is the proportion of the rise of tide above the mean state to the mean depth of water in the river. The quantity b therefore will be proportional to $\sqrt{\{M_2^2+2M_2S_2\cos\overline{2(A'-A)}+S_2^2\}}$, where A' is the moon's right ascension and A the sun's, computed for t', the time whose expression is at the end of (458.); or supposing S_2 much smaller than M_2, b will be proportional to $M_2+S_2\cos\overline{2(A'-A)}$. Substituting this in $C-\frac{3x'}{2v}b$, it takes the shape $E-Gx'.\cos\overline{2(A'-A)}$. Now the time of high water on the sea-coast is determined by making $\cos\overline{2n't-\chi'+F}$ maximum, where $F=\frac{S_2}{M_2}\sin\overline{2(A'-A)}$ nearly; and where $\chi'=\chi+T-\frac{2n'.f}{4n'^2-gk\frac{4}{b}}$. As this requires that $2n't-\chi'+F=2m\pi$, m being a whole number, we have the time of high water on the coast $=\frac{2m\pi+\chi'}{2n'}-\frac{F}{2n'}=\frac{2m\pi+\chi'}{2n'}-\frac{S_2}{2n'M_2}\sin\overline{2(A'-A)}$, and therefore the time of high ect. VI. xpres- ions for Tides idered Waves Canals.

water at the inland station =

$$\frac{2m\pi+\chi'}{2n'}+E-\frac{S_2}{2n'M_3}\sin\overline{2(A'-A)}-Gx'\cos\overline{2(A'-A)}.$$

Let $\frac{2m\pi+\chi'}{2n'}+E=K$, $\sqrt{\left(\frac{S_2}{2n'M_2}\right)^2+G^2x'^2}=L$, and $\frac{2n'M_2Gx'}{S_2}=\tan N$: then the time of high water at the inland station is

$$K-L\sin\overline{2(A'-A)+N}.$$

Now $\overline{2(nt-n't)+N}$, or $(2n-2n')\left(t'+\frac{N}{2n-2n'}\right)$ is the difference of mean right ascension of the sun and the moon at the time $t'+\frac{N}{2n-2n'}$; therefore $\overline{2(A'-A)+N}$ is very nearly the difference of true right ascension of the sun and moon at that time. Thus it appears that for computing the time of high water it is necessary to use, not the positions of the sun and moon at the true time of the tide, nor the positions at that anterior time which is employed in computing the height of high water, but a time later than that which is used for computing the height, and therefore a time which is nearer to the true time of high water.

The time for a river-tide is to be computed with the places of the Sun and Moon corresponding to a later epoch than that used for the heights.

(464.) It appears also that the effect of the passage of the tide along the shallow river, as shown by the variation in the time of high water as referred to the moon's transit, if computed by the formulæ of the equilibrium-theory, is to give a mass of the moon which is a little smaller than that corresponding to the variation of heights. For we adopt the quantity L as the representative of $\frac{S_2}{2n'M_2}$; but L really is $\sqrt{\left(\frac{S_2}{2n'M_3}\right)^2+G^2x'^2}$: therefore we adopt for $\frac{S_2}{2n'M_3}$, a quantity which is too great, or for M_2, a quantity which is too small.

The mass of the Moon inferred from these times of tide will be a little too large.

(465.) If we investigated the effect of the passage up the shallow river upon the time of low water, we should find that the positions of the sun and moon corresponding to an earlier time than that used for the height of the high water must be employed; but we should still find that the mass of the moon inferred from the variations of the time of low water as referred to the moon's transit is too small.

Modification in the statement for the times of low water.

(466.) We shall here close our exposition of the Wave-Theory as applied to the tides. As nearly the whole of this theory is published for the first time in the present treatise, we shall not remark upon it at great length. We think it right, however, to point out to the reader its great and important defect as applied to the explanation of tides upon the earth, namely, that in the case of nature the water is not distributed over the surface of the globe in canals of uniform breadth and depth, or in any form very nearly resembling them. In this regard its fundamental suppositions are probably as much, or nearly as much, in error as those of Laplace's theory. But we also think it right to point out that in regard to the completeness of detail with which the principles can be followed out, there is no comparison between the two theories. This will be seen by the reader who has remarked the facility with which the results of "difference between the angular velocities of the sun and moon," "variable coefficients of force," and "friction," are obtained in finite form. For these, Laplace's theory is quite useless. And though (as we have stated) the fundamental suppositions differ much from the real state of the seas, yet no one can hesitate to admit that the same general conclusions will appply:—for instance, that the moon's mass inferred from the height of the tides is too great, and by different degrees in different places: that the effect of friction will be a retroposition of tides in reference to the places of the sun and moon, &c. The peculiarities of river-tides, which no other theory has touched upon, are almost completely mastered by this.

Advantages and disadvantages of the theory of waves as applied to tides.

(467.) With these remarks we terminate our Theory of Tides. Any mathematical deduction which may be required in reference to any special phænomenon of observation will be given in the place where such phænomenon is mentioned. The remainder of our Essay will be devoted to the Observations of Tides and their Comparison with the Theory.

SECTION VII.—METHODS USED FOR OBSERVING THE TIDES, AND FOR REDUCING THE OBSERVATIONS.

(468.) The greater part of the observations of tides hitherto made have been observations of time and height of high water only, made at the entrances of the docks of our principal commercial towns. These observations, as regards *time*, are all affected by the circumstance treated in (208.) and (463.), namely, that the time of transmission of the tide from the sea is less for a large tide than for a small one; and, as regards *height*, they do not even give the coefficient of vertical oscillation. Both these defects are removed by adding observations of time and height of low water: and such a system of observation, if made under favourable circumstances, and where the water is quiet, will usually give results of considerable accuracy for the times of high and low water on the coast.

(469.) But this supposes that the rise of the water is continuous and its fall continuous, and that both follow simple laws; a thing which is by no means to be assumed, and which we shall find incorrect in application to various instances. Moreover, as regards time, it is inaccurate, because it is impossible to fix precisely on the time when the surface of the water, having risen with a decreasing velocity that at last is imperceptible, begins to fall with a velocity which at first is insensibly

Observations of time of greatest height and greatest depression are inaccurate.

Mr. Whewell's proposed method of observation.

Objections to that method.

small. To obviate the latter inconvenience, it was proposed by Mr. Whewell that the time should be noted at which the surface of the water passes any fixed points on a wall in its ascent and in its descent. If the rise and fall followed the same simple law as in the sea, (the elevation above a mean point being expressed by sin nt,) the time intermediate to these observed times would give the time of high or low water with precision, because the instant at which the water passes the line, when in rapid rise or fall, can be very accurately observed. But in fact, the laws of rise and fall are so different that this deduction would be erroneous for high water, and very greatly in error for low water. The author of this paper endeavoured to use, for the time of low water, observations of height made at equal intervals of time for an hour and half in the neighbourhood of and including low water, but even in that time the fall and rise occurred with such different velocities that it was necessary to abandon the use of the mean of any of the times, and to judge as well as could be done, under all circumstances, from the general course of the fall and rise during the whole interval.

It is highly important to observe the whole course of the tide.

(470.) There is no method, in fact, which will give satisfactory results as to low and high water, and none which gives any knowledge whatever of the general course of the tide, except the observation—by the senses of an observer stationed for the purpose, or by the indications of a self-registering tide-gauge—of the height of the water at every instant of time, or at least of the height at very small intervals. When a self-registering instrument is established, it is as easy to keep it in action constantly as occasionally, and thus the register of every tide may be preserved. When the observations of a special observer are used, it is necessary to limit the observations, either to two or three days which exhibit the principal changes of circumstance, (as a day near spring tides and a day near neap tides,) or to a period which embraces those changes (as a half-lunation). We shall mention the cautions with which both kinds of observations ought to be made, and shall notice the principles of construction of a self-registering tide-gauge.

Caution necessary for accurate observation.

(471.) The first thing is, to obtain a surface of water, communicating so freely with the sea as to assume the same mean level, and yet unaffected by the agitations of ordinary waves. A sheltered situation ought therefore to be chosen; but, in parts opening immediately to the sea, it is necessary to use other precautions. The most effectual is, to place in the water a large vertical trunk or trough, communicating with the water only by a small hole at or near to its bottom. Suppose, for instance, this hole to be 10 feet below the surface; the agitation of the water by waves 10 feet long is, by (178.), diminished to $\frac{1}{535}$ part of that at the surface, and therefore would not sensibly disturb the water in the trunk even if there were no limitation of the communicating aperture. But if a wave be very long—as for instance any of the modifications of the tide wave—then the agitation caused by it is as great at 10 feet depth as at the surface (180.), and its time is so great that it will be able always to maintain the water in the trunk sensibly at the same level as the external water, even though the communicating aperture be small. If then a float be placed in the trunk, carrying an index above, this index will rise or fall with the general mean level of the water as affected by the tides only. We have had great pleasure in watching the steady motion of the index on the admirable tide-gauge erected at the Royal Dockyard of Sheerness, while the swell on the outside was so heavy that to judge of a mean level within the accuracy of many inches appeared quite impracticable. The instrument, however, is more likely to fail for observations near low water. For suppose the surface to drop till the hole is only one foot below the surface, then the motion of the water produced by waves 10 feet long is nearly as great as that at the surface, and therefore, however much the aperture be limited, irregularity in the height of the surface will be produced by the waves. The only simple way of preventing this is to let the bottom of the trunk and its communicating aperture be carried as low as possible below low water. It might perhaps be advisable to have the trunk divided into two chambers by a vertical partition, the first chamber receiving the water from the sea by a small hole in its bottom, the second receiving the water from the first by a small hole in the partition; the motion of the water in the second would be extremely steady. It is almost needless to observe that a fixed vertical scale of feet and inches, or other measures of length, is indispensable; in simple observations it may be traced upon the quay wall or post at which the elevation of the surface is noted; where a float carries a vertical rod, the rod may be marked as a scale of feet and inches, and the indication opposite to a fixed index may be noted, or the rod may carry an index which in rising or falling will point to different divisions on a fixed scale.

Sect. V Method used fo observi the Tic and fo reducin the Ob rations

(472.) In some of these ways, observations of the height and time of high water (and for the most part of low water also) are regularly made by direction of the Board of Admiralty at Portsmouth, Plymouth, Ramsgate, Liverpool, Dublin, and occasionally at Harwich and other ports when maritime surveys are in progress. Observations of the same kind are also usually made at the principal docks in the Thames, the Mersey, and the Clyde, as well as at other ports. The principal data for determinations of the time, &c., of tides in ports all over the world have been obtained by some of these methods, either from the loose observations made by harbour-masters and merchant-sailors, or from the more accurate observations conducted by the officers of government surveying-ships.

Gen prin of se regi tide-

(473.) The principle of the self-registering tide-gauge is in all cases the following. By means of a pendulum-clock urged by a sufficient weight, a sheet of paper either spread upon a flat surface, or rolled as required upon a large cylinder, or fixed in a tubular form upon a solid cylinder, is made to travel uniformly. The first of these methods is used for Osler's anemometer, in which the self-registering principle is similar to that of a tide-gauge; the second in Palmer's tide-gauge, (*Phil. Trans.* 1831;) the third in Bunt's tide-gauge. A pencil, carried by mechanism connected with the float, is made to move through a space proportional to the vertical motion of the float, and in a direction perpendicular to the direction of the paper's motion (where the paper is on a cylinder, the motion of the pencil is parallel to the cylinder's axis). A curve is thus traced, whose abscissa represents time, and whose ordinate represents rise of the surface of the water. Occasional examination is always necessary to verify the correctness of action of the machinery. We cannot perhaps do better than copy (with some alterations) from the *Phil. Trans.* 1838, the description of Mr. Bunt's tide-gauge, erected on the bank of the river Avon, nearly a mile below Bristol.

Sect. VII. Methods and for Tides, Obser- tions.

of Bunt's

(474.) The principal parts of Mr. Bunt's tide-gauge (figures 34 to 39) are A, an eight-day clock, which turns a vertical cylinder B once in 24 hours; the upper end of B carrying on its circumference a toothed contrate-wheel, in which works a pinion p carried by the axis of one of the clock-wheels. C is a wheel with grooved circumference; to which is attached the wire E, which passes over the upper part of C, (lying in its groove,) and over a large pully F attached to the outside of the quay-wall, and depends in the water-trunk, supporting the float D at its lower end. A counterpoise G is suspended by a wire attached to a smaller barrel carried by the same axis as C, and thus keeps the wire E constantly stretched, and moves the wheel C when, by the rising of the water, the float D ceases to pull upon E. H is a still smaller drum carried by the same axis as C; a finer wire is attached to it and wrapped round it, and on this wire is suspended the bar I which carries the pencil K. The diameters of the drum H and the wheel C are so adjusted that the vertical motion of the pencil is one-eighteenth part of the vertical motion of the surface of the water. a is a strong oak frame attached to the quay-wall; from it project arms cc whose ends are supported by pillars dd; there also projects an arm e whose end is supported by the pillar f. cc carry the mahogany frame b, to which the clock, the bush for the upper pivot of B, and one bearing of the spindle of C, are attached, (the other bearing of the spindle of C being in another upright S;) e carries the bush for the lower pivot of B. The nature of its bearing may be seen in figure 38; it is in a plug b, which may be lowered by a screw and winch, either for adjustment, or for taking the cylinder out, (for mounting papers, &c., upon it;) as by lowering it, first the upper pivot is disengaged, then the lower, and then the end of the cylinder may be made to slide upon the pieces aa.

(475.) The upper end of the bar I slides between two guides P and N, and the lower end between two guides QQ. It carries the small brass bar d (fig. 37), which has movement upon an axis whose projection is at e, (the movement being in the direction to or from the surface of the cylinder, and the axis being sufficiently long to permit no other sensible movement.) The bar d carries the pencil-holder K, which is pressed towards the great barrel by the crooked lever carrying the small weight L. h is a screw for adjusting the height of the pencil-frame in reference to its suspending wire. The great barrel B is 24 inches in length and 48 in circumference; it is made of mahogany staves, screwed upon mahogany ends and diaphragm, and covered with white enamel.

(476.) The action of this machinery will be understood from the remarks in (473.). Referring to the *Philosophical Transactions*, 1838, for some parts which we have omitted, we think the following points important. The pallets (in the escapement of the clock) may be detached from the train, by lifting a latch behind the clock, and drawing them backward; this arrangement is required from its being necessary to fix the hands so that they cannot, as in other clocks, be made to slide without carrying the train along with them. The pinion which drives the cylinder may be detached by pulling it forwards, so as to allow the cylinder to be turned freely. From inequalities in the teeth of the wheels the cylinder is not moved through exactly equal spaces in equal times; to prevent error from this cause, the places of the hours and minutes marked on the top of the large cylinder were thus determined: the pallets were detached from the clock, (the large cylinder remaining connected with it,) and the hands were moved to indicate 0 hours 0 minutes, 0 hours 20 minutes, 0 hours 40 minutes, &c., and at each of these positions a pencil line was drawn on the cylinder by sliding the pencil-frame between its guides. The scale of height was determined by marking feet and inches on the outside of the float-trunk, and noting the internal indication of the gauge as the tide rose to each successive foot on the trunk. A small scale M, carried by the frame b, may be pushed in contact with the barrel, and thus the heights and the times may be read; or lines of feet may be *turned* on the barrel, by causing it to revolve while the pencil is held to it. The float is of pine, well saturated with oil; the aperture by which the water enters is about $\frac{1}{100}$th of the sectional area of the trunk.

(477.) A sheet of paper is wrapped round the cylinder and expanded by moisture; its ends are then pasted together, and it may (if necessary) be fixed with pins or bands. The curves are then well traced by the mechanism upon the paper, and it may be removed at pleasure.

The same sheet may be retained on the tide-gauge during a fortnight.

(478.) If it were desired to take the record of each tide so as to exhibit the course of a great number of tides in sequence, as in fig. 40, it would be necessary to apply a fresh paper every day to the barrel. But remarking that the tide comes later on each successive day by nearly an hour, and that the same hour of high water recurs only in 15 days, it is evident that the same paper may be kept upon the cylinder for a fortnight without risk of the curves interfering, although there may be a great complication of lines on the paper. In figure 41 we give a copy of the curves delineated by the self-registering tide-gauge at Sheerness, (extracted by permission of Captain Beaufort, R. N., Hydrographer,) from 1840, December 23, (new moon,) to 1841, January 7, (full moon.) The reader, in tracing the curves, must conceive the two ends of the drawing to be united, and must begin at the point marked with the word "Change." We have selected this period, because it exhibits one of the greatest irregularities that we have ever known in the tides, namely, that of 3d January, 1841, morning tide, when the water was five feet lower than was expected. This is fully confirmed by observations made at the same time at Woolwich, at Deptford, and at the London and St. Katherine Docks. It followed a very heavy gale which had blown partly from S.W., and partly from N.W. or N. In figure 42 we give a copy of some of the curves traced by the Bristol tide-gauge at the same time, (with which we have been favoured by Mr. Bunt.) In figure 43 are represented a few curves, (corresponding to another period,) traced by the self-registering tide-gauge at Swansea, (for which we are indebted to the kindness of J. W. G. Gutch, Esq.) It must be remarked that the floats of the tide-gauges at Bristol and Swansea do not descend sufficiently low to record the phænomena of low-water; that at Sheerness fully records the circumstances of low water. The reader will at once see that the information furnished by this instrument is infinitely more valuable than could have been obtained by any system of personal observation.

Specimens of the curves traced by self-registering tide-gauges.

Methods of reducing tidal observations

(479.) We shall now proceed with the methods of reducing tide-observations. And first, in regard to the law of rise during each tide at any given locality.

applicable to the course of a single tide at any place.

Although times of high water and of low water have been observed, and their difference of velocities up the same river have been remarked, and although curves exhibiting to the eye the laws of rise and fall have been traced, (by some of the means above described,) we are not aware that they have been reduced to algebraical form except by the writer of this paper in the *Philosophical Transactions*, 1842. The elevation of the water had been observed at Deptford at every quarter of an hour during half a lunation. The spring-tides and those near them were classed together as one group, and the neap-tides and those near them as another group. In order to combine those of each group, it was assumed that the predicted time of high water in the Nautical Almanac was correct, (a constant difference excepted,) and the interval from one predicted high water to the next was conceived to correspond to 360° of *phase*, and the time of every intermediate observation was converted into *phase* by that proportion. (In a subsequent discussion of tides observed every five minutes at Southampton, we have, instead of using any predicted time, fixed upon the estimated times of low water as the origin of phase.) To bring all the observed heights to a comparable state, the range from high water to low water in every half-tide was supposed to correspond to 2·000, and the depression below the nearest high water at every observation was converted into number by that proportion. The various tides in each group were thus made entirely comparable. The means of all the phases and all the converted depressions within every 10° of phase were taken, and thus a series of mean phases very near to 5°, 15°, 25°, &c., and the corresponding converted depressions, were obtained. By observation of the progress of the numbers, it was easy to alter the latter so as to obtain converted depressions corresponding exactly to 5°, 15°, 25°, &c. Then it was assumed that these could be represented by the following formula:—

$$\begin{aligned}\text{Converted depression} = {} & A_0 + A_1 \cos.\,\text{phase} + A_2 \cos.\,2\,\text{phase} + \text{\&c.},\\ & + B_1 \sin.\,\text{phase} + B_2 \sin.\,2\,\text{phase} + \text{\&c.},\end{aligned}$$

which, it is well known, is sufficient for the representation of a function which is periodical for 360° of phase. Then the values of A_0, A_1, B_1, &c., are determined with comparative facility in the following manner. 1st. A_0 is the mean of all the converted depressions. 2nd. Multiply every converted depression by cos. phase, and take their sum; then, (since $\cos 5° + \cos 15° +$ &c. to $355° = 0$; $\cos 5°.\sin 5° + \cos 15°.\sin 15° + \text{\&c.} = 0$; $\cos 5°.\cos 10° + \cos 15°.\cos 30° + \text{\&c.} = 0$; and so for every one except the multiplier of A_1, where $\cos^2 5° + \cos^2 15° +$ &c. to $355° = 18$), that sum $= 18\,A_1$. 3rd. Multiply every converted depression by sin. phase, and take their sum; it will be found to be $= 18\,B_1$. 4th. Multiply every converted depression by cos. 2 phase and take the sum; it $= 18\,A_2$, and so on. Thus the values of all the coefficients are obtained.

Methods of reduction applicable to the laws of height and time at any place in different positions of the sun and moon.

(480.) Secondly, in regard to the laws of time and height of tide at the same place in different positions of the sun and moon. Every examination referring to this object proceeds on the supposition that the times and heights may be represented generally by the forms given by the equilibrium-theory, (45.), (46.), (53.), and (54.), though perhaps with altered proportion of coefficients, arguments altered by addition or subtraction of constants, and (in some cases) altered form of function. Laplace is (so far as we are aware) the first person who combined observations in considerable groups for comparison with theory. His labours will be found in the second and fifth volumes of the *Mécanique Céleste*. In the second volume he treats the observations made at Brest from 1711 to 1716. He commences with the height of syzygial tides. These he divides into four classes, corresponding to the two equinoxes and the two solstices, and uses at least two syzygies (one new and one full moon) for each equinox or solstice, the whole number being 24 syzygies of each class. For each of these he takes the heights for several neighbouring days; and uses, as the whole range of tide on any day, the difference between the mean of two high waters on that day and the intervening low water. In order to determine the interval by which the greatest tide follows the syzygy, he does not remark which tide appears to be the greatest, but he remarks that the tides on the second day before syzygy, and the fifth day after it, are very nearly equal; then, observing the extent of change of tide in one day, (which at those points of the lunation is considerable,) he is able to correct this approximation, and thus to find very exactly the times at which the tides are equal; the time intermediate to these is that at which the total tide is highest. It is found to be almost exactly 36 hours after the syzygy.

Sect. VII. Methods used for observing the Tides, and for reducing the Obs vations.

Laplace's methods treating the heig of the tides.

His methods f the ag of the tide.

For the alteratio of the moon's effect, d pending on her motion right a cension

(481.) Laplace has assumed (without assigning any reason for it except the possibility of a communication between the port of observation and two tidal seas, as in (121.) and (312.)) a result similar to that which we have found in (455.), namely, that the rapidity of the moon's motion in right ascension increases her effect on the tides, as compared with the sun's effect. To discover the value of the coefficient, he proceeds in this manner. Assuming that in the mean of his syzygial tides the moon's declination is sensibly the same as the sun's, the syzygial solstitial tides ought to bear to the syzygial equinoctial tides the proportion of the mean value of the square of the cosine of declination at the solstices to the similar quantity at the equinoxes. Now they are found to be somewhat greater than this proportion gives. The difference is attributed to the moon's quicker motion in right ascension, or slower motion in hour-angle, at the solstitial syzygies than at the equinoxial syzygies; and, assuming the moon's mean effect to be to that of the sun as 3 : 1, or to be $\frac{3}{4}$ of the whole mean effect, the proportional change in the moon's effect caused by that difference of velocities in right ascension is found, and from this the proportional change caused by the whole mean velocity in right ascension is inferred, (supposed to be always proportional to that velocity in right ascension.) From this Laplace finds the moon's effect to be increased $\frac{1}{10}$: this, as we have seen (455.), implies that the sea is 4 miles deep.

For chang parall

(482.) For the effect of the sun's variation of distance, Laplace compares the heights at the winter solstices with those at the summer solstices. For the effect of the moon's variation of distance, Laplace compares 12 apogeal tides with 12 perigeal tides (in syzygies), and finds that their magnitudes are precisely in the proportion given by theory, without any allowance for the difference of the moon's movement in right ascension at perigee and at apogee. (The effect of this, in our theory, will be found in (448.).)

For nal t

(483.) The effect of diurnal tide is found on comparing the morning syzygial tides with the evening syzygial tides, at the solstices. In the summer, the evening tides are the greater at Brest; in the winter the morning tides. See (48.) and (63.). But Laplace remarks that observations of low water are necessary for a complete determination, (we shall hereafter find an instance of such a determination.)

(484.) For the quadratures, Laplace first determines the time of smallest tide by a process nearly similar to that for the time of the largest tide near syzygies, and finds exactly the same value for its retardation. In order to determine the proportion of the sun's effect to the moon's effect, by comparing the neap tides with the spring tides, (see (51.) and (52.)) it may be assumed in the mass of observations that the declinations of the two bodies will be equal; but a correction is required, because the inequality in the moon's motion called the *variation* always diminishes her distance and increases her velocity in right ascension at syzygies and produces the opposite effect at quadratures. Making due allowance for this, it is found that a corrected mean spring tide is double a corrected mean neap tide, or that the moon's effect is three times as great as the sun's. On comparing those in which the declinations are remarkably different, the coefficient $\frac{1}{10}$ is again found for the increase of the moon's effect depending on her motion in right ascension. The effect of change of the moon's distance is said to be as distinct in the quadratures as in the syzygies.

(485.) The diurnal tide in the equinoxial quadratures follows the same law as in solstitial syzygies, the moon's declination being the same; but as in the former the sun's declination vanishes, the amount of diurnal tide is only $\frac{3}{4}$ of its amount in the latter. This is verified by the observation.

(486.) To determine the proportions of the effects of the sun and moon from the times of high water, Laplace has taken observations nearly 7 days apart, (nearly $3\frac{1}{2}$ days before and nearly $3\frac{1}{2}$ days after the greatest tides.) For the first of these $2(m-s)$ in (49.) is nearly $-90°$, and for the second it is nearly $+90°$, and therefore these two values give nearly the two greatest possible values for F with opposite signs, and their difference is particularly well adapted to determine the proportion of S' and M'. The effect of the moon is thus also found to be three times that of the sun, or a little greater.

(487.) The hours at which the greatest tides and the least tides occur are determined by interpolating among the times of the observed tides following the syzygies and quadratures. It is found thus that the hour of smallest tide is not quite six hours later than the hour of greatest tide. There are many other deductions compared with theory, but those which we have mentioned are the most important, and they will serve to give the reader an idea of the process which Laplace has followed, using no great number of tides, and not comparing the general laws of particular phænomena, so much as the special values which the expressions assume in extreme cases.

(488.) In the fifth volume of the *Mécanique Céleste*, Laplace has discussed the observations made at Brest during sixteen years, from 1807 to 1822. The theory which he has used is precisely the same as that of his second volume, with this addition, that he has pursued to great length the consequences of his assumption that the effect of each of the attracting bodies, both as regards the coefficient of tide and as regards the constant in the argument, will contain a multiple of the body's angular movement round the earth. In this respect his theory is greatly superior to that of the English philosophers whom we shall mention shortly. The method of expansion which he has adopted is exactly similar to that of (447.) and (450.), though its principles are absolutely arbitrary. We shall defer to the next Section the statement of his results; and shall only mention here that his method of discussion is exactly the same as in his second volume, not using all the observations made at all times, but only comparing those which are made at or near to the times at which the irregularity which he is seeking has its extreme values.

Laplace's method much superior to methods employed before him.

(489.) The method of discussing the observations which we have above described as Laplace's (independently of the advances, however arbitrary their foundations may be considered, in the theory) was undoubtedly a great improvement upon that used by Lalande in his *Traité du Flux et Reflux de la Mer*, who had contented himself with picking out, from the same collection as that first used by Laplace, a single observation here and there, and thus (taking them as affected by winds and other accidents) had sometimes arrived at conclusions opposite to those which Laplace established. But the great principle of employing masses of observations was first used in its greatest extent by Mr. (now Sir J. W.) Lubbock, in the discussion of the observations of high water made at the London Docks during nineteen years (from 1808 to 1826).—See the *Philosophical Transactions*, 1831. The process used by Mr. Lubbock was nearly as follows. The quantity treated in regard to times was, the interval between the moon's passage over the meridian and the time of high water: the quantity treated in regard to heights was, the height of high water above a certain fixed mark on the dock-wall. Then, first, the observations were divided by months, (the observations of every month of January during all the nineteen years being collected into one group, those of every month of February into another group, and so on.) As the moon's node has performed one revolution, and the moon's perigee two revolutions, almost exactly, in the nineteen years, and as the inequalities in the moon's motion not connected with the time of year depend only upon these elements, and have gone through all their changes in the nineteen years, it is plain that the means inferred from these groups will give an accurate representation of all the phænomena which depend solely upon the time of year. The groups were then subdivided into parcels, each parcel including all the observations at which the moon's passage over the meridian occurred in each half hour of apparent solar time. Thus for the month of September, the first parcel included all the observations corresponding to the moon's passage over the meridian within half an hour after the sun for every September through the nineteen years; the second included all in which the moon passed more than half an hour and less than an hour after the sun, and so on. Thus the first table of rough results was obtained, which, when its irregularities were smoothed down, gave a table of results adapted to further use. Secondly, the observations were divided into groups corresponding to minutes of the moon's horizontal parallax, (the first group including all in which the moon's parallax was greater than 54′,

Mr. Lubbock's methods of treating times and heights of high water.

For mean values depending only on the time of the year, and the time of the moon's transit.

For the effect of variation of parallax.

and less than 55′, and so on,) and each group was subdivided into parcels corresponding to each hour of apparent solar time at which the moon passed the meridian; the observations made in the afternoon were, however, alone employed here. Thirdly, the observations were divided into groups corresponding to every three degrees of declination of the moon, (the middle group containing all in which the declination was between $1\frac{1}{2}^\circ$ north and $1\frac{1}{2}^\circ$ south,) and each group was subdivided into parcels corresponding to each hour of apparent time in which the moon passed the meridian. The mean of each parcel was in all cases taken, as well for the times as for the heights. Thus three sets of tables were obtained, the leading division of the first being the month, that of the second being the parallax, that of the third being the declination; and all being subdivided according to time of moon's transit. In the first table, the means of all the results for the different months corresponding to the same half hour of moon's transit were taken. These means were subtracted from all the quantities of the three sets of tables, and thus new tables were formed. Then it was intended by the author that a tide (either in time or in height) should be computed as follows:—1st. The quantity depending on the moon's transit only should be taken. 2nd. The correction to this depending on month and moon's transit should be added. 3rd. The correction depending on parallax and moon's transit should be added. 4th. The correction depending on declination and moon's transit should be added. It was, however, pointed out by Mr. Whewell and acknowledged by Mr. Lubbock (*Philosophical Transactions*, 1834) that the last correction is nearly included in the second, because for a given month and given hour of moon's transit the moon's declination is given, excepting that part which depends on the inclination of her orbit to the ecliptic.

For the effect of variation of declination.

(490.) Observations were also selected in classes, to show that there is no sensible diurnal tide at London; and others showing that the direction of the wind produces no sensible effect. Although little of mathematical deduction accompanied this work, we must allow that it was far more complete as a classified discussion of observations than any that had preceded it.

(491.) In the *Philosophical Transactions*, 1833, Mr. Lubbock applied the same method (merely so far as the process for the first table mentioned above) to observations made at St. Helena, Brest, Plymouth, Portsmouth, and Sheerness. In the volume for 1834 he has modified the tables of 1831, so as to correct the error which we have mentioned. In the volume for 1835 he has discussed an immense number of observations, made at Liverpool during nineteen years from 1774 to 1792. They are treated in exactly the same manner as the London tides, except that the observations when the moon's declination is north are separated from those in which it is south, the difference between these showing the existence of a diurnal tide. In the volume for 1836, the same observations are discussed specially for the discovery of the diurnal tide; the process is simply to divide by months and to subdivide by half hours of transit, (as before,) which defines in every case the moon's declination nearly, and then to divide each parcel once more into two parts, one part including upper transits of the moon with north declination, and lower transits with equal south declination, (the tides corresponding to which ought to be similar,) and the other part including upper transits of the moon with south declination, and lower transits with north declination.

Sect. VI Method used fo observin the Ti and fo reducin the Ob servatio

Mr. Wh well's n thods o treatin Mr. Lu bock's results

(492.) Thus far, however, we have merely numerical values, embodying the result of all the observations in a convenient form, and adapted to prediction, but not giving mathematical laws. The first step to this object was made by Mr. Whewell in the *Philosophical Transactions*, 1834. The following is his method, for the times of high water; it being premised that the parallaxes and declinations spoken of are the same as those used by Mr. Lubbock, and therefore are those which correspond to the time of high water, or a time near it, and not those which correspond to the anterior time indicated by theory in (452.). First, he remarks that (as pointed out by Mr. Lubbock) the mean of all the intervals between the moon's transit and the high water contains a term corresponding very exactly in value for different hours of moon's transit to the first term in (54.) increased by a constant (for London 1 hour 26 minutes), provided we diminish $\overline{m-s}$ by another constant (for London 2 hours); the value of $\frac{S}{M}$ being properly determined $\left(\text{for London it is } \frac{1}{2\cdot 99}\right)$. Next, he takes the tables of difference for each half hour of moon's transit between the mean interval and interval corresponding to different values of the moon's parallax; and, by inspection, he sees that in regard to the changes produced by change of parallax, the numbers in the table change sign when they pass 57′ (the mean parallax); and, in regard to changes of hour of transit, they may be represented by $\sin^2$ (hour of transit—4^h), and therefore that the formula is something like a multiple of $p'.\sin^2$ (hour of transit—4^h). Determining the multiplier so that the sum of all the numbers in the table will be represented by the formula, he obtains finally $3^m \times p' \times \{1+\sin(2.\overline{m-s}-2^h)\}$. This does not correspond exactly to the second term in (54.). For the declination, he changes all Mr. Lubbock's numbers expressing the difference from the mean state depending on declination, to the difference from the numbers when the declination is 0, and shows that in regard to change of declination the sum for all the different hours of transit may be expressed nearly enough by a multiple of the square of the sine of declination, and that when the mean for declination 0 is restored, the mean correction may be expressed by $11-132\times\sin^2$ declination. He then applies this quantity with sign changed to Mr. Lubbock's numbers, and finds that there remains another set of numbers whose law is to be investigated. From inspection, nearly as before, this is found to be represented nearly by

Deter mines mathe tical e pressi for th correc by its tion of Lubb numb

$$84\left(\frac{1}{12}-\sin^2\text{declination}\right)\sin\left(2.\overline{m-s}-8^h\right);$$

and thus the whole correction for declination is

$$\left(\frac{1}{12}-\sin^2\text{declination}\right)\left\{132+84\sin(2.\overline{m-s}-8^h)\right\}.$$

The observations of height are discussed in a similar manner; the general principle being, to take the principal term of the expression in (53.), and to examine whether the principal part of the height agrees with it, (the correction to $m-s$ being somewhat different from that used for the times of high water.) Then the differences depending on parallax and on declination are resolved into parts nearly in the same manner as above. We shall not delay further on this, but shall remark that, however much the conclusions were modified by later suppositions or by choice of expressions analogous to those of (457.), &c., we confidently refer the reader to this investigation as one of the best specimens of the arrangement of numbers given by observation under a mathematical form. In the *Philosophical Transactions*, 1836, Mr. Whewell has used the same method with some small additions, for reducing to law the numbers given by Mr. Lubbock's discussion of the Liverpool tides.

(493.) In the *Philosophical Transactions*, 1833, Mr. Lubbock exhibited the inequalities of the time of tide, (neglecting those depending on parallax and declination,) by graphical construction, for six different places. The method is, to construct a curve, in which the time of the moon's transit is the abscissa, and the interval from transit to high water is the ordinate. In the same volume, page 232, Mr. Whewell recommended the adoption of this as a general method of obtaining the numbers useful for prediction of tides. In discussing a series of observations made by the persons employed on the Preventive Service, (*Philosophical Transactions*, 1835,) he appears to have used projections extensively. In examining the effect of the sun's declination in the Liverpool tides, graphical projection was used by Mr. Whewell, to exhibit the numbers remaining after the application of other known corrections; and, a curve being drawn with a free hand among the points laid down from the actual numerical data, this curve was treated as the proper representation of those remaining numbers, and the values at different times were measured from the curve, instead of adopting the numbers themselves. Since that time, the use of curves has been commonly adopted by Mr. Whewell and Mr. Lubbock, (see the *Philosophical Transactions* for 1837, and especially the investigation of the progress of the diurnal wave by Mr. Whewell;) and in the *Philosophical Transactions*, 1838, Mr. Whewell (adopting Mr. Bunt's methods) has given rules for the most advantageous employment of the method of curves. They are as follows:

(494.) "Upon a series of parallel ordinates corresponding to the times of moon's transit, I lay down the successive tides, that is, the heights or the lunitidal intervals, as the one or the other are the subject of examination. This curve is more or less irregular, but for most places the leading feature is the zigzag form which arises from the diurnal inequality. A curve is drawn by the eye so as to cut off this inequality, leaving equal differences above and below. We may then proceed as follows to find the other inequalities.

"Having laid down the observed intervals and heights, referring both to the *apparent* time of the moon's transit, and having drawn through each series of points the dotted line which cuts off the diurnal inequality only, but retains every other, I trace off on a piece of transparent paper, having an axis drawn on it extending from 0 hours 0 minutes to 12 hours 0 minutes transit, the successive portions of the dotted line of observation just mentioned, which are included between those hours during the first three months of the year; fitting the tracing paper in its place every time by means of the two extreme points of the axis. I thus obtain six irregular curves, [the same curves, nearly, occurring twice in each lunation,] the mean of which is found by drawing across them, at equal distances, twenty-four vertical lines, and finding by my scale a point in each which is the exact mean of the six intersections. In this manner I get four mean curves [one for each time of three months] on separate pieces of paper, which by repeated combinations are reduced into one, being the mean semimenstrual curve for the year.

"The next step is to reduce this curve to a mean parallax (57′·2) at each hour of transit. For this purpose an arrangement must be made, showing the mean parallax for that year at each of the twelve hours, which will be found to vary from about 56′·9 to 57′·5. [That is, for each of the days throughout the year, at which the moon's transit occurs between 0 hour and 1 hour, the parallax must be taken from the Nautical Almanac, and the mean of all these must be supposed to apply to 0 hour 30 minutes; and so for other hours.] The parallax table of the preceding year, if already discussed, will be sufficiently near for making the requisite small alteration of the curve to the mean parallax; otherwise an approximate parallax table for the current year must be first made.

"I then calculate [in the same manner] the mean declination, [for each hour of the moon's apparent transit,] which varies, not only as the parallax, slightly from hour to hour, but also considerably from year to year. The hourly differences (being only about half a degree from the mean) I have disregarded, and I prefer marking on each annual curve the mean declination of that year, to any attempt to reduce the different annual curves to one common declination.

"Having [as before mentioned] very carefully obtained the mean semimenstrual curve, I cut it out nicely on a piece of thick drawing-paper, and laying the intersections of the vertical hour lines of 0 hour and 12 hours with the axis, on the corresponding points on my sheets, [viz. those mentioned in the first paragraph,] I pencil-in the mean curves, and then ink them. The residue, or space between the mean curve and that of observation, is next transferred to a straight line below [as an ordinate to a new curve.]

"In examining this residue, the first step is to lay on an *approximate* line of parallax. For this I make an arrangement for every hour of transit, and for 54′, 55′, 56′, and 59′, 60′, 61′ of parallax [that is, two groups for each hour] (omitting 57′ and 58′) of all the vertical distances, at the successive hours of transit, of the curve from the straight line, adding to each a constant to avoid negative quantities. I thus obtain twenty-four parcels, the means of which give an approximate correction for 55′ and 60′ at every hour of transit. From this a first line of parallax is laid down, preparatory to the obtaining of the declination-corrections.

"These are obtained by collecting the measured distances from the parallax line to the curve, into parcels of 0° decl. to 13° decl., and 21° decl. to 28° decl. for every hour of transit, omitting those of 14° to 20° decl., and taking the axis, with the mean declination of the year, as a better representative of the mean declinations. The means of these twenty-four parcels give me a declination-correction very near the truth. From this I lay down, on the parallax line, the effect of declination, and thus get an approximate curve of declination combined with parallax. Both this and the former curve of parallax are drawn in with pencil only, being merely used as approximations, whence *corrections* of the first parallax and declination-*corrections* are obtained. This is done by an arrangement (as before) of the spaces still remaining between the pencil curve of declination combined with parallax, for hours of transit and for 54′, 55′, 56′, and 59′, 60′, 61′ parallax, which gives a small additional correction of the parallax corrections first obtained. From this corrected parallax correction, I draw in, with ink, the true parallax line, making the requisite alteration in the line of declination combined with parallax, which is then also inked in. Finally, a *correction* of the declination-corrections being made from this latter line, is considered as giving the true effect of the declinations."

The accuracy of result depends on the assumption of a correct law.

(495.) We have only to remark further on this, that much will depend upon the operator's mental assumption as to the *law* of the inequality as depending on either of the elements of correction. If, for instance, he assumes (as required by theory) that the correction for declination is nearly proportional to the square of the declination, it will be better to use the square of declination throughout. It is evident that there is nothing in the precepts above to prevent the operator from referring the parallax, declination, &c., to any time previous to the transit which immediately precedes the tide; and this, in fact, is done by Mr. Whewell in some discussions of tides.

Comparison of Laplace's methods with Mr. Lubbock's and Mr. Whewell's.

(496.) In remarking on these methods we cannot fail to observe that Mr. Lubbock's method of using *all* the observations for his first results, and the methods founded on this by Mr. Whewell, are in some respects greatly superior to Laplace's, which used only observations made at particular times. Thus Laplace *assumed* that the principal corrections for parallax *must* occur on the days when parallax was greatest or least; Mr. Lubbock's method, if properly used, would show whether that is true or not. On the other hand, Laplace's method is much superior in the facility which it gives for introducing such considerations as that of the variation of effect produced by variation of velocity in right ascension, (a real quantity, as shown by the second terms in our expression of (448.), and by the remarks in (455.), though for a reason very different from Laplace's.) But, viewing the two independent methods introduced by Mr. Whewell, of reducing the tabular numbers to law by a process of mathematical calculation, and of exhibiting the law to the eye without any mathematical operation by the use of curves, we must characterize them as the best specimens of reduction of new observations that we have ever seen; although, with a more accurate knowledge of theory, they might have been much improved.

Methods applying to the progress of the tide-wave across the ocean.

(497.) Thirdly, in regard to the progress of the tide over the different parts of the sea covering the greater portion of the earth. As the tide is itself a changeable state of the water, and as its elements vary from day to day, it is necessary to fix upon some definite phænomenon at some definite time in order to be able to compare the times of tide at different places. By common consent of mariners, the time adopted is "the time of high water on days of new moon and full moon," or rather the interval from the moon's transit at which high water occurs on those days. This is called the *establishment* of a port. It is to be observed that the interval taken on the day of new or full moon is not the same as the mean of all the intervals taken under all circumstances; this latter is termed by Mr. Whewell the *corrected establishment*, and it is by far the more important element in scientific discussion. The former however is most easily understood by practical men, and it is therefore the element most usually adopted in such comparisons as those of which we are speaking.

Establishment; its meaning.

Sect. V. Method used fo observin the Tid and for ducing Observ tions.

(498.) Now the establishment is commonly given in the time of the place. But in order to make the establishments of different places comparable, with the view of tracing the general course of the tide, we must express them all in the time of one standard place, Greenwich for instance. For this purpose we have only to subtract the east longitude or add the west longitude, (expressed in time,) and we have then a set of numbers which are strictly comparable, and which express the Greenwich time of high water at each of the places on the day of new or full moon.

(499.) Suppose now that these last numbers are marked on a chart, and that, on inspecting the chart, we see at two points on opposite sides of a sea and at several small islands between them the same indication III^h. This denotes that it was high water at all those places at the same time, which on a day of new or full moon was 3 o'clock. We may then consider the tide as a great wave whose ridge passed through those places at 3 o'clock on that day. Suppose that, on looking at another part of the same sea, we find a series of points marked IV^h. From this we infer that the ridge of the wave passed through this series of places at 4 o'clock on the same day. We conclude therefore that the ridge of the wave has travelled from one of these lines to the other in one hour; not by the motion of the particles of water through that space, but by the change in the relative motion described in (135.), and other parts of Section IV. If now we draw a line through the first series of points that we have mentioned, it is called the *cotidal line* of III^h; a line drawn through the second series of points is called the *cotidal line* of IV^h; and so on.

Cotid lines.

(500.) Cotidal lines of this kind had been drawn by Dr. Young and other writers, but to a small extent. The first instance (so far as we are aware) in which they were traced on a large scale, was in the charts inserted by Mr. Lubbock in the *Philosophical Transactions*, 1831. But greater extent, as well as greater accuracy, were given by Mr. Whewell's investigations in the *Philosophical Transactions*, 1833, 1835, and 1836.

(501.) It is proper to remark that the whole of our directions regarding this matter go on the supposition that the semidiurnal tide is the only one of any importance; at least that the diurnal tide, though perhaps sensible, does not materially disturb the times and general order of the semidiurnal tide. We shall however find instances in which the diurnal tide is far greater than the semidiurnal tide. In these cases the word *establishment* ceases to be applicable. And though it would not be difficult to extract, from a long series of observations, a fundamental number bearing the same relation to the semidiurnal tide which the ordinary establishment bears to the semidiurnal tide of other places, yet it is not easy so to state a rule that nautical persons would be able speedily to ascertain its value for such a place. In regard to these localities therefore cotidal lines are yet wanting.

(502.) We cannot close this part of our work without remarking on the confusion, and the consequent difficulty of drawing cotidal lines, produced in many places by the inaccurate habits of seamen and all who minister to them, (in England at least,) in not distinguishing between high water and the termination of flood or slack water. On this point see (5.) and (184.). In French works these are carefully distinguished: thus in Romme (*Tableau des Vents et des Marées*) the words *flot* and *jusan* are appropriated to the flow and ebb, while *montant* and *perdant* are used only for the rise and fall; and the want of synchronism between them is clearly explained. But in some of the best English charts, from ignorance of this circumstance, the times of high water on the coast and in the sea at a few miles distance are marked as differing 2½ hours or 3 hours; and even in the table of tides in the *Nautical Almanac*, the establishments at Portland Road and Portland Race are marked as differing 3 hours. We trust that this stain on the scientific character of our mariners will soon be removed.

SECTION VIII.—COMPARISON OF THE PRECEDING THEORIES OF THE TIDES, WITH OBSERVATIONS.

(503.) In the present Section we propose to bring together the principal results obtained by the methods described in the last Section, and to confront them with the theories of the preceding Sections. For convenience we shall divide this Section into the following Subsections:

- Subsection 1.—On the individual tides in rivers, and in bays and estuaries in which the character of the tides is nearly similar to that of rivers.
- Subsection 2.—On the individual tides in some small seas.
- Subsection 3.—On the laws of the tides for varying positions of the Sun and Moon, at several different places.
- Subsection 4.—On the progress of the tide over different parts of the ocean.

Subsection 1.—On the individual Tides in Rivers, and in Bays and Estuaries in which the character of the Tides is nearly similar to that of Rivers.

(504.) The common property which unites the various classes of canals considered here is, that the elevation and depression of the surface of the water bear a sensible proportion to the depth of the water. The theories, therefore, which are to be considered as specially applying to them are, the whole of the Subsection commencing at (192.) and illustrated by figures 9, 10, 11, 12, 13, 14, 15; and the theory from (307.) to (309.), illustrated by figures 16 and 17. Besides these, however, we shall find it necessary to apply the theories relating to variation of breadth and depth (238.) to (264.), because in far the greater number of rivers, &c., the breadth and depth diminish in proceeding from the sea. And in all cases the laws of friction must be supposed to apply, and the theorems from (332.) to (335.) must therefore be used. We shall now advert to special instances.

(505.) The theories from (238.) to (264.) lead us to expect that, where a river contracts rapidly and shoals rapidly, the range of tide will certainly increase. We are not prepared to say that the law which we have laid down in (264.) would apply with extreme accuracy, because the assumptions of very slow contraction and very slow variation of depth on which the process of (262.) is founded might not be safe except the contraction, &c., extended through the length of several waves. Still there is no doubt of the general correctness of the result. But the theorem of (332.) shows, as a consequence of friction, that if the channel be uniform the range will decrease. Combining these, we see that there is a certain rate of contraction with which the range of tide will be stationary: if the river contracts more rapidly, the range will increase from the preponderating effect of contraction: if it contracts less rapidly (and *à fortiori* if it expands), the range will diminish from the preponderating effect of friction. We can easily supply the reader with instances.

Instances of the change of magnitude of tide in passing up a river; first increasing, afterwards decreasing.

In the Thames, the mean range at Sheerness is about 13 feet, at Deptford about 17 feet, at London Bridge about 15 feet, and from this point it diminishes gradually to the weir drawn across the river at Teddington, (a few miles above Richmond,) where it is about 2 feet. A longitudinal section of the river, given by Messrs. G. and J. Rennie in the *Fourth Report of the British Association*, is copied in figure 44, (as far as relates to the tides,) and exhibits clearly to the eye this change of extent of oscillation.

The ranges in different parts of the Severn we have mentioned in (7.).

On approaching the Seine, the mean range is about 13 feet; at Havre it is 20 feet; at Quillebœuf it is about 13 feet; and from this point it decreases rapidly.

At the Cumbray islands, in the Firth of Clyde, the mean range is about 6 feet; at Greenock about 7; at Port Glasgow about 9; at Glasgow about 7; after which it decreases.

In the river St. Lawrence, the range increases from 4 or 5 feet at its mouth to 14 feet at Quebec; after which it dies away.

These instances might be multiplied to any extent, the alteration of range of tide in all contracting rivers following nearly the same laws.

Instances of large tides in interrupted estuaries.

(506.) There is, however, another cause which sometimes operates to increase the tides considerably without any convergence; it is the interruption of the canal, supposed uniform, by a barrier. This case is treated theoretically in (307.) and (333.). From (307.) it appears that, if there is no friction, the high water will occur at the same time in every part of the canal, and its range may become very great at the upper end: the horizontal motion, or tide-current, will be very great at the mouth. In (333.) it appears that, from the introduction of friction, the height will not increase so much; and the time of high water will be later as we ascend the canal. Perhaps the best instance of this case is in the Bay of Fundy. At its entrance the currents are very rapid, but the range is only about 8 feet. But at the head of the bay (where it branches into two shoaly arms) the range of tide sometimes amounts to 60 or 70 feet. The high water is later here than at the entrance of the bay by one hour nearly. In the Gulf of California the tide rises to a great height, though small at its entrance. In like manner, the range of tide in the Wash is about 26 feet, while it is only 6 feet at Yarmouth; and at St. Malo, Avranches, &c., it is nearly 40 feet, while at Cherbourg it is only 15. We consider this last instance analogous to the others, because we imagine that the islands of Jersey, &c., almost effectually prevent the tide from flowing on the eastern side of the bay (in any important degree as regards the supply of water for the bay); and, therefore, the tidal entrance to Avranches is, in reality, one of much less breadth than it at first appears.

(507.) The next circumstance in river-tides which we shall notice is, the relation of the times of slack water (or the turn of the current) to the times of high and low water. In (184.) we have seen that if the river-tide were a wave propagated without friction along a uniform channel of indefinite length, the times of turn of the tide would be exactly intermediate to the times of high and low water, or the cessation of flow would be three hours after high water, and the cessation of ebb would be three hours after low water. But every modifying circumstance which occurs in common rivers brings the cessation of flow nearer to the time of high water, and the cessation of ebb nearer to the time of low water. Thus, in (256.) we find that the shoaling of the bottom produces this effect; in (257.) the contraction of its breadth does the same; in (332.) friction produces a similar effect; and in (335.) it does so in a greater degree if the river is stopped by a barrier: this last effect, however, is small at the mouth of the river. From all these causes combined, the turn of current ought to follow the high and low water at a small interval, especially on advancing near to anything like a barrier in the river. It is notorious among all persons acquainted with river-navigation that this is strictly correct in fact; but we are unable to refer to any numerical values, except for Deptford on the Thames. The mean of a great number of observations (discussed by the author of this Essay in a paper in the *Philosophical Transactions*, 1842) gave, for the interval between high or low water and slack water, 37 to 40 minutes of time.

Instance of small interval between high or low water and stationary water.

(508.) The theoretical circumstance to which we shall next allude is that, in a tidal river affected by a general current towards the sea, and subject to friction, the low water in the upper part may be higher than the high water near the sea (343.). We cannot refer to a better exhibition of the observed fact than that in figure 44; the same thing, however, (we believe,) has been ascertained from accurate levelling along the river Forth.

Instance of low water in river higher than high water in the sea.

(509.) The next theoretical point, and the most difficult, (from the imperfection of limited solutions where the convergence of the series employed is very slow,) is the general law of rise and fall of the water at some distance from the sea, the extent of vertical oscillation of the surface bearing a sensible proportion to the depth of the water. Where there is no barrier across the river, (at least within a great distance of the sea,) and where the oscillation is not *very* great, the theory of (192.) to (221.) will apply. From this we find as follows.

(510.) First, supposing the place not very far from the sea, the principal effect will be, that the rise of the water will occupy a shorter time than the fall (see figure 11); and the inequality will be greater far from the sea than near the sea, and greater at spring-tides than at neap-tides. In illustration of this, we are able to place before the reader figure 45, representing the registered tidal curve at Sheerness on the spring-tide of 1841, February 24, afternoon; figure 46, representing the tidal curve formed from observations of the same tide at Deptford; and figure 47, representing the tide of 1821, July 29, (in nearly similar position of the moon, &c.,) near London Bridge (*Fourth Report of British Association*, page 495). In figure 48 is represented the course of the neap-tide of 1841, March 2, afternoon, at Sheerness; and, in figure 49, that of the same tide at Deptford. All these curves are drawn to the same scale, and illustrate fully the points that we have mentioned. In figures 45, 46, 47, the times of rise and fall are, respectively, at Sheerness 6 h. 5 m. and 5 h. 55 m.; at Deptford 5 h. 0 m. and 7 h. 0 m.; and at London Bridge, 4 h. 48 m. and 7 h. 59 m. (the whole time being accidentally too small in the former and too large in the last). In figures 48 and 49 the times of rise and fall are, at Sheerness, 6 h. 30 m. and 6 h. 30 m.; and at Deptford, 6 h. 0 m. and 6 h. 30 m. At Teddington the times are about 1 h. 15 m. and 11 h. We may also state from Lalande, that the tide at Havre occupies six hours in its rise, but that at Quillebœuf and places above it, it occupies not more than two hours. A better instance is that of the St. Lawrence: at 40 leagues below Quebec, the rise and fall occupy equal times; at six leagues below Quebec, the rise occupies five hours, and the fall seven hours; at 20 leagues above Quebec, the rise occupies three hours, and the fall nine hours.

Instances of the change in the form of the tidal curve in passing up a river.

(511.) Secondly, supposing the place somewhat further from the sea, there will be a sensible check to the descent of the water; there may even be a small rise near the middle of the descent. That such a check does occur in fact will appear from figure 50, which is copied from a diagram given by Mr. Russell in the *Seventh Report of the British Association*, representing the tidal curve on the river Dee, in Cheshire.

(512.) Thirdly, supposing the place still further from the sea, and the tide somewhat larger, so as to make another term in the approximation necessary, it appears, from figure 14, (remarking that the tidal curve for any station may be formed nearly enough by reversing the form of the wave near that station,) that there may be a treble elevation in the course of one tide; and comparing this with figure 15, it appears that this phenomenon may be very conspicuous for spring-tides at the same station at which it cannot be perceived at neap-tides. Now this treble tide does occur in the Forth, where it is known by the name of the Leaky. (Something like it occurs also in the Tay, and probably in the Thames and other long rivers.) It is understood that Mr. Russell has in preparation an elaborate account of observations of the Leaky; as it is not yet published, (a short notice only being given in the *Tenth Report of the British Association*,) we must draw our information from Wright's account in the *Philosophical Transactions* for 1750, page 412. The principal points mentioned are, that the Leaky begins at Queen's Ferry, or a few miles above it, and in neap-tides extends 25 miles up the river above Queen's Ferry, and in spring-tides 19 miles further (three miles above Stirling); that the highest water is not that from the first rise, but that from the second rise. (In this respect it appears to differ from the tide represented in figure 14, in which the first rise is the highest; but it is extremely probable that the consideration of friction and of other impediments might sensibly alter this form.) It is stated, also, that there are no Leakies at full moon, though there are at new moon. We doubt the accuracy of the writer in regard to this point, because the circumstances of sea-tide, which alone could affect the river-tide, (namely, semi-diurnal and diurnal tide,) are the same at new and full moon. On the whole, while we see beyond doubt that the Leaky is a legitimate instance of the application of our theory, (having been observed 90 years before the theory explaining it was formed,) we think it has not yet been described with the accuracy that a phænomenon so remarkable deserves.

(513.) But suppose the tide to be so very large in proportion to the depth of the water that our series of terms in (210.) ceases to be convergent; what shall we conclude to be the form of the tide-wave? Our mathematics here are at fault; and (till the analytical difficulty has been overcome) we must refer to observation. We may state this, then, as the result. As the very large tide progresses, its time of rise becomes shorter, and its time of fall longer; but the descent is not uniform, the greater part of the descent occupying not much more time than the rise, and the last part of the descent being almost imperceptibly slow, which again is succeeded by a very sudden and rapid rise of the next tide. The course up the Severn may be gathered from figures 51, 52, 53. At the lower part of the Bristol Channel the rise and fall, we believe, occupy nearly equal times, (although we are not aware of any careful observations,) and figure 51 may be taken as the representation of the tidal curve there. Figure 52 is a copy of a curve traced by a self-registering tide-gauge erected at Hung Road, (near the confluence of the Avon and the Severn,) for which we are indebted to the kindness of Mr. Bunt. The whole time of rise appears to be four hours at the least. Figure 53 represents the tidal curve at Newnham, drawn generally from our own rough observations. The whole time occupied by the rise ($1\frac{1}{2}$ hour) is accurate. We believe that this may be taken as a type of the tide-wave in rivers where the entering tide is remarkably large.

(514.) Connected with this rapid rise of the tide, in the case of the last article, is the Bore; a phænomenon on which, we believe, some misconception prevails. We believe that the following description of its cause and appearance will be found correct. It is necessary for its formation that there be a very large tide rising with great rapidity (thus, at Newnham, where the water rises 18 feet in an hour and half, the bore is considerable). It is necessary, also, that the channel of the river be bordered with a great extent of flat sands, near to the level of low water. These circumstances hold in the Severn, the Seine, the Amazons, the bays at the head of the Bay of Fundy, (Chignecto Bay and the Bay of Mines,) and other places where the bore is remarkable: the second does not hold in the Thames; and, in consequence, that river has no bore. When the rise of the tide begins, the surface of the water is disturbed in mid-channel, so as to distort reflexion, but the water is not *broken;* it is merely like a common wave. This point (which we state from our own observation) is fully confirmed by De la Condamine's account of the bore in the Amazons, and by the practice, in the Hoogly river, (near Calcutta,) and other places subject to a bore, of rowing boats, &c., into the middle of the channel on the approach of the bore, in order to place them out of danger. But as this rapid rise elevates the surface suddenly above the level of the flat sands, the water immediately rushes over them with great velocity and with a broken front, making a great noise. And this is the whole of the Bore. It is, however, a majestic phænomenon, especially when witnessed from a station which commands the river for several miles above and below, (we may particularly mention Newnham churchyard, on the Severn,) and at an hour when other sounds are stilled. The rise of the water continues, after the Bore has passed, with unabated rapidity, as far as can be seen by general observation, and the tidal current flows rapidly up the river, which is now quite full. At last its rapidity of rise diminishes, and at 90 minutes after the bore, at the place which we have mentioned, it begins to drop, the current still flowing up. About 15 minutes after the beginning of the drop, a singular line of ripple (of which we can give no further explanation) is seen, stretching across the whole river, and moving very slowly downwards. This appears to be the place at which the ascending current and the descending current meet; for, as soon as it has passed, the water is seen to be running slowly downwards, and in a very short time it is running with a speed which is scarcely to be seen under any other circumstances of any river, except, perhaps, some of the largest rapids. The remarkable point attending this last phænomenon is, that the phase of change of current moves *down* the river. In every other instance, the phases, whether of high water, of low water, or of change of current, move upwards; although that of low water (208.) moves upwards much more slowly than that of high water. It would seem here that one of the velocities has actuallly changed its sign.

Instance of Deptford tide expressed by a mathematical law.

(515.) The only instance in which the phænomena of tides in a continuous river have been reduced to mathematical law by such a process as that of (479.) is in the tides of Deptford (*Phil. Trans.* 1842). Referring to (479.) for the process used, it appears that the result expressed the depression of the water for every value of *phase;* the *phase* being an angle increasing by 360° from high water to high water, and the unit in terms of which the depression is expressed being the half oscillation. Thus it was found that at Deptford, when the range of tide was 15 feet 3 inches, putting $p =$ phase $-77°.50'$, the depression of the water below a fixed mark might be represented by

$$13\text{ ft. }10\text{ in.} + 7\text{ ft. }7\cdot5\text{ in.} \times \{0\cdot939 \sin p - 0\cdot066 \sin(2p - 38°.22') - 0\cdot048 \sin(3p - 48°.40') \\ + 0\cdot012 \sin(4p - 97°.2')\}$$

and that when the range of tide was 19 feet 2 inches, putting $p =$ phase $-86°.23'$, the depression of the water below the same mark might be represented by

$$13\text{ ft. }3\text{ in.} + 9\text{ ft. }7\text{ in.} \times \{0\cdot902 \sin p - 0\cdot106 \sin(2p - 19°.11') - 0\cdot069 \sin(3p - 62°.19') \\ + 0\cdot033 \sin(4p - 75°.35')\}.$$

Difficulties in reconciling the observed law with the theoretical law.

The first thing to be remarked is, that the mean level (or the term independent of sines) is higher in the large tides than in the small ones. Probably a part of this arises from the influence of the second term in the expression of (309.); but a part also is produced by the difference of the same kind at the mouth of the river, as it appears in Mr. Lloyd's paper (*Phil. Trans.* 1831) that the mean level at Sheerness is higher in spring tides than in neap tides by 7 inches nearly. The next thing which deserves notice is, that the coefficient of sin $(2p-19^\circ.11')$ is larger than that of sin $(2p-38^\circ.22')$ in a greater proportion than that of the range of tides; whereas the expressions of (210.) and (309.), supposing them to be put under brackets with the coefficient of the first term as a general multiplier, would give for the coefficient of the term depending on $2mvt$ a quantity proportional to the range. This seems to show merely that the approximation is not carried far enough for such a tide as that of the Thames. The third point to be noticed is, that the argument of the second term (or the angle whose sine enters into the second term) is not double the argument of the first term, as it ought to be by the expression of (200.) or (210.), but is double the argument of the first term diminished by a constant. This may arise from the same imperfection of the mathematics; or it may be explained thus. The bridges and other impediments may produce in some degree the effect of a barrier, and therefore the true expression ought to be intermediate to those of (200.) and (309.). The former with changed sign, and putting C for bk, gives for the variable part of depression

Explained in some degree by the impediments to the free motion of the water.

$$C\left\{\sin(mvt-mx')-\frac{3}{4}b.mx'.\sin(2mvt-2mx')\right\}.$$

The latter, with changed sign, making $\frac{A}{\cos ma}.\cos\overline{ma-mx'}=C=bk$, and putting $B=180^\circ$, gives for the variable part of depression

$$C\left\{\sin mvt-\frac{3}{4}b.mx'.\tan(ma-mx').\cos 2mvt\right\}.$$

If then the true expression were the mean of these two, it would be

$$C\left\{\cos\frac{mx'}{2}.\sin\overline{mvt-\frac{mx'}{2}}-\frac{3}{8}b.mx'.(\cos 2mx'.\sin 2mvt-\overline{\sin 2mx'-\tan(ma-mx')\cos 2mvt})\right\}.$$

If $\frac{\sin 2mx'-\tan(ma-mx')}{\cos 2mx'}=\tan\overline{2mx'-D}$, where D will be small if the place of observation is near to the bridges, &c., this will become

$$C\left\{\cos\frac{mx}{2}.\sin\overline{mvt-\frac{mx'}{2}}-E.\sin\overline{2mvt-2mx'+D}\right\};$$

and if we put $\overline{mvt-\frac{mx'}{2}}=p$, it becomes

$$C\left\{\cos\frac{mx'}{2}.\sin p-E.\sin\overline{2p-mx'+D}\right\}$$

or

$$C\left\{\cos\frac{mx'}{2}.\sin p-E.\sin\overline{2p-F}\right\},$$

an expression possessing the peculiarity in the form of the argument of the second term to which we have adverted. On the whole, we regard the phænomena of the Deptford tides as agreeing pretty well with the laws given by our mathematical investigations.

Instance of a river (the Amazons) with several high and low tides existing upon it at once.

(516.) Before quitting the subject of tides in continuous rivers we may remark, that it is easy to conceive a river so long that there may be at the same instant several tides of high and low water alternately at different points along the river, its course being so long that the wave of high water occupies several days in passing up. We are aware of only one instance in which this is recorded as actually having been observed, namely the river Amazons. De la Condamine, who descended this river in 1743, (see the French *Memoirs* for 1745,) has stated that the tide is observable at Pauxis, 200 leagues from the mouth of the river, and that between this place and the mouth there are at any instant a score of places, more or less, [*une vingtaine de parages, plus ou moins,*] at which it is high water at that instant; the places intermediate to these having low water at those times. He conceives the tide-wave to advance there at the rate of one league per hour nearly.

Instance of estuary tide (Southampton) reduced to mathematical law. Difficulty of explaining it.

(517.) When the river is stopped by a sudden barrier, (a circumstance which holds nearly in the Southampton Water, the Orwell, the Stour, several arms of the sea on the coast of Cornwall, many of the sea-lochs of Scotland, &c., and many other estuaries,) the theory of (309.) illustrated by figures 16 and 17 ought to apply. We are not aware that sufficient observations have been made upon any estuary-tide except that of Southampton, and there they give the very singular curve represented in figure 54. Here is a double high water, as in figure 17, and it appears therefore that there is some agreement between the theoretical and the observed forms. But this is not so obvious when the height is expressed algebraically by the process of (479.). It appears, then, that the variable part of the depression below a fixed point (as applying to seven tides between 24th February and 27th February, 1842) may be expressed by

$$7\text{ ft. }3\text{ in.}\times\{0\cdot 898.\sin p+0\cdot 194\sin\overline{2p-1^\circ}+0\cdot 191\sin\overline{3p-68^\circ.8'}+0\cdot 034\sin\overline{4p+5^\circ.43'}\}$$

where p is an angle increasing uniformly with the time, and changing through 360° in the course of one tide. The theoretical expression (309.), as modified in (515.) is

$$C\times\left\{\sin mvt-\frac{3}{4}b.mx'.\tan(ma-mx').\cos 2mvt\right\}.$$

This matter is open to further investigation.

(518.) The phænomenon of long continued high water or double high water in estuaries is, we believe, not uncommon. Thus at Havre, as described by Dicquemare, (*Journal de Physique*, 1779,) there is a long continued elevation called *la tenue du plein*. The tidal curve, as far as we have been able to construct it from Dicquemare's description, is given in figure 55. On the coast of Holland, (which possesses all the properties of an estuary in this respect, that the tidal water runs for a great distance over a shoaly bottom and then is suddenly stopped by the coast,) there is a double high water (see Moll, *Nieuwe Verhandelingen der eerste classe ... van het instituut ... te Amsterdam, zevende deel*). The first high water appears to be considered by the Dutch, in common language, as the real high water, and the second is called the *agger*, but so little difference is there between them, that, in making the extensive series of simultaneous tide-observations proposed by Mr. Whewell, the agger was sometimes observed for high water.

(519.) We may here properly advert to the anomaly which has been observed in the tides at Christchurch, Poole, and Weymouth, and which by some writers (and by nautical persons on the coast in general) is ascribed to the effect of a tidal current from the Solent or western channel behind the Isle of Wight. We shall first state, that we conceive this explanation to be untenable. Without laying stress on the algebraic circumstance, that the union of two separate tides, one of the form $a.\sin\overline{nt+A}$, and the other of the form $b.\sin\overline{nt+B}$, will produce a simple tide of the form $c.\sin\overline{nt+C}$, it will be seen from figure 56 that the line of the mainland is continued by a long projecting shoal from the visible mouth of the Solent, so as in reality to prolong that channel to a length which, by discharging its water at once into the open sea, must effectually prevent it from affecting a long line of coast. Now in figures 57, 58, 59, we give the tidal curves of these places; in which the part marked with a strong line has been carefully observed by ourselves, (by noting the height of the water every five or ten minutes,) and the rest has been supplied from the information of persons on the spot. It is quite evident, on comparison with figures 12, 52, 53, that these are simply the tides produced by running over a shallow bottom; that at Weymouth corresponding to a case in which the tide is greater than at Christchurch and Poole; which is correct, the tide at Weymouth being double that at Christchurch and Poole. The two latter tides were observed at the mouth of the Avon and at the quay at Poole, and in each of these places the tide has flowed over a shoal, (Christchurch Bay being very shallow,) and has still a considerable distance to flow over it; so that they may be regarded as tides in continued shallow channels. With regard to the Weymouth tide, we cannot explain fully the length of the shoal; but it is remarkable that the cotidal lines follow in close sequence near to Weymouth, which implies that the tide-wave travels slowly *in the same manner* as if the water were shallow, whether that be or be not the cause of it. It would be a curious circumstance if it should be found, theoretically or experimentally, that the alteration of the cotidal lines by the form of the coast produces the same modification of the tides as a shoal which retards the velocity to the same degree. In all three instances also the form of the coast compels the tide to turn backward to these parts, (by passing round Portland Bill to Weymouth, round St. Alban's Head to Poole, and round the reef projecting from Hengstbury Head to Christchurch;) it would be a curious circumstance if it should be found that this assists to produce that modification.

Tidal curves at Liverpool, Portsmouth, Plymouth.

(520.) In the *Philosophical Transactions*, 1840, Mr. Whewell has given tidal curves for Liverpool, determined by observations every half hour and also by observing the exact time at which the surface of the water passed two fixed marks; and tidal curves determined from observations of high water and the time of passing two fixed marks at Plymouth. He remarks that, at Liverpool, the rise occupies less time than the fall; but his tables and his curves imply the contrary for Plymouth. This however is an error, arising from an error in the tabular arrangement of his figures (see page 264, January 4, where the figures 3.28.0 in the last column are improperly raised). On correcting this, it is found that the rise occupies less time than the fall, as, theoretically, it ought to do (204.). And this is the general rule. The tide-observations published by the Admiralty seem to show that at Portsmouth the rise is the longer; but we have good authority for saying that the observations of low water there are very uncertain. It is not impossible, however, that Portsmouth may share in some degree in the peculiarities of Southampton.

Subsection 2.—On the Individual Tides in some Small Seas.

Small tides in the Mediterranean.

(521.) The small information that we possess with regard to the tides of the Mediterranean Sea may be first mentioned. It is notorious that the tides are so small that they cannot usually be recognized; or cannot be distinguished from the effects of wind, (except in the neighbourhood of the Strait of Gibraltar, where they are affected by the tide of the Atlantic Ocean.) This agrees with the result of (300.), in which the greatest value of Y for a closed canal contains as a factor the length of the canal, which for the Mediterranean (considered with reference to tidal phænomena) is small. Yet that there is a tide in every part is shown by the observations of Toaldo at Venice (*Phil. Trans.* 1777). The spring tide there is about four feet, although at the mouth of the Adriatic it can hardly be recognized. It is plain that this case is similar to that of (307.), or to those of the Bay of Fundy, &c., mentioned in (506.), and that a tide, insensible at the mouth, has by virtue of the factor $\frac{1}{\cos ma}$ become sensible at the head.

Tides in the Adriatic Sea.

(522.) The tides in the English Channel claim notice, Tides in the English Channel. False notions on the meeting of tides.

as having been the subject of careful examination by many persons, English and French. A paper in the *Phil. Trans.* 1819, by Captain Anderson, deserves to be mentioned. This writer conceives, that if there is any where a *meeting* of two tides, as from the English Channel and from the North Sea, there must be a terrible disturbance of waters, as if two streams ran to abut each against the other. The reader who has entered into the Theory of Waves will at once perceive that no such consequence follows. While calling to mind the analogy of two ordinary waves on water running in opposite directions and crossing each other without any shock, he may also refer to the result of the investigation in (310.), which is precisely that of two tides from two tidal seas meeting in the same canal, and which shows that at every point the motion of the water is similar to that in ordinary tides, except that there is no simple relation between the times of high water and slack water. If the consideration of friction were introduced, the general expression of (321.), making $H=0$, must be applied, and the same limiting conditions must be used as in (310.), which will show that at both entrances the tide-waves travel towards the centre (except one is much greater than the other). But, dismissing this writer's speculations, we find his information valuable. It appears that in the upper part of the Channel (to which his detailed remarks are confined) the water flows up the Channel nearly three hours after high water, and runs down nearly three hours after low water. He mentions this as a most singular and astonishing fact, although it is merely the law of (184.), which is that of the simplest case of waves. We may mention here, that this continuance of the current after high water, &c., if it last three hours, is called by sailors *tide-and-half-tide;* if it last one hour and a half, it is called *tide-and-quarter-tide*, &c.

Reversion and revolution of currents in the English Channel.

(523.) The results of far more extensive observations are collected by Monnier, in his *Mémoire sur les Courants de la Manche, &c.* From these it appears, as a universal rule throughout the English Channel, that at any great distance from either shore the current runs up the Channel nearly three hours after high water, and down the Channel nearly three hours after low water; and that on the English side of the Channel, especially opposite the entrances of bays, the directions of the currents turn in 12 hours in the same direction as the hands of a watch; and that on the French side they turn in the opposite direction. This is entirely in conformity with the theories of (184.) and (363.). The same laws are recognized as holding in the British Channel, and in the German or North Sea near the Scotch and English coasts. Two instances are mentioned, (off the Start Point and off Ushant,) in which it seems that the direction of the tide, after having turned through a certain angle, turns back through the same directions; but they do not appear to be well established.

Different height of tides in different parts of the Irish Channel.

(524.) With regard to the Irish Channel, we have little to remark, except that there is a very great difference in the height of the tide on the different sides, the tide on the east side being considerably the greater. They are also greater in the northern part (north of Wicklow, on one side, and of Bardsey Island on the other side) than in the southern part. Between Wexford and Wicklow they are very small. For these facts, and for information regarding the height of the tides along a considerable extent of coast, we would refer to fig. 60, (*Chart of British Isles and North Sea,*) in which the small figures along different parts of the coast denote the extreme range of the tide in yards (Whewell, *Phil. Trans.* 1836). The theory of the motion of waves on a large surface of water bounded by an irregular figure is so imperfect that we cannot explain this mathematically; although it seems likely enough that the great wave coming from the Atlantic and passing the south-eastern coast of Ireland should not produce a great rise on its eastern coast. The greater rise in the north is undoubtedly due to the similarity to estuary tides, for which we have had to refer so frequently to (307.) and (333.).

(525.) The tides of the German Sea present a very remarkable peculiarity. Along the eastern coast of England, as far as the mouth of the Thames, the tide-wave, coming from the Atlantic round the Orkney Islands, flows towards the south. Thus, on a certain day, it is high water in the Murray Firth at 11 o'clock, at Berwick at 2 o'clock, at Flamborough Head at 5 o'clock, and so on (see the cotidal lines in figure 60) to the entrance of the Thames. But on the Belgian and Dutch coasts immediately opposite, the tide-wave flows from the south towards the north. Thus, on the day that we have supposed, it will be high water off the Thames at 11 o'clock, (the tide having travelled in 12 hours from the Murray Firth,) and at Calais nearly at the same time: but at Ostend it will be at 12, off the Hague at 2, off the Helder at 6, and so on. This circumstance is so strange, that Mr. Whewell, in order to explain it, has had recourse to the supposition of a revolving tide in the German Ocean, in which the tide-wave would run as on the circumference of a wheel, the line of high water at any instant being in the position of a spoke of the wheel. Although our mathematical acquaintance with the motion of extended waters is small, we have little hesitation in pronouncing this to be impossible. The only conceivable case in which it could hold would be, when there was a shoal in the middle nearly touching the surface of the water: a supposition which does not apply here, the sea between Suffolk and Belgium being somewhat deepest in the middle.

(526.) We believe that a complete explanation may be found in the arrangement of the great shoals of the North Sea. It must be remarked that (except within a very small distance of Norway) the North Sea is considerably deeper on the English side than on the German side; so much so that the tide-wave coming from the north runs into a deep bay of deep water, bounded on the west side by the Scotch and English coasts as far as Newcastle, and on the east side by the great Dogger Bank. As far as the latitude of Hull, the English side is still the deep one: and though a species of channel through the shoal there allows an opening to the east, yet immediately on the south of it is the Wells Bank, which again contracts the deep channel to the English side. After this (that is, in the latitude of Yarmouth) the deep channel expands equally to both sides. It seems reasonable to conclude from this that the great set of north tide is on the English side of the North Sea, both between the Dogger Bank and England and between the Wells Bank and England, (a branch stream of tide having been given off to the east between these two banks:) and that any passage of tide-wave over these banks may be neglected. Now this view is supported in a remarkable degree by the tidal observations on two dangerous shoals called the

Ower and Leman, lying between Cromer and the Wells Bank, but nearer to the latter. It appears that, on these shoals, the direction of the tide-current revolves in the same manner as the hands of a watch. (See Norie's or any other charts, or Monnier, p. 23.) Now, in conformity with the remarks in (363.), this proves beyond doubt that the Ower and Leman are on the left hand of the main stream of tide, (supposing the face turned in the direction in which the tide proceeds,) or are on its eastern border; and therefore that the central stream is still nearer to the coast of Norfolk. From a point not far south of this we may suppose the tide to diverge in a fan-shaped form over the uniformly-deep Belgian sea. Along the English coast, the wave will flow to the south: but it will reach the whole of the Belgian and Dutch coast at the same instant: and, if this tide alone existed, we doubt not that the time of high water would be sensibly the same along the whole of that coast.

(527.) But there is another tide of great magnitude, namely, that which comes from the English Channel through the Straits of Dover. This also diverges, we conceive, in a fan-form, affecting the whole Belgian sea: the western part turns into the estuary of the Thames: the eastern part runs along the Dutch coast, producing, at successive times, high water (even as combined with the North Sea tide) along successive points of that coast from Calais towards the Helder. And this we believe to be the complete explanation of the apparently opposite tide currents. The branch tide of the North Sea running between the Dogger Bank and the Wells Bank will assist in propagating the tide along the German coast from the Helder towards the mouth of the Elbe. We have gone into some detail in this explanation for the purpose of showing the importance of considering the form of the bottom in explanations of specific tides.

(528.) A remarkable set of observations was made by the late Captain Hewett, R.N., on the depth and motion of the water at a strictly definite point (a boat being moored over a small hillock discovered in the bottom of the sea) in latitude 52° 27′ 30″ N., longitude 3° 14′ 30″ E., or a few miles south of the Wells Bank, near the middle of the Belgian sea. They have since been communicated to the British Association. The result was, that the change of elevation of the surface was insensible: but that there was a considerable stream of tide alternately N.E. and S.W. (magnetic). The point in question corresponds pretty well to the intersection of the cotidal lines of 9 o'clock of the North Sea tide, and 3 o'clock of the English Channel tide (ordinary establishment), and these tides would therefore wholly or partially destroy each other as regards elevation. As regards the compound tide-stream, the greatest positive current from one tide will be combined with the greatest negative current of the other, and this will produce a stream whose direction agrees well with Captain Hewett's. At 3^h on the day of new moon, the North Sea tide would be running north (magnetic), and the English Channel tide would be running east, and therefore the compound current would be running north-east; at 9^h it would be running south-west. Both currents, and consequently the compound current, would cease at about 0^h, 6^h, &c., on the day of new moon: and as Captain Hewett's observations were made rather more than a day before new moon, the slack water would occur an hour or more before noon. The whole of this also agrees well with the observation.

Tides and Waves.

Races—Portland Race.

(529.) The phænomenon known by the term *Race* is peculiar to promontories projecting into narrow channels. Thus nearly every headland of the English and Irish channels has more or less of a race. The most remarkable of these is Portland Race. When the rising tide in the neighbourhood is nearly at its mean level, the water begins to run eastward past Portland Bill and over the sunk ledge which projects from the Bill: when the tide has reached its greatest height, the Race is raging most furiously, the velocity of the current to the east being 6 or 7 miles per hour. When the water has dropped to its mean level nearly, the current turns, and at the time of low water it is raging towards the west. It is plain that this current is only the ordinary tide-current treated in (184.), but it necessarily runs past the promontory with great rapidity in order to transfer the proper quantity of water from the bay on one side of the promontory to the bay on the other side.

Rapid currents from bays communicating with tidal seas by two channels.

(530.) It is scarcely necessary to mention at length the rapid currents which are sometimes produced in the channels communicating from a surface of water to two tidal seas, or to two parts of the same sea in which the hours of high water are different. The more rapid current is always that which passes through the narrower channel. Thus, the mouth of the Southampton water communicates with the English Channel by two courses, namely, by the east and by the west of the Isle of Wight: the former, being wide and deep, allows the water to take nearly the same level as that at the east end of the island, and this at some states of the tide is different from that at the west end of the island, and therefore the water runs with considerable velocity in the western channel (the Solent). A more remarkable instance is that of Loch Alsh, on the west coast of Scotland, opposite the Isle of Skye: this island very much interrupts the great tidal channel between Scotland and the Long Island (Lewis, Harris, &c.), and the times of high water on the north and south coasts of Skye are therefore different: Loch Alsh is principally supplied from the north side by the broad entrance called Kyle Haken, and its water therefore nearly takes the level of the northern sea: its height is therefore at some stages of the tide considerably different from that of the southern sea, with which it communicates by the narrow strait of Kyle Rhea; and the water consequently rushes through Kyle Rhea with a current of fearful rapidity, changing its direction twice in every tide.

Mean level of the sea nearly independent of the range of tide.

(531.) We shall close this subsection by stating that, at the expense of the British Association (see their 8th *Report*), a series of levels was carried across the land from Portishead on the Bristol Channel to Axmouth on the English Channel, by Mr. Bunt, and simultaneous observations of the tides were made at these stations, and were referred to the marks whose difference of level was obtained. Although the whole tide at Portishead was 35½ feet, and that at Axmouth only 10 feet, the mean level at Portishead was only 9 inches higher than that at Axmouth: its high water being 13 feet 7 inches higher, and its low water being 12 feet 2 inches lower. Thus it appears that the Theory of Waves, in the manner in which we have throughout used it, considering the greatest elevation above the mean level, and the greatest depression below it, as very nearly equal, is properly applicable to the tides. We have also been informed that the levellings in the Ordnance Survey have shown that the high water in the upper part of the Bristol Channel is higher than at its mouth, and the low water in the upper part lower than at its mouth, by nearly equal quantities: but we possess no documentary information on this point.

Subsection 3.—On the Laws of the Tides for varying Positions of the Sun and Moon.

(532.) The Equilibrium-Theory (44.), Laplace's Theory (98.), (101.), and (107.), and the Theory of Waves (436.) and (283.), (439.) and (441), modified in (448.) and (452.), agree in the general form of the expressions for the elevation of the sea, supposing the coefficients altered and the arguments of the angles altered. We shall therefore (for convenience), in the first instance, use the formulæ of the Equilibrium-Theory in our comparisons, introducing the modifications given by the other theories as may appear necessary.

Dependence of the mean level of the sea on the Moon's declination.

(533.) The first line in the expression of (44.), with which (436.) agrees, gives us the slowly varying effect of the two attracting bodies, in feet,

$$(1{\cdot}34 \times \sin^2 \mu + 0{\cdot}61 \times \sin^2 \sigma) \times (\cos 2 .\ \text{terrestrial latitude} + \mathrm{C}),$$

μ and σ being the declinations of the Moon and the Sun.

In the expression of (44.) C is $\frac{1}{3}$: in that of (436) it is 0. The constant, in both cases, depends on the condition of giving a certain external form to a certain quantity of fluid; the form is the same in both, but the different proportions of the polar to the equatorial surface in the two suppositions (one, of the earth completely covered with water, the other, of a canal passing through the poles) give different absolute elevations. In either case, however, the elevation at mean latitudes is small; it will be most conspicuous near the equator or near the poles. The quantity of information which we have bearing upon this point is small. In the *Phil. Trans.*, 1839, p. 157, Mr. Whewell shows that the observations of high and low water at Plymouth give a mean height of water increasing as the Moon's declination increases, and amounting to three inches when the Moon's declination is 25°. This is in the same direction as that corresponding in the expressions above to a high latitude. The effect of the Sun's declination is not investigated from the observations. In the *Phil. Trans.*, 1840, p. 163, Mr. Whewell has given the observations of some most extraordinary tides at Petropaulofsk in Kamschatka, and at Novo-Arkhangelsk in the island of Sitkhi on the west coast of North America. From the curves in the *Phil. Trans.*, as well as from the remaining curves relating to the same places (which, by Mr. Whewell's kindness, we have inspected), there appears to be no doubt that the mean level of the water at Petropaulofsk and Novo-Arkhangelsk rises as the Moon's declination increases. We have no further information on this point.

(534.) The third line of (44.), which we shall next treat, gives the expression for the ordinary semidiurnal tide, on the Equilibrium-Theory: the corresponding term for one body on Laplace's Theory will be found in (108.); and that on the Wave-Theory for the general combined effect of two bodies, in (457.) and the preceding articles. It appears that the forms of (53.) and (54.), with extensive changes of angles, &c., may be adopted as representing any theory. We shall consider the different parts of these formulæ separately.

Theoretical formulæ for semimenstrual inequalities.

(535.) *Semimenstrual inequality of time and of height.*—This is the name given by Mr. Whewell to the variation of that term, in the expression for the time of high water, or for the height of high water, which in (489.) is called the quantity depending on the Moon's time of transit only; and which, for the time, putting θ for the Moon's hour angle to the west of the meridian at high water, is represented in the first line of the last expression of (54.) by

$$2\theta = -\frac{720^{m}}{\pi} \cdot \frac{\mathrm{S}' .\ \sin 2 . \overline{m-s}}{\mathrm{M}' + \mathrm{S}' .\ \cos 2 . \overline{m-s}},$$

or more correctly by

$$\tan 2\theta = -\frac{\mathrm{S}' .\ \sin 2 . \overline{m-s}}{\mathrm{M}' + \mathrm{S}' .\ \cos 2 . \overline{m-s}} = -\frac{\mathrm{S}_{\blacktriangle} .\ \sin 2 . \overline{m-s}}{\mathrm{M}_{\blacktriangle} + \mathrm{S}_{\blacktriangle} .\ \cos 2 . \overline{m-s}},$$

(see (56.)): and for the height, by the first term in the expression of (53.), which is proportional to

$$\sqrt{\{\mathrm{M}_{\blacktriangle}{}^2 + 2\mathrm{M}_{\blacktriangle}\,\mathrm{S}_{\blacktriangle} . \cos 2 . \overline{m-s} + \mathrm{S}_{\blacktriangle}{}^2\}}.$$

The expressions of (457.), and the articles preceding it, show that, on the wave-theory, these expressions will be changed to

$$\tan (2\theta - 2\lambda) = -\frac{\mathrm{S}'' .\ \sin (2 . \overline{m-s} - 2\alpha)}{\mathrm{M}'' + \mathrm{S}'' .\ \cos (2 . \overline{m-s} - 2\alpha)}.$$

$$\text{Height} \quad \propto \sqrt{\{\mathrm{M}'''^2 + 2\mathrm{M}'''\,\mathrm{S}''' . \cos (2 . \overline{m-s} - 2\alpha) + \mathrm{S}'''^2\}}$$

where the proportion of S'' to M'', or S''' to M''' is not the same as on the equilibrium-theory, in consequence of the relation of the magnitude of the effect to the periodic time of the forces (455.). In considering the mean of many observations in all relative positions of the Sun, the Moon, the perigee, and the equinox, the variable term

Tides and Waves.

T in (457.) may be neglected. Now the points which we shall examine are, 1st, whether consistent values of $\frac{S''}{M''}$ can be found; 2nd, whether consistent values of α can be found; 3rd, whether, with adopted values of $\frac{S''}{M''}$ and α, the general forms of the observed results agree with those of the formulæ.

Methods of determining the proportion of solar and lunar effects.

(536.) 1st. On the value of $\frac{S''}{M''}$. For the times this may be found by choosing one mean of observations in which $m-s-\alpha$ is as near as possible to 3^h (say 3^h+x) and choosing another mean of observations in which it differs 6^h from the former (or is 9^h+x). These will be respectively the times when the Moon's transit (in solar time) is later by 3^h and by 9^h (nearly) than the time when the tide is greatest. For the first of these, $\tan(2\theta_1-2\lambda)=-\frac{S''.\cos 2x}{M''-S''.\sin 2x}$: for the second, $\tan(2\theta_2-2\lambda)=+\frac{S''.\cos 2x}{M''+S''.\sin 2x}$: and half the difference of these, when x is small, will not differ sensibly from $\tan(\theta_2-\theta_1)=\frac{S''}{M''}$. Or it may be found by taking the least and greatest values of $\theta-\lambda$: for the first of these, $\sin(2\theta_3-2\lambda)=-\frac{S''}{M''}$: for the second, $\sin(2\theta_4-2\lambda)=+\frac{S''}{M''}$: taking half the difference, $\sin(\theta_4-\theta_3)=\frac{S''}{M''}$.

For the heights, the easiest way is to take the greatest and least ranges, which correspond to $M'''+S'''$ and $M'''-S'''$ in the formula, from which the value of $\frac{S'''}{M'''}$ is found.

Different determinations of this proportion

(537.) Thus the following results have been obtained:

At Brest, by all the observations near to 128 syzygies and 128 quadratures (*Méc. Cél.* liv. xiii. p. 204.), from heights, $\frac{S'''}{M'''}=\frac{1\cdot643}{4\cdot755}=0\cdot3456$.[*] There is no deduction from the times, except that made by Mr. Lubbock (*Phil. Trans.*, 1832) from a year's observations, which gives $\frac{S''}{M''}=0\cdot33945$.

At London, by 19 years' observations, from times (Lubbock, *Phil. Trans.*, 1831), $\frac{S''}{M''}=0\cdot37887$,[†] or from another discussion (Lubbock, *Phil. Trans.*, 1836) 0·38386. There is no satisfactory determination from heights, the whole range not having been observed: but supposing the mean range to be 15 feet, and the greatest difference in the height of high water at spring tides and neap tides to be 3·4 feet as shown by Mr. Lubbock's observations, and supposing that (as in the open sea) the variations between spring tides and neap tides are the same for low water as for high water (which does not agree with the observations at Plymouth, where the variation for low water is the greater in the proportion of 3 : 2), the value of $\frac{S'''}{M'''}$ would be $\frac{1\cdot7}{7\cdot5}=0\cdot2267$. This result is worthless.

At Liverpool, by 19 years' observations, from times (Whewell, *Phil. Trans.*, 1836), $\frac{S''}{M''}=0\cdot37866$, or (Lubbock, *Phil. Trans.*, 1837) $=0\cdot37124$. From heights, (Whewell, *Phil. Trans*, 1836,) $\frac{S'''}{M'''}=0\cdot39875$; but as there were no observations of low water, this result is valueless. If the mean range were considered $=24$ feet, and the difference of high water for springs and neaps $=5\cdot48$, $\frac{S'''}{M'''}$ computed as for London $=0\cdot228$. This is worthless.

These determinations (omitting those to which we have taken exceptions) may be considered as first-rate. The following are greatly inferior:

From times only (Lubbock, *Phil. Trans.*, 1833, page 20; and Whewell, *Phil. Trans.*, 1834, page 20).

At Sheerness, from 12 months' observations . . . . $\frac{S''}{M''}=0\cdot37865$

At Portsmouth, 12 months' . . . . $=0\cdot34611$

At Plymouth, 9 months' . . . . $=0\cdot40673$

---

[*] Mr. Whewell (*Phil. Trans.*, 1834, p. 20) has quoted as Laplace's value $\frac{1}{2\cdot6157}=0\cdot38231$. We know not on what authority this is given; it is certainly not on that of the *Mécanique Céleste*.

[†] Mr. Whewell has given the number $\frac{1}{2\cdot9884}=0\cdot3346$: we know not on what authority.

From times (Whewell, *Phil. Trans.*, 1838, page 245).

At Plymouth, from 4 years' observations . . . . $\frac{S''}{M''} = 0{\cdot}4025$

At Bristol, 4 years' . . . . $= 0{\cdot}394$

At Leith, Portsmouth, Pembroke, and Ramsgate, (periods not mentioned), $\frac{S''}{M''}$ appears a little less than at Liverpool.

From heights, at Portsmouth $\frac{S''}{M''} = 0{\cdot}2$; at Plymouth $= 0{\cdot}294$; at Bristol $= 0{\cdot}303$.

From heights at Plymouth (Whewell, *Phil. Trans.*, 1839, page 153, &c.), by 6 years' observations of high and low water . . . . $\frac{S''}{M''} = \frac{43{\cdot}5}{144} = 0{\cdot}3021$

At Dundee (page 157), by one year's observation of high and low water, from times . . . . $\frac{S''}{M''} = 0{\cdot}3584$

From heights . . . . $\frac{S''}{M''} = 0{\cdot}2774$

At Dundee, Mr. Mackie (*British Association, 7th Report*) has found by 7 months' observations from times . . $\frac{S''}{M''} = 0{\cdot}3420$.

In the *Philosophical Transactions*, 1836, page 305, Mr. Whewell has insisted on the difference of the extreme values of the semimenstrual inequalities $\left(\text{and the consequent difference of deduced values of } \frac{S''}{M''}\right)$ at different places, as ascertained by three weeks' observations. We have not the smallest confidence in such a result, having in our own observations, for four days only, encountered a discordance of two hours between the times occupied by two successive tides.

The proportions deduced from different places do not agree.

(538.) Confining ourselves now to the values of $\frac{S''}{M''}$, deduced from the times only, which are incomparably more exact than those deduced from the heights (the Brest and Plymouth observations excepted), the following remarks suggest themselves. The two places (London and Liverpool), at which the greatest number of observations have been made, agree precisely in the value which they give for $\frac{S''}{M''}$. Yet it seems impossible to deny that at some places (we particularly cite Plymouth and Bristol) the value of $\frac{S''}{M''}$ deduced from the times is certainly greater by $\frac{1}{10}$th part, and that at other places (as Portsmouth and Dundee) it is less by nearly $\frac{1}{10}$th part. And these we consider to be real and certain differences in the comparative effects of the Sun and Moon in the seas near to those places. They cannot be explained by any difference in the speed of spring-tide-waves and neap-tide-waves, as in (463.), because, by the rules of (536.), the value of $\frac{S''}{M''}$ is obtained by comparing two times of tide when (the values of $m-s-\alpha$ being the same with opposite signs) the magnitude of the tide, which depends on $\cos 2.\overline{m-s-\alpha}$, was the same. Indeed we consider it perfectly certain that the value of $\frac{S''}{M''}$ deduced from the times is an accurate representation of the proportion of the magnitudes of the solar and lunar tide-waves which come to the port. And the question now is, whether such a difference for different ports, as we consider to be established, is consistent with our theory? We answer that it is, and that it may be ascribed to one or more of the following causes.

(α.) If tides were formed independently (or nearly so) in different channels of different depths, the proportion of the solar and lunar waves, which by (455.) contains the factor $\frac{n''^2 b^2 - gk}{n^2 b^2 - gk}$, would be different in the different channels. This can scarcely apply to the different ports of England, but it may well apply in comparing the tides of the Atlantic with those of the Pacific.

(β.) If tides are communicated by different channels to the same port, the proportion of the solar and lunar waves, (121.) and (312.), will depend on the length, &c., of those channels, and may be different at different places. This applies, probably, to every port in England.

(γ.) The harbour-tides are, without exception, tides which have acquired a greater magnitude than the ocean-tides, in consequence of the tide having passed over a sloping bottom. Now though we cannot give accurately the values of the expressions used in (246.) and (247.), still it is certain that they will depend on n and m as well as on the depth and slope, and, therefore, that the solar and lunar tides will be altered in different degrees.

(539.) The difference in the values of $\frac{S''}{M''}$, therefore, however difficult to be explained from the actual circumstances of each port, presents no difficulty in the general theory. One point, however, we must specially remark. Our explanations of the difference depend entirely on the difference of the periodic times of the forces, and, therefore, the consideration introduced by Laplace (481.) for the varying alteration of the effect of *each* body as connected with its varying velocity in right ascension, applies to all of them. This consideration is embodied in our formulæ of (448.). And if the observations applying to this were properly treated, in a manner equivalent to that of Laplace, (481.), and if the observations were sufficiently numerous and good, we ought to obtain the same value of the Moon's mass from every port. Unfortunately, the philosophers who have reduced the English observations, do not appear to have been aware of the principle on which the true value of the mass may (theoretically, at least,) be deduced from $\frac{S''}{M''}$; Mr. Whewell has even expressly said (*Phil. Trans.*, 1838, page 245): "We see, therefore, how different the mass of the Moon would be found to be by calculations from the tide-observations of different places." This would be true for an equilibrium-theory; but, as that contemptible theory is entirely inapplicable, except for some forms which require such extensive changes that they are now useless, it is scarcely worth while to refer to it. For a wave-theory it is not correct. We shall have occasion to revert to this subject.

(540.) Now, considering the values of $\frac{S'''}{M'''}$ deduced from the vertical range of tide, we find that there are but three accurate determinations (those from Brest, Plymouth, and Bristol), to which that of Dundee may be added as somewhat inferior. They agree in giving a smaller value at each place than that given by the times. We cannot explain this, but we assert distinctly that there is nothing in it contradictory to theory in its present state. We believe it to depend upon circumstances purely local, upon the depth and breadth of the channels through which the tide passes, and the like. For here, unlike the case of (538.), the determination depends *entirely* upon the difference of spring tides and neap tides. The most singular circumstance is, that, apparently at London and Liverpool, and certainly at Plymouth (Whewell, *Phil. Trans.*, 1839, page 151, &c.), the semimenstrual inequality is greater for low water than for high water. That is, upon increasing the general magnitude of the sea-wave, it produces a greater effect on shore-low-water than on shore-high-water. From these observed facts, as well as from those of (513.), &c., we are induced to fix upon the subject partially discussed in the third subsection of Section IV., as more strongly deserving attention at the present time than any other point in the Theory of Tides.

(541.) 2nd. On the value of 2α. This is determined from the times by taking that value of $2.\overline{m-s}$ which is found from observation to give to θ at high water its mean value. For, if we take pairs of equal values of $\overline{m-s}-\alpha$ with opposite signs, we obtain pairs of equal values of $2\theta-2\lambda$ with opposite signs: the mean of all is $2\theta-2\lambda=0$, which corresponds to $2.\overline{m-s}-2\alpha=0$ or gives $2\alpha=$ the corresponding value of $2.\overline{m-s}$. We may here observe that the quantity λ, which is the value of θ corresponding to $2.\overline{m-s}-2\alpha=0$, or which is the mean value of θ, is that upon which Mr. Whewell has with great propriety fixed as the characteristic of the time of high water at any place. He has sometimes called it "the mean lunitidal interval," (or the mean hour-angle of the moon at high water,) or sometimes "the corrected establishment," for a reason to which we shall advert shortly.

Tides and Waves.

The value of 2α is determined from the heights by taking that value of $2.\overline{m-s}$ which gives to the height its greatest value. For, the expression for the height is evidently greatest when $2.\overline{m-s}-2\alpha=0$.

Since $m-s$ is the angle in right ascension by which the Moon has separated from the Sun, and since the mean separation in a solar day is 49 minutes nearly, the number of days after syzygy corresponding to the separation $\overline{m-s}$ (supposed to be expressed in minutes of time) is $\frac{m-s}{49}$ nearly, or $m-s=$ number of days × 49. Therefore α, if expressed in minutes of time $=49$ × number of days after syzygy, or α, if expressed in degrees, $=12°\,12'$ × number of days after syzygy, at which the lunitidal interval $=$ mean lunitidal interval, or at which the highest tide occurs. In the same manner, $\alpha=49^m$, or $12°\,12'$ × number of days after quadrature at which the lunitidal interval has its mean value, or at which the lowest tide occurs. At solstices (separately considered) these numbers are to be increased $\frac{1}{11}$th, and at equinoxes to be diminished $\frac{1}{12}$th.

Determinations from different places.

(542.) Thus the following determinations have been obtained:—

At Brest (*Méc. Cél.*, vol. v., pages 187 to 200), from observations of heights at equinoxial syzygies, the highest tide follows syzygy by $1^d\cdot480$, or . $\alpha=16°\ 36'$

At solstitial syzygies by $1^d\cdot547$, or . $\alpha=20°\ 29'$

From observations of heights at equinoxial quadratures, the lowest tide follows quadrature by $1\cdot5097$, or . $\alpha=19°\ 56'$

At solstitial quadratures by $1\cdot5127$, or $\alpha=16°\ 25'$

Laplace has not given the details of computation applying to the times, but he remarks that the hour of low water (expressed in fractions of a day) corresponding to the greatest tide, supposed to occur at $1^d\cdot5$ after syzygy, is $0\cdot441170$, and the hour of high water corresponding to the least tide, supposed to occur at $1^d\cdot5$ after quadrature, is $0\cdot431600$. If a later epoch were used, the first of these numbers would be increased by a less quantity than the Moon's daily motion ($\theta-\lambda$ being then negative, and increasing in its negative value), and the second would be increased by a greater quantity than the Moon's daily motion: and thus they might be made exactly equal. The value of $\overline{m-s}$ at this time would determine α. Thus it appears that α, as found from the times, is greater than as found from the heights. Mr. Lubbock, from one year's observations of times (*Phil. Trans.*, 1832), found . $\alpha=22°\ 0'$

At London, from times (Lubbock, *Phil. Trans.*, 1831, page 400) . . . . $\alpha=32°$
From heights (page 403) . . . $\alpha=26°$
At Liverpool, from times (Lubbock, *Phil. Trans.*, 1835, page 283; and Whewell, 1836, page 8, observing that the tide occurs 11 hours after the moon's transit) . . . . . . $\alpha=24° 15'$
From heights . . . . $\alpha=20° 30'$
At Bristol, from times (Whewell, *Phil. Trans.*, 1838, page 237), the value of α is the Moon's motion during 56 hours, or . . . . $\alpha=28° 30'$
From heights, the value of α is the Moon's motion during 40 hours, or . . . . $\alpha=20° 20'$
At Dundee, from times (Whewell, *Phil. Trans.*, 1839, page 157) . . . . $\alpha=23°$
From heights . . . . . . $\alpha=20°$
At Portsmouth, from times (Lubbock, *Phil. Trans.*, 1833, page 21) . . $\alpha=26° 30'$
At Plymouth, from times (same reference) . . . . $\alpha=28° 45'$
At Sheerness, from times (same reference) . . . . $\alpha=30°$

(543.) We have now to consider how the existence and variety of magnitude of this quantity α can be explained. And first we must remark that a part of it depends on the circumstance that we have not observed the tides in the ocean in which they are actually formed by the Sun and Moon, but on rivers and narrow seas up which they have been propagated as waves without external forces. Now the tide at London (the mean effect of two waves at 12 hours' interval, as we shall hereafter explain) has travelled from Brest in 16 solar hours nearly, and, therefore, to refer the London tide to its origin in that part of the Atlantic Ocean we must subtract from α the Moon's motion in 16 solar hours, or 8° 15′. In this manner we find the following table of values* of α referred to that part of the Atlantic ocean which is near Brest:—

Reduction of all the values of retard to one locality.

Place.	Number of hours occupied by passage of tide from Brest.	Corresponding correction to α.	Corrected value of α from times.	Corrected value of α from heights.
Brest . . .	0h. 0m.	0° 0′	22° 0′	18° 20′
London . . .	16 10	−8 15	23 45	17 45
Liverpool . .	7 40	−4 0	20 15	16 30
Bristol . . .	3 30	−1 50	26 40	18 30
Dundee . . .	10 50	−5 30	17 10	14 30
Portsmouth. .	7 52	−4 0	22 30	
Plymouth . .	1 45	−1 0	24 45	
Sheerness . .	14 51	−7 30	26 0	

The values of α from the heights agree as well as we can expect. The only sensible discordance is that of Dundee, where the result is deduced from the observations of a single year. The values of α deduced from the times cannot be made to agree.

(544.) Now a little consideration will show that the amount of α cannot possibly be explained by delay in the transmission of the tide. The smallest value of α implies a delay of 29 hours; while it will appear that the tide at the Cape of Good Hope is earlier by only 15 hours, and that at Cape Horn by a still smaller quantity, than that at Brest; and thus it would seem that, even in the southern sea, where no reason for delay of tide can be imagined, it has already been delayed at least 14 hours. Putting this aside, we shall at once state our conviction that the apparent delay arises entirely from friction, as explained from theory in (459.). We may remark that the expression there found has the same sign whether the depth of the sea be greater or less than 14 miles. We do not deny that it is possible to explain the same thing by the interference of two tides with nearly opposite phases, of which one has suffered no retardation, and the other a small retardation; and that, in the instance of Brest, two such mingling tides may be produced, one from S. to N., and the other from E. to W. But the other explanation is so much more natural that we shall adhere to it.

(545.) But, as we have one system of values of α given by the heights of tide, and another given by the times, it may be asked which is the true one? We answer, without doubt, that given by the heights. We have shown in (462.) that local circumstances do not alter, except by a constant quantity, the times of high water for a given range of tide, and therefore do not alter the day of highest tide (upon which α, as deduced from the heights, depends); but in (463.) it appears that local circumstances do alter the day when the tide occurs at mean lunitidal interval, or do alter the time for which the relative positions of the sun and moon are to be used in computation of the time of tide. They may be expected, therefore, to alter it differently in different ports, and thus the discordance of values of α in the first column is explained. It is remarkable that the difference between the time-values and the height-values of α is less at the two most open ports (Dundee and Brest) than at any of the others, as might have been expected.

(546.) It is, however, worthy of remark, that all the time-values of α are greater than the height-values. This implies that the effect of the local circumstances is opposite to that assumed in (463.), and therefore that the great tides travel more slowly from the sea than the small tides. We cannot venture positively to explain this, but we may suggest the following consideration for the reader's judgment. Before the old London Bridge was removed, the higher passage of small tides was materially obstructed by the sterlings of the bridge; that of great tides much less. The small tides were therefore nearly similar to tides in an interrupted canal, in which the time of high water is the same as that at the sea (307.); while the large tides partook of the nature of tides in an uninterrupted canal, and the time of high water up the river was progressive. Similar considerations may apply to the other ports. The quantity α is sometimes called the *retard*, and the time in which the Moon moves through that angle from the Sun is called the *age of the tide*.

(547.) 3rd. On the agreement of the laws of the observed semimenstrual irregularities with those given by the for-

---

* We have been anxious to combine with these the value of α, deduced from the observations of height at Leith, which are tabulated in the Report of the 11th meeting of the British Association, page 36. But in the want of explanation of the table, and the apparent inference from it as it stands, that the highest tide *precedes* syzygy (contrary to universal experience), we have not ventured to use it.

mulæ. With regard to the times we may state, that for those places for which the comparison has been made with the values of $\frac{S''}{M''}$ and α peculiar to those places, the agreement is perfect. We subjoin a Table similar to Mr. Lubbock's, of observed and computed intervals between the Moon's transit over the meridian at London and the time of high water (altered only so as to adapt it to the value of $\alpha = 32°$ as above, instead of 30° which Mr. Lubbock has used,) and we copy from the *Philosophical Transactions*, 1836, Mr. Whewell's table of the observed and computed intervals for Liverpool.

Observed and computed values of θ for London; the computed values being found by the second formula of (535.), supposing $\frac{S''}{M''} = 0{\cdot}37887$, $\alpha = 32°$, λ (in time)$= 1^h.25^m.35^s$.

Comparison of theoretical law and observed law of semi-menstrual inequalities of time.

Observed and computed values of $\theta-\lambda$ for Liverpool, supposing $\frac{S''}{M''} = 0{\cdot}37866$, and $\alpha = 24°.15'$ nearly. (*Note.*—Our α is not the same quantity as Mr. Whewell's α, *Philosophical Transactions*, 1836, page 8. Mr. Whewell uses α as the correction to the Moon's distance from the Sun at the time of transit preceding the tide; ours is the correction to the Moon's distance from the Sun at the time of high water.) λ for Liverpool is $11^h\ 6^m$.

It would scarcely be possible to obtain closer agreement. In figure 61 we have represented the values of $\theta-\lambda$ for London by the ordinates of a curve, the abscissa representing the solar time of the Moon's transit. The dark line is the curve representing the values of $\theta-\lambda$ computed from theory, and the dotted line is that representing the observed values. The same form precisely is given by the observations at other places; we leave to the reader the task of laying down that for Liverpool, and we refer him to the *Philosophical Transactions*, 1833, page 19, for the curves of six different places.

Tides and Waves.

Difference between Vulgar Establishment and Corrected Establishment.

(548.) We may now point out the difference between the vulgar *Establishment* of which we have spoken in (2.) and (497.), and Mr. Whewell's *Corrected Establishment.* At London, for instance, the vulgar Establishment, taken from the table above, would be $1^h\ 57^m$. But the mean interval between the Moon's transit and the time of high water is $1^h\ 25^m\ 35^s$; and this is the *Corrected Establishment*, differing 31^m from the other. It is better for adoption as a mathematical element, because it expresses a simple quantity (namely, the delay of high water after the Moon's transit, supposing no Sun to exist); and it is better for practical use, because it differs less, upon the whole, from the real interval on any day, than the vulgar Establishment does. Thus at London, if we roughly computed the time of high water with the interval $1^h\ 57^m$ from Moon's transit, we might sometimes be $1^h\ 15^m$ in error; if we used $1^h\ 26^m$, we should never be more than 44^m in error.

Comparison of theoretical and observed law of semimenstrual inequalities of heights.

(549.) With regard to the heights, it is possible to use such constants in the second formula of (535.) as will give a very close approximation to the observed heights. Thus, for the representation of the heights of high water at Liverpool, Mr. Whewell has used the values $M'=6\cdot872$ feet, $S'=2\cdot74$ feet, $\alpha=15°$ (applicable to the Moon's distance from the Sun at the preceding transit), and has subtracted from the result of the computation, the constant 7·19 (the mean of all the computed numbers). This he compares with the difference between each of the heights, and the mean of all the heights, as measured from a certain fixed point. The result is as follows:—

Solar Time of Moon's Transit.		Difference of computed height from mean.	Difference of observed height from mean.
h	m	Feet.	Feet.
0	30	+2·35	+2·35
1	30	+2·35	+2·39
2	30	+1·83	+1·88
3	30	+0·84	+0·90
4	30	−0·48	−0·38
5	30	−1·89	−1·76
6	30	−2·90	−2·91
7	30	−2·90	−2·94
8	30	−1·89	−1·85
9	30	−0·48	−0·38
10	30	+0·84	+1·04
11	30	+1·83	+1·81

The agreement is good, but it has been obtained only by taking for M″ a quantity which shall make a good agreement, and not by taking it from the range of the tide. To make an equally good agreement for the heights in the London tides (*Phil. Trans.*, 1831, page 390), it is necessary to use a value of M″ much smaller than that used by Mr. Lubbock, so that the value of $\frac{S''}{M''}$ is unreasonably large. But, for the reasons mentioned in (540.), we do not think this important. In figure 62 we give the curve representing the semimenstrual inequality of height for London; the abscissa is the Moon's solar time of transit, and the ordinate is the height of high water above a fixed point.

(550.) We now come to the corrections in these semimenstrual formulæ depending on the varying declinations and varying distances of the Moon and Sun. And first, the correction for the Moon's declination. The term which the equilibrium-theory gives for correction of time, (54.) and (56.), is

$$-\frac{360^m}{\pi}.\frac{M_{\Delta}S_{\Delta}.\sin 2.\overline{m-s}}{(M_{\Delta}+S_{\Delta}.\cos 2.\overline{m-s})^2\cos^2\Delta}(\sin^2\mu-\sin^2\Delta)$$

and that for correction of height, (53.) and (56.),

$$-3.\frac{M_{\Delta}^2+M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}}{\surd\{M_{\Delta}^2+2.M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}+S_{\Delta}^2\}\cos^2\Delta}(\sin^2\mu-\sin^2\Delta)$$

where the whole height is represented by $3\surd\{M_{\Delta}^2+2M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}+S_{\Delta}^2\}$. Here μ is the Moon's declination, and μ and $\overline{m-s}$ are to be taken for the time of the tide. The theory of waves, (448.), (449.), and (452.), makes several important modifications in this expression. First μ and $\overline{m-s}$ are to be taken for a time anterior by a *constant* quantity $\rho_{\prime}$ (452.) and (459.), (not by a quantity which makes α constant). This quantity $\rho_{\prime}$ for Brest is about 36 hours, for London 52 hours, for Liverpool 44 hours, and for Bristol 40 hours. Secondly, in computing the retardation or its tangent, or $\theta-\lambda$ (the expression which in (535.) we have found it necessary to use) from the formula

Formulæ for lunar declination corrections of times.

$$-\frac{360^m}{\pi}\times\frac{(S_{\Delta}+T).\sin 2.\overline{m-s}}{M_{\Delta}+N+(S_{\Delta}+T)\cos 2.\overline{m-s}}$$

and in computing the height from the formula

$$\surd\{M_{\Delta}^2+2M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}+S_{\Delta}^2+(2M_{\Delta}+2S_{\Delta}.\cos 2.\overline{m-s})N+(2S_{\Delta}+2M_{\Delta}.\cos 2.\overline{m-s})T\},$$

we must increase $2m$ further by $\frac{n'b^2l}{n'^2b^2-gk}\omega^2.\sin 2lt$ (ω=obliquity of Moon's orbit to equator, lt=Moon's longitude or right ascension); and for M+N, so far as depends on declination, we must put

$$M\left\{1-\frac{\omega^2}{2}+\left(\frac{1}{2}-\frac{n'b^2l}{n'^2b^2-gk}\right)\omega^2\cos 2lt\right\}.$$

The mean of all the values of this expression is $M.\cos^2\Delta$, or $M_\Delta = M\left(1-\frac{\omega^2}{2}\right)$, and this expression is therefore

$$M_\Delta\left\{1+\frac{1}{\cos^2\Delta}\left(\frac{1}{2}-\frac{n'b^2l}{n'^2b-gk}\right).\left(\omega^2-\omega^2.\overline{1-\cos 2lt}\right)\right\}$$

$$=M_\Delta\left\{1+\frac{1}{\cos^2\Delta}\left(1-\frac{2n'b^2l}{n'^2b^2-gk}\right)\left(\frac{\omega^2}{2}-\omega^2.\sin^2lt\right)\right\}$$

$$=M_\Delta\left\{1-\left(1-\frac{2n'b^2l}{n'^2b^2-gk}\right).\frac{\sin^2\mu-\sin^2\Delta}{\cos^2\Delta}\right\}.$$

$$\text{Therefore } N=-M_\Delta\left(1-\frac{2n'b^2l}{n'^2b^2-gk}\right)\frac{\sin^2\mu-\sin^2\Delta}{\cos^2\Delta}.$$

Also, putting $2m'$ for $\frac{n'b^2l}{n'^2b^2-gk}\,\omega^2.\sin 2lt$, $\sin 2.\overline{m-s}$ is to be changed to $\sin\overline{2m-2s+2m'}=\sin 2.\overline{m-s}+2m'.\cos 2.\overline{m-s}$, and $\cos 2.\overline{m-s}$ is to be changed to $\cos\overline{2m-2s+2m'}=\cos 2.\overline{m-s}-2m'.\sin\overline{2m-s}$. Omitting therefore all variations depending on the varying distance and declination of the sun, and all except those of declination of the moon, we have to compute the time of tide after transit, or $\theta-\lambda$, by the formula

$$-\frac{360^m}{\pi}\times\frac{S_\Delta\{\sin 2.\overline{m-s}+2m'.\cos 2.\overline{m-s}\}}{M_\Delta+N+S_\Delta\{\cos 2.\overline{m-s}-2m'.\sin 2.\overline{m-s}\}}$$

or (expanding to the first power of N and $2m'$), by the formula

$$-\frac{360^m}{\pi}.\frac{S_\Delta.\sin 2.\overline{m-s}}{M_\Delta+S_\Delta.\cos 2.\overline{m-s}}-\frac{360^m}{\pi}.2m'\frac{M_\Delta S_\Delta.\cos 2.\overline{m-s}+S_\Delta^2}{(M_\Delta+S_\Delta.\cos 2.\overline{m-s})^2}+\frac{360^m}{\pi}N.\frac{S_\Delta.\sin 2.\overline{m-s}}{(M_\Delta+S_\Delta.\cos 2.\overline{m-s})^2};$$

and putting for N and m' their values, we have for the second and third term, which constitute the declination-correction of time of high water,

$$-\frac{360^m}{\pi}\left\{\frac{n'b^2l}{n'^2b^2-gk}\,\omega^2.\sin 2lt.\frac{M_\Delta S_\Delta.\cos 2.\overline{m-s}+S_\Delta^2}{(M_\Delta+S_\Delta.\cos 2.\overline{m-s})^2}\right.$$
$$\left.+\left(1-\frac{2n'b^2l}{n'^2b^2-gk}\right)\frac{\sin^2\mu-\sin^2\Delta}{\cos^2\Delta}.\frac{M_\Delta S_\Delta.\sin 2.\overline{m-s}}{(M_\Delta+S_\Delta.\cos 2.\overline{m-s})^2}\right\}.$$

We proceed now to advert to the bearing of observations, as far as they have yet been discussed, upon these terms.

One term has been omitted in comparisons with observations.

(551.) The first term, depending upon $\omega^2\sin 2lt$, has not been elicited from observations at all, for very good reasons. The square of the sine of declination is $\omega^2\sin^2lt$, and therefore $\omega^2\sin 2lt$ is proportional to the increase of the square of the sine of declination. Now Laplace gave very little attention to the times of tides; and moreover, in the discussion of solstitial and equinoxial observations, he confined himself to the times bordering very closely on solstices and equinoxes, on both sides of them (480.), &c., and therefore the increase of the square of declination could not appear. Mr. Lubbock and Mr. Whewell, though they have used observations made with all values of declination, have unfortunately (from inattention to this theory) classified the tides, as regards declination, only by the amount of declination, grouping together the observations at which the declination was increasing and those at which it was diminishing: in the mean of these, therefore, the term depending on the increase or decrease of declination has been entirely lost. We regret this much, because that term would be of singular use in giving the value of the important constant $\frac{n'^2b^2l}{n'^2b^2-gk}$; of which we shall shortly speak further.

(552.) For the second term, the observations were arranged with reference to the declination, (though somewhat complicated at first by the introduction of the calendar month,) and they are therefore so far in a fit state to compare with theory. It must be remarked that m, s, and μ, are to be taken for the moon's place at a period anterior by that constant which we have called the *age of the tide* or $\rho_{\prime}$; and therefore that the interval of the time of tide from the moon's transit, or $\theta-\lambda$, ought not to be reckoned from the last transit of the moon, but from that transit of the moon over some meridian at which it occurred at the time $\rho_{\prime}$ nearly before the tide. Mr. Whewell, in discussing the intervals of tides from the nearest transit of the moon at London and Liverpool, (*Phil. Trans.* 1834 and 1836,) found, besides terms multiplying $\sin 2.\overline{m-s}$, terms of the form $132^m(\sin^2\Delta-\sin^2\mu)$ for London, and $84^m.(\sin^2\Delta-\sin^2\mu)$ for Liverpool. These terms, not at first understood, are a singular proof of the theory as regards the necessity of referring the interval to a transit earlier by the age of the tide. For the moon's velocity in right ascension $=$ vel. in long. $\times\frac{\cos\text{ obliquity}}{\cos^2\text{ declination}}=$ vel. in long. $\times\frac{\cos^2\Delta}{\cos^2\mu}=$ vel. in long. $\times(1-\sin^2\Delta+\sin^2\mu)$, therefore, supposing the theory correct, the moon's right ascension or time of transit would be increased, from the true anterior epoch to the transit near to the time of tide, by vel. in long. × age of tide $\times(1-\sin^2\Delta+\sin^2\mu)$ or by $\alpha\times(1-\sin^2\Delta+\sin^2\mu)$; of which the part that depends on declination is $\alpha\times(\sin^2\mu-\sin^2\Delta)$; and therefore the interval from that transit to the tide would be increased by $\alpha(\sin^2\Delta-\sin^2\mu)$; which, with the values above for α, gives for London $128^m(\sin^2\Delta-\sin^2\mu)$, and for Liverpool about $80^m(\sin^2\Delta-\sin^2\mu)$, (referring the end of α, in Mr. Whewell's manner, to the place of the moon at the transit preceding the tide;) the agreement of which with the quantity deduced from observation is very close.

Explanation of a difficulty produced by using a wrong place of the moon.

Difficulty of comparing theory with existing results of observation.

(553.) The general comparison, however, of the results for declination-correction of times deduced by Mr. Whewell (*Philosophical Transactions*, 1834, 1836, 1838) with the term given by theory, is almost impracticable. Where the tide ought to be compared with a transit of the moon earlier by two days, it is evidently unsafe to attempt to use results deduced from comparison with a transit on the same day, especially for an element which changes so rapidly as declination, and more particularly as one term whose influence would probably then be sensible is entirely neglected. This consideration excludes all but the investigation in the *Philosophical Transactions*, 1838. In that paper Mr. Whewell has gone through the labour of reducing two years' observations at Bristol by reference to three different transits of the moon, (a process which, with proper management, would give the results depending on the change of the moon's declination and change of the moon's elliptic inequality, which we are seeking;) and he finds that the same transit (B), to which it is necessary to refer for semi-menstrual inequality of height, will give a declination-correction agreeing *generally* with theory. But how nearly this agreement holds is not explained. Our theoretical term is

$$-\frac{360^{m}}{\pi}\left(1-\frac{2n'b^2l}{n'^2b^2-gk}\right)\frac{\sin^2\mu-\sin^2\Delta}{\cos^2\Delta}\cdot\frac{M_{\Delta}S_{\Delta}.\sin.2.\overline{m-s}}{(M_{\Delta}+S_{\Delta}.\cos 2.\overline{m-s})^2};$$

Mr. Whewell's has the form + a factor × $s\,(2\phi-12^h)$, s being a periodical function which is positive when its argument is less than 12^h and negative when its argument is between 12^h and 24^h, and has for maximum and minimum values +1 and −1, these values occurring, the first before 6^h in the argument, and the second after 18^h. (This appears clearly, from the instance p. 239, to be the nature of the curve.) Now this law agrees well with that of the theory. The factor is $+6^m$ for declination 24° and -7^m for declination 7°; or the difference for decl. 24° and decl. 7° is 13^m. But if from the theoretical term we compute, with $\frac{S_{\Delta}}{M_{\Delta}}=0{\cdot}394$, as found from the times at Bristol (537.), the maximum value of that term (occurring when $2.\overline{m-s}=129°$), we find the difference of its values for declination 7° and 24° to be $10^m{\cdot}1\times\left(1-\frac{2n'b^2l}{n'^2b^2-gk}\right)$. Are we to make this equal to 13^m, and to infer from it that gk is greater than n'^2b^2, or that (444.) the depth of the sea is greater than 14 miles? We think not. Calculations on the equilibrium-theory, assuming the received mass of the moon (33.) and (35.), give for the proportion of the moon's effect to the sun's effect 0·596 : 0·271, or 1 : 0·45 nearly; and the only way in which we can explain the raising of that ratio to the proportion 1 : 0·394 is by supposing n'^2b^2-gk to be positive. (455.) A contradiction of the same kind will be found if we use any other supposition, as Laplace's: but will the reduced observations justify us in drawing any theoretical deduction? We scarcely think that they will. Independently of the general omission of steps of the reduction, we may remark that, as appears from Mr. Whewell's description of the mode of reducing, (extracted in 494.) the means of corrections were supposed to apply to the means of declinations, instead of to the means of the squares of declinations. This error cannot fail to injure the whole deduction.

Formulæ for lunar declination-correction of heights.

(554.) The declination-correction for heights will be thus found. In the expression

$$\sqrt{\{M_{\Delta}^2+2M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}+S_{\Delta}^2+(2M_{\Delta}+2S_{\Delta}.\cos 2.\overline{m-s})N\}},$$

(53.), (56.), and (535.), omitting T, we are to put $\cos 2.\overline{m-s}-2m'.\sin 2.\overline{m-s}$ for $\cos 2.\overline{m-s}$; and then to expand to the first power of m' and N. This gives for the small terms

$$-2m'\frac{M_{\Delta}S_{\Delta}.\sin 2.\overline{m-s}}{\sqrt{\{M_{\Delta}^2+2M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}+S_{\Delta}^2\}}}+N\frac{M_{\Delta}+S_{\Delta}.\cos 2.\overline{m-s}}{\sqrt{\{M_{\Delta}^2+2M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}+S_{\Delta}^2\}}};$$

or, restoring for m' and N their values, the small terms are

$$-\frac{n'b^2l}{n'^2b^2-gk}\omega^2\sin 2ll.\frac{M_{\Delta}S_{\Delta}.\sin 2.\overline{m-s}}{\sqrt{\{M_{\Delta}^2+2M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}+S_{\Delta}^2\}}}$$

$$-\frac{M_{\Delta}^2+M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}}{\sqrt{\{M_{\Delta}^2+2M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}+S_{\Delta}^2\}}}\left(1-\frac{2n'b^2l}{n'^2b^2-gk}\right).\frac{\sin^2\mu-\sin^2\Delta}{\cos^2\Delta}.$$

Now the first of these terms has been neglected, for the same reasons which we have assigned in (551.). The treatment of the second term by English mathematicians has been unsatisfactory, in the same manner as that for the declination-correction of times. Moreover, as the whole range has not been observed, except at Plymouth, it can generally lead to no result as to the value of $1-\frac{2n'b^2l}{n'^2b^2-gk}$; and at Plymouth the two phases (high and low water) appear to depend upon such different laws that we cannot use the variations for high water only in conjunction with the whole range.

Laplace's deduction of the mass of the moon from de-

(555.) Laplace's deductions for the whole ranges of tide at Brest are so important that we must devote a few words to them. The proportion of the small term above to the whole mean range is

$$\frac{M_{\Delta}^2+2M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}}{M_{\Delta}^2+2M_{\Delta}S_{\Delta}.\cos 2.\overline{m-s}+S^2}\left(1-\frac{2n'b^2l}{n'^2b^2-gk}\right).\frac{\sin^2\mu-\sin^2\Delta}{\cos^2\Delta}.$$

clination-corrections.

Now Laplace had found $\frac{S_\vartriangle}{M_\vartriangle}$, as we have explained (536.); and using this value with the values of $\overline{m-s}$ and μ in the observations which he discussed, and comparing the difference of the observed ranges when $\mu=0$ and $\mu=23°$, and the ratio of that difference to the whole range, with the formula, he obtained a value for $1-\frac{2n'b^2l}{n'^2b^2-gk}$, and therefore for $\frac{n'b^2l}{n'^2b^2-gk}$, or for $\frac{l}{n'}\cdot\frac{\frac{n'^2b}{g}}{\frac{n'^2b}{g}-\frac{k}{b}}$. It is evident that $\frac{n'}{l}$ = number of lunar days in moon's sidereal period; that $\frac{n'^2b}{g}=\frac{n'^2}{n^2}\cdot\frac{n^2b}{g}=\left(\frac{\text{solar day}}{\text{lunar day}}\right)^2$ × the proportion of centrifugal force at the equator to gravity; and that $\frac{k}{b}$ is a constant which in our theory represents the proportion of the depth of the sea to the earth's radius. Thus a constant in Laplace's theory, analogous to the depth of the sea in our theory, was found. Then using that constant in the fraction discussed in (455.), he finds that the proportion of the moon's effect to the sun's has been *increased*, in consequence of this value of the depth of the sea, in the ratio of 4 : 5. (In his first investigations he had found the ratio to be 10 : 11.) That is to say, $\frac{M_\vartriangle}{S_\vartriangle}$ or $\frac{M''}{S''}=\frac{5}{4}\cdot\frac{M'}{S'}$. Now $\frac{M''}{S''}$ is known from the semimenstrual inequality; therefore $\frac{M'}{S'}$ is known; and (43.)

$$\frac{M'}{S'}=\frac{M}{(\text{Moon's distance})^3}\cdot\frac{(\text{Sun's distance})^3}{S};$$

and the sun's and moon's distances and the sun's mass are known, therefore the moon's mass is known. Thus Laplace found for the moon's mass a value very nearly $=\frac{1}{75}$ of the earth's mass.

It is to be remarked that Laplace's expressions are more complicated because (as is evidently necessary for accuracy) he combines, with these considerations applying to the moon's declination, analogous considerations applying to the sun's declination. Moreover, Laplace does not ascribe the alteration of the proportion of effects to the depth of the sea, (his own theory not admitting of a solution so general as to exhibit that effect,) but to the assumed interference of waves coming by different channels. But the expressions introduced are exactly the same. We cannot sufficiently admire the union of sagacity and ingenuity in this process; the sagacity of perceiving that the effects would not be proportionate to the forces, but would also depend on the periodic times of the forces; and the ingenuity of inventing a conceived combination of circumstances which, mathematically speaking, would account for the difference of proportion and would afford means of calculating it, but which probably were not the grounds of his original conjecture, and which can scarcely be supported as applicable, locally, to Brest. We do not at all imagine that Laplace believed in his hypothesis of two canals.

(556.) We shall not delay long on the corrections for the moon's varying parallax. It will be sufficient to state here that, in conformity with (448.) and (452.), $2.\overline{m-s}$ ought to be increased by $\frac{3n'b^2h}{n'^2b^2-gk}e\sin ht$; and that instead of using $1+3e\cos ht$ as representing the factor for the effect of the moon depending on parallax, we ought to use $1+\left(3+\frac{4n'b^2h}{n'^2b^2-gk}\right)e\cos ht$. The former of these terms is lost in all the investigations, for the same reason as the analogous term in the declination-corrections. In a discussion of the Liverpool tide-observations, (*Philosophical Transactions*, 1836,) Mr. Whewell found that the correction of the time of high water for parallax implied that the coefficient $3e$, instead of being increased, was to be diminished. But we attach little importance to this, as in that discussion the tides were compared with the next preceding transit of the moon, and the parallaxes, &c., were taken for that transit, instead of taking one long before it. In the *Philosophical Transactions*, 1838, the Bristol observations were discussed in reference to several transits in order to ascertain which gave the most consistent results for parallax-correction. The result was that a transit later than that which represented best the semimenstrual inequality and the declination-correction was necessary for the parallax-correction. But this conclusion is by no means certain. It was founded upon the consideration that such a transit made it unnecessary to introduce any constant multiple of p', and therefore brought the observed inequality to a form approaching nearly to the term in (54.). But, on the other hand, an earlier epoch (the same which gave best results for semi-menstrual inequality of height and for declination-correction) exhibited more distinctly, in the magnitude of the coefficient of the variable term, the influence of the parallax-correction; and this alone is a strong proof that the earlier epoch was better. Moreover, the existence of a constant multiple may be accounted for by the supposition, that the larger tide corresponding to a larger parallax, travelling further up the small river above Bristol, does not make high water at Bristol so soon as a smaller tide which is almost stopped there. The law of the variable part of correction obtained by Mr. Whewell, as depending on the interval of the sun and moon, agreed pretty well with the theoretical law.

Difficulty of comparing them with existing results of observation.

(557.) In the same place, Mr. Whewell has stated the result of reducing the observed heights of the tides at Bristol. It appears that the same age of the tide which represents the other inequalities is proper for this. With respect to the agreement of the law of correction, as depending on the moon's distance from the sun, we can pronounce nothing precise. Mr. Whewell has however stated that this factor is, from observations, nearly constant; which agrees with theory; inasmuch as the theoretical term

$$\frac{M_{\triangle}+S_{\triangle}\cos 2.\overline{m-s}}{\sqrt{\{M_{\triangle}^2+2M_{\triangle}S_{\triangle}\cos 2.\overline{m-s}+S_{\triangle}^2\}}}$$

differs from 1 only by a quantity of the order of $\left(\frac{S_{\triangle}}{M_{\triangle}}\right)^2$, and not of the order of $\frac{S_{\triangle}}{M_{\triangle}}$, as Mr. Whewell has stated.

(558.) The effect of parallax on the height of the tides at Brest was discussed by Laplace in the following manner. From the discussion of the declination-observations, to which we have already alluded (555.), he took the value of the quantity $\frac{n'b^2l}{n'^2b^2-gk}$. He then substituted this, as a known quantity, in the expression $\left(3+\frac{4n'b^2l}{n'^2b^2-gk}\cdot\frac{h}{l}\right)e\cos ht$, and computed with it the ranges of tides for large parallaxes and small parallaxes, and took their differences. Thus he obtained as a computed number representing the theoretical sum of the differences for a certain number of observations, 51·52. The number actually deduced from the observations themselves was 47·27. Thus the observed difference was less than the theoretical difference. But this theoretical difference, it must be remarked, depends entirely on the circumstance that Laplace has chosen to use only the declinations for finding $\frac{n'b^2l}{n'^2b^2-gk}$; whereas, in our opinion, both declinations and parallaxes ought to have been used, and a value of that quantity ought to have been found from their combination.

Laplace's comparison of observed parallax-inequality with theoretical corrections.

Verification of the theoretical law depending on the magnitude of declination and parallax.

(559.) The theoretical law of the declination and parallax-corrections (that they depend on the square of the sine of declination and on the simple difference of the parallax from mean parallax) is fully proved by Mr. Whewell in the various discussions of the tides at London, Liverpool, and Bristol, to which we have so often referred. It may be interesting to the reader to remark that the whole difference in the height of high water at London, depending on declination, is about six or eight inches, and that depending on parallax is about one foot; and that at Liverpool the corresponding quantities are nearly two feet and three feet. At Bristol they are greater.

Observed inequalities depending on the sun's place.

(560.) The corrections depending on the sun's declination and parallax, being much smaller than those for the moon, (both because the absolute effect of the sun is less, and because the proportionate variations of its distance are less,) are not so easily extracted from observations. But in the *Philosophical Transactions*, 1836, pages 131 and 218, Mr. Whewell and Mr. Lubbock, taking the observations at Liverpool and London, and subtracting the effects due to semi-menstrual inequality and to corrections for the moon's declination and parallax, have obtained those which depend on the sun's place. The results appear to agree well with theory. Those at London are more completely worked out by Mr. Lubbock (the observations being referred to an earlier transit) in the *Philosophical Transactions*, 1837, p. 97, &c. In the *Ninth Report of the British Association*, p. 13, will be found some results as to solar corrections deduced by Mr. Bunt from the observations at Bristol.

(561.) The second line of (44.), which is considered at length in (46.), (47.), and (48.), contains the expression for the diurnal tide. The reader will readily understand that, upon applying to these terms the theory of (439.), modified by the theory of friction nearly as in (451.), results of the same kind but with different constants will be obtained; the relative effects of the sun and moon will be altered in a proportion different from that of the alteration in the semi-diurnal tide; the magnitude of the tide will be determined by the positions of the bodies at an epoch anterior by a different quantity; and the absolute time of diurnal high water on any day will bear no distinct relation to that of semi-diurnal high water. In fact, the diurnal tide is to be worked out with little reference to the semi-diurnal tide.

tide.

(562.) In (63.) we have pointed out the way in which the diurnal tide shows itself most obviously, by making the two semidiurnal tides appear unequal. Many notices of this kind are to be found in early records (as *Philosophical Transactions*, 1668, Colepresse on the tides at Plymouth, and Sturmy on those at Bristol: 1684, Davenport on those at Tunkin: 1776, a remarkable instance of their effect on the coast of New Holland, described by Captain Cook, &c.) In the same manner, observing the times as well as the heights of tide, it has been extracted from later observations. Thus in the *Philosophical Transactions*, 1836, page 57, &c., Mr. Lubbock has found that at Liverpool, in the month of January, when the moon's transit occurs in the afternoon at any time before 8 hours 30 minutes P.M., or in the forenoon after 8 hours 30 minutes A.M., the high tide which precedes that transit is greater than the high tide which follows it by a quantity which varies in magnitude, but which when greatest is nearly a foot. But if the moon's transit occurs at the opposite time of the day, the high tide which precedes that transit is less than that which follows it. The same rule applies to February, if, instead of 8 hours 30 minutes, we take 7 hours 30 minutes; for March, we must take 6 hours 30 minutes; for April, 3 hours 20 minutes; for May, 0 hours; for June, 9 hours in the opposite part of the day; and so on. The maximum difference is greatest in January and July, and least in April and October. From this it is plain that a considerable part of the diurnal tide depends on the sun. In the middle of January the sun's right ascension is 19 hours 30 minutes nearly; therefore the moon's right ascension, when her transit occurs at 8 hours 30 minutes P.M., is 4 hours nearly, and the diurnal tide therefore does not vanish till several days (5 or 6) after the moon has crossed the equator. The same appears from the other months. There is no sensible diurnal inequality in times. Mr. Lubbock (*Philosophical Transactions*, 1837, page 101) considers that the Liverpool diurnal tide corresponds to the position of the moon 4 days before the tide.

(563.) In the *Philosophical Transactions*, 1836, page 289, &c., in which Mr. Whewell has given the results of the simultaneous observations of tides made at his representation on a great extent of coasts of Europe and America, he has stated the relation of the diurnal inequality to the position of the moon. On the North American coast, it corresponds to the moon's place at the same time; on the coast of Spain, Portugal, the west of France, Cornwall, the west of Ireland, the north of England and Scotland, and the Cape of Good Hope, it corresponds to the moon's place 2 days earlier;

at Cowes, Portsmouth, &c., to the place 4 days earlier. These differences suggested the notion that the diurnal wave travelled at a different rate from the semidiurnal wave. To ascertain this, a very admirable investigation was given by Mr. Whewell in the *Philosophical Transactions*, 1837, page 227, &c. The height of low water as well as high water on every day for 19 days having been observed, the effect of diurnal inequality at high waters separately and at low waters separately was found by the use of curves, as is described in (494.). Thus the effect of diurnal tide was ascertained at four times in each diurnal tide; these being used as ordinates, the curve drawn through them represented the diurnal wave; and the time of its maximum was easily found and compared with the time of semidiurnal high water. Thus from Ferrol, by the west coast of Ireland and north coast of Scotland to Lincolnshire, it precedes one of the semidiurnal tides about $3\frac{1}{2}$ hours, (with some irregularities); so also from Ferrol to Havre; but at Bridport the two tides are together, and at Lulworth and Portsmouth the diurnal tide is 4 or 5 hours later, after which it is traced with difficulty. It is to be remarked that in this paper Mr. Whewell considers the position of the moon, on which the diurnal tide depends, to be 4 days earlier than the tide (instead of 2 days for many of the places, as stated before). This seems to reconcile the phænomena much better, though it shows the great uncertainty of the conclusions from observation.

(564.) In the same volume, page 75, &c., Mr. Whewell has treated the diurnal tide at Plymouth and Singapore, and finds that the Plymouth tide corresponds to a position of the moon 4 days earlier, and that at Singapore to a position $1\frac{1}{2}$ day earlier. He remarks, however, that the agreement is best in May, June, and July, and that there are discrepancies in March, April, and August. We imagine that this arises from the circumstance that Mr. Whewell has nowhere taken account of the sun's part of the diurnal tide; and if this is sensible, (and the Liverpool observations discussed by Mr. Lubbock seem to show that in January and June it is not much inferior to the moon's part,) Mr. Whewell's determination of the corresponding position of the moon is worth little. We consider this subject as still open to investigation.

(565.) That the tide should follow the sun's and moon's positions by four days is quite conceivable on the theory of canals. The investigation of (451.) and (452.), putting n for $2n$, applies to diurnal tide; and thus we find for the interval preceding the tide at which the moon's place is to be used,

$$\frac{f b^2 (n^2 b^2 + 4 g k)}{(n^2 b^2 - 4 g k)^2}.$$

Now this retard may be considerably greater than

$$\frac{f b^2 (4 n b^2 + 4 g k)}{(4 n^2 b^2 - 4 g k)^2}$$

if the value of k be much nearer to $\frac{n^2 b^2}{4 g}$

than to $\frac{n^2 b^2}{g}$;

that is, if the depth of the sea be much nearer to $8\frac{1}{2}$ miles than to 14 miles.

(566.) Laplace, in the fifth volume of the *Mécanique Céleste*, page 226, has determined the effect of diurnal tide at solstitial syzygies at Brest, to be about 7 inches at high water, (increasing one and diminishing another each by $3\frac{1}{2}$ inches,) and about 5 inches at low water. And he has found from this that the diurnal tide precedes one of the semidiurnal tides by 2 hours 17 minutes nearly, which, though not quite accordant with Mr. Whewell's determination, agrees perhaps as nearly as can be expected.

Cause of doubt in the results as to epoch of diurnal tide.

(567.) There is, however, one cause of doubt in these determinations, to which we must call the reader's attention. We have seen that, in examining the fluctuations of height of high water depending on semimenstrual fluctuations of force (537.), the effect is far less than seems properly to be expected from the cause, and in one instance at least it is smaller than at low water. It would seem probable therefore that all the high water fluctuations depending on diurnal tide ought to be multiplied in a certain degree, in order to be comparable with those of low water. This would vitiate the determination of the epoch of high diurnal tide as compared with high semidiurnal tide.

Diurnal tide insensible at London.

(568.) At London there is scarcely a sensible diurnal tide in the height of high water. This might arise from the maximum and minimum stages of diurnal tide occurring very nearly at low waters (semidiurnal), the mean stages occurring at high waters; and this is partially supported by the observation that Mr. Lubbock has discovered traces of diurnal inequality in the times of high water at London, (*Philosophical Transactions*, 1837, page 120,) not however, in our judgment, very distinct. But (as will be seen in the chart of cotidal lines) there appears to be no doubt that the tide at London is produced by the mixture of two tides, one coming from the English Channel, and the other, which has been 12 hours longer on its way, coming from the North Sea; and that while the semidiurnal fluctuations of these, being in the same phase, corroborate each other, the diurnal waves, being in opposite phases, (high diurnal tide of one corresponding to low diurnal tide of the other, &c.,) destroy each other.

Instances of very great diurnal tides.

(569.) The equilibrium-theory (47.), and Laplace's theory (101.), lead us to expect that the diurnal tide will be large in middle latitudes, and small near the equator and near the poles. The theory of canals (440.) gives the same result, supposing the canal to be a complete circle passing through the poles; if the canal is incomplete or interrupted, considerations similar to those of (296.), &c. apply, and no simple law like that of (440.) can be enunciated. The fact of observation is, that the diurnal tide is as large near the equator as in middle latitudes, at least in some very remarkable instances pointed out by Mr. Whewell, and which have been made the subject of very careful examination (although the existence of very large diurnal tide, as the general law in those parts of the earth, may be ascertained at once from Romme or any other good account of tides). Near the equator are Singapore, King George's Sound, in lat. 35° S. (*Philosophical Transactions*, 1837), Coringa Bay, Cochin, Surat Roads, Gogah, Bassadore (*Philosophical Transactions*, 1839), and others less carefully observed. In the northern seas are Petropaulofsk (Kamschatka), and Sitkhi (Norfolk Sound). In some of these localities the diurnal tide, when its range is greatest, greatly exceeds the semidiurnal. Mr. Whewell appears to imagine that the actual tides cannot be completely represented by the combination of a diurnal and a semidiurnal tide; but, so far as we can perceive, there is no difficulty at all in thus representing them.

(570.) We cannot here enter into a consideration of all the various effects produced by the mixture of these tides in various proportions. But, for a general idea, we invite the reader's attention to figures 63, 64, 65. Fig. 63 represents the course of a fortnight's tides at Plymouth; and here the diurnal inequality, though sufficiently marked, does not conspicuously disturb the semidiurnal tides. Fig. 64 represents the course of several days' tides at Singapore, and fig. 65 that at Petropaulofsk. It will easily be perceived that at Petropaulofsk there appears to be but one tide in a day, sometimes because one of the semidiurnal high waters is made so low as to be little perceptible, but more remarkably at other times, because one of the semidiurnal low waters is made so high as scarcely to disturb the appearance of a single tide.

(571.) We here close our remarks on the discussion of "the laws of the tides for varying positions of the sun and moon" as ascertained from observation. And we cannot do so without formally pointing out to the reader that absolutely the whole of these, as regards the tracing out the laws of the phænomena, and very nearly the whole as regards the determination of constants and coefficients, is due to Mr. Lubbock and Mr. Whewell. Yet while acknowledging that nearly all that we know is due to these philosophers, we cannot help expressing our wish that they had taken as guide a more complete theory than the miserable equilibrium-theory, and for this reason—we believe that so we should have known much more. Where observations are so rude and so numerous that they can be treated only in large groups, every thing depends on the assumption of the theory which is to direct the selection of the groups. We cannot, however, be too grateful for so much which has been done well, and which must suggest so clearly the critical points that will demand special attention in future discussions of observations.

Effect of the barometrical pressure on the tides.

(572.) A circumstance affecting the height of the tides, to which we have hitherto made no allusion, is the state of atmospheric pressure. It was first pointed out (we believe) by the French hydrographer, M. Daussy, (*Connaissance des Temps*, 1834,) that a low state of the barometer is accompanied with high tides. This has been carefully examined by the English investigators, and M. Daussy's result is fully supported. On this point we cannot do better than refer the reader to Mr. Lubbock's paper, *Philosophical Transactions*, 1837, page 97, &c. It appears there that in a set of observations considered by Mr. Lubbock, the unexplained fluctuations of the tide correspond precisely to those of the barometer; and Mr. Lubbock has laid it down as a rule, that a rise of 1 inch in the barometer causes a depression in the height of high water amounting to 7 inches at London, and to 11 inches at Liverpool. Mr. Bunt also, in the *Eleventh Report of the British Association*, page 31, has discussed with great skill the effect of the barometer on the tides at Bristol, and has shown that a rise of 1 inch of barometer produces a depression of 13·4 inches. He has also shown that the height of the tide, as depending on the barometer, is properly to be computed with the *contemporaneous* barometer. The explanation of this circumstance, by considering that a heavy atmosphere acts as a weight pressing down the water, is plausible enough; but as we cannot conceive air of different pressures in different parts of the earth, without supposing that there is a violent effort to restore equality of pressures, we cannot say that it is quite satisfactory.

Sect. VII Compari son of Theory and Ob servatio of Tides. Subsec. On the Lawsof Tides fo varying sitions o the Sun and Mo

Effect of the wind on the tides.

(573.) Connected with this is the effect of wind upon the tides (as distinguished from barometric pressure). Both M. Daussy and Mr. Lubbock, on comparing the differences between observed heights and computed heights with the directions of the wind, have come to the conclusion that the effect of the wind is insensible; see *Philosophical Transactions*, 1831. Nevertheless all practical men believe that the wind has a considerable effect, different in different localities; the rule for London is given with great clearness by Mr. Lubbock in the *Philosophical Transactions*, 1834, page 145. In fig. 41 we have shown the effect at Sheerness of a single gale (January 3, 1841), which lowered the tides in the Thames five feet, as we ascertained from examination of the registers at St. Katharine's Docks, the London Docks, Deptford, Woolwich, and Sheerness; and which produced a depression of about three feet at Hull and at Dover, and a sensible effect at Bristol. At Dublin and at Glasgow the tides were raised by it. But the want of regular observation at any great number of ports has made it impossible to trace the course of this great depression in all the seas round Britain.

Subsection 4.—On the Progress of the Tide over different parts of the Ocean.

(574.) Our remarks on this subject will consist principally of observations on figure 66, the chart of the world with cotidal lines marked on it. It is almost entirely copied from Mr. Whewell's chart in the *Philosophical Transactions*, 1833, with some modifications suggested by his papers in the *Philosophical Transactions*, 1835 and 1836. The Roman numerals upon the cotidal lines denote the hour, in Greenwich time, of high water on the day of new moon or full moon, as far as can be judged from the various considerations collected by Mr. Whewell, principally in the *Philosophical Transactions*, 1833.

The co lines o Northe Atlanti are pro bably v accura

(575.) The reader's first inquiry, on looking at this chart, will probably be, what are the extent and value of the evidence upon which these lines are traced? In a matter like this, depending entirely on numerous details, we can only, as a complete answer, refer to the original discussions, but we may here state our opinion very generally. The tidal hours on the coasts of Britain, Holland, France, Spain, Portugal, and North America, are now well known, from the simultaneous observations made at a great number of stations, for which we are entirely indebted to the zeal of Mr. Whewell, and to the liberality of the various governments to whom his representations were addressed. The tidal hours at the islands of the Atlantic appear also to be well known. We conceive therefore (recognizing also the justness of the principles on which Mr. Whewell has generally drawn his curves) that the cotidal lines of the Northern Atlantic are now drawn with very great accuracy. But when we remark the importance of the alterations which those simultaneous observations have introduced in the lines on the coast of North America, (although the evidence, upon which the first draft of those lines was made, was at least as good as that upon

The cot lines in other are ver doubtf

which the lines in other parts of the world are drawn,) and when we see the discordance of accounts as to the time of high water at many places, we cannot imagine that they are drawn with great certainty in other parts. Even the African side of the South Atlantic is not free from serious doubts, the Indian Sea is still less known, and for the Pacific Ocean east of New Zealand we have scarcely grounds for conjecture.

(576.) Taking them, however, in those parts in which they are best known, we may find many circumstances which admit of direct and instructive comparison with theory. In all places where the circumstances of depth, &c., vary much in a small extent of sea, we may consider the alteration in the tides through that extent as following simply the laws of waves on which no force is acting (because the length of the column of water on which the Sun or Moon acts is too small to allow their attraction sensibly to modify the pressures). Suppose now that in the neighbourhood of any particular coast the bottom shelves gradually from deep sea to one comparatively shallow. This would be attended, theoretically, with two consequences. The first is, that the wave would travel more slowly (174.), and therefore the separation of the cotidal lines corresponding to successive hours would be less, or the cotidal lines would appear to be crowded together on the map. The second is, that the magnitude of the tides would be much increased (247.), &c. And these circumstances might be found in places where the change in the depth was not known from observation; for the usual limit of sounding is 200 fathoms, which is probably a small quantity compared with the depth of the ocean. We may then expect that, where the cotidal lines approach closely, the magnitude of the tides will be increased. Now this does occur. A well-marked instance is the Bay of St. George in South America, in which a close approximation of cotidal lines is accompanied with large tides. It is possible here that the tides may be still further increased by the converging form of the waves (254.).

(577.) Another curious effect of the same cause is the distortion of the lines produced by islands, surrounded by shoals, in the ocean. The shoals prevent the tide-wave from advancing rapidly, and the cotidal line is therefore thrown back; but, conceiving the ridge of the wave to be thus bent, it is easy to imagine that after passing the island the two lateral parts of the wave will bend round it till they unite, and will then form a straight front nearly as before coming to the island. The successive cotidal lines will have forms corresponding to the forms of the ridge of this wave at successive times. Of this there are several instances apparently beyond doubt. Thus the 1 o'clock line is thrown back by the Azores; the 11 o'clock line is bent by the Bermudas, and its lateral branches nearly meet; the 10 o'clock line, after having been interrupted, just meets behind New Zealand. A similar effect of the same cause is, the universal dragging of the wave along the shore, as we have mentioned in (359.).

(578.) The velocity of the tide-wave ought, with the assistance of the table in article (174.), to give us good information as to the depth of the sea. Thus in the North Sea, figure 60, the tide-wave in 9 hours appears to describe somewhat less than 6 degrees of latitude, or, on the average, about 45 miles per hour. This, by the table in (174.), corresponds to a depth of 140 feet. We believe that the average depth along the line of deep channel is greater than this, and that at the sides less; and it is probable that the actual velocity is affected by both these. If the tide-wave of the Atlantic were purely derivative, it might be considered as describing 90 degrees of latitude, from the southern 1 o'clock line to the northern 1 o'clock line, in 12 hours, or to move about 520 miles per hour, which would imply a depth of about 18,000 feet or $3\frac{1}{2}$ miles. The reader will have no difficulty in extending similar remarks to other seas.

These remarks do not apply to large seas.

(579.) But these remarks apply *solely* on the supposition that the seas which are the subject of remark are so small, that the action of the Sun or Moon on a column of water as long as the sea will produce a pressure which is insignificant in proportion to the height of the tides or the changes in the heights. And this consideration, of which the justice is obvious, does, in our opinion, make it impossible to receive one of Mr. Whewell's speculations as to the tides of the Atlantic. The general course of the tide-wave there being from S. to N., or rather from SSE. to NNW., Mr. Whewell has inferred from this that the tides of the Atlantic are mainly of a derivative character, produced by the tides of the Southern Ocean and transmitted up the Atlantic in the same manner in which the tides of the Atlantic are transmitted up the English channel. We doubt this entirely. A channel as large as the Atlantic, if it ran due north, would have large tide-waves of a stationary character (440.) and (448.); but being in some degree inclined, the tide-waves would travel towards the NW. (439.) and (441.), but with a very irregular velocity, not dependent on the depth of the water (supposed uniform.) And even if the waves were stopped by a barrier (such as we may conceive the coast of North America to be, omitting the comparatively narrow channel between Britain and Greenland), yet the investigation of (838.) shows that the effect of friction is to give nearly the same formula for the tides in mid-sea as if no barrier existed. Indeed we may remark as the general effect of friction, that the tides at a distance from shore, or at a distance from a communicating channel, will depend more, so far as regards their form and succession, on the acting external forces than on reflection from barriers or communication from other seas, their magnitudes, however, being diminished and their epochs being altered. Without, therefore, denying entirely the effect of the Southern Sea, we conceive it to be extremely small.

The tides of the Atlantic cannot be treated as derivative tides.

Difficulty of explaining theoretically the transmission of tide-wave in the Atlantic.

(580.) But, whatever supposition we make as to effects of friction, &c., the power of mathematics fails totally in the attempt to express the transmission of the tide-wave or waves through the Atlantic Ocean. It has some analogy to a canal, (an analogy which, though distant, gives us confidence in applying some of the results deduced from canal investigations, as for instance the effect of the depth on the magnitude of the tide, and the effect of friction in producing the age of the tide.) But it has not so much as to enable us to predict what will become of the tide-wave in its general progress; and of course the analogy fails totally as regards the effect of those very important features which have no existence in a canal; huge promontories projecting into its sides, or vast bays opening large lateral expanses for the spread of the tide-wave.

(581.) There is moreover another consideration which must not be left out of sight in estimating the difficulty of reconciling our observations of the tides of an ocean with such a theory as we are able to give even for the simplest cases. It is that, supposing the cotidal lines to be accurately what they profess to be, namely, the lines connecting all the points at which high water is simultaneous, we have nevertheless, in (366.), &c., given reasons for supposing that they may not at all represent the ridges of the tide-waves that run over the ocean. Thus, an eye at a great distance, capable of observing the swells of the tide-waves, might see one huge longitudinal ridge extending from the mouth of the Amazons to the sea beyond Iceland, making high water at one time from Cape de Verde to the North Cape, and at another time from Florida to Greenland; and another ridge, transversal to the former, travelling from the coast of Guiana to the northern sea; and the cotidal lines which we have traced may depend simply on the combination of these waves. It does not appear likely that we can ever ascertain whether it is so or not; but it is certainly possible that the original waves may have these or similar forms; and if so, it is vain for us to attempt entirely to explain the tides of the Atlantic.

The cotidal lines may not represent the ridges of the tide-waves.

The interference of wave-ridges may explain the cotidal lines west of America.

(582.) To the Pacific Ocean the same remark applies still more strongly. There is however one part in which we seem to discover, from the considerations mentioned above, some explanation of the singular form of the curves as traced by Mr. Whewell; namely, the western coast of South and Central America. It seems not unlikely that the east-and-west action of the tidal forces, acting as if on the water in canals stretching east-and-west, would produce waves running east-and-west, (the length of their ridges being north-and-south,) according to the laws of (296.) and (337.). It seems probable also that the north-and-south action of the tidal forces would produce another wave, either running north or south, or of stationary character. The effect of the composition of these, as in (366.), &c., would be to produce cotidal lines, having considerable resemblance to those on the American shore of the Pacific.

Difficulty of explaining the diurnal tides in the Pacific.

(583.) If we look to the Pacific Ocean with reference to diurnal tides, and consider the southern sea as a part of it, we seem to have a case which possesses considerable analogy with Laplace's assumption. Yet it is remarkable that here we appear to find a more complete failure than anywhere else, of Laplace's celebrated result as to the non-existence of diurnal tide, (all the large diurnal tides being in that sea.) It is true that this failure might be explained by supposing the depth of the sea to be extremely unequal.

(584.) Upon the whole, therefore, we are driven to the conclusion, that we cannot at all explain the cause of the form of the cotidal lines in the ocean, so far as they have been traced with any probability. And, supposing us to know with tolerable certainty those corresponding to the semidiurnal tide, we cannot at all predict those which should hold for the diurnal tide.

Laws which nevertheless will apply everywhere.

(585.) Nevertheless we are able to lay down one law of vast theoretical importance, (or rather two laws, one applying to the group of semidiurnal tides and the other to the group of diurnal tides.) It is simply that assumed by Laplace, and which also applies to, or includes the effect of, our theories of "the relation of the magnitude of the tide to the depth of the water" and "friction." Whatever be the number of communications from other seas, or reflections from barriers, whatever the depth of the water or the amount of friction, still the result of a given periodical force will be a periodical effect whose period is the same, but whose coefficient is represented by the coefficient of the force multiplied by a function of the period, and whose argument also contains a term which is a function of the period. This law completely brings under our management all terms depending on the slow variation of forces (as those which depend on ellipticity, declination, &c.) For $(1+3e\cos ht)\cos nt$ is

$$=\cos nt+\frac{3e}{2}\cos(n+h)t+\frac{3e}{2}\cos(n-h)t,$$

and, h being small, either of the functions of n mentioned above, and which we will call N, is changed for the additional terms to $\mathrm{N}+\frac{d\mathrm{N}}{dn}h$ and $\mathrm{N}-\frac{d\mathrm{N}}{dn}h$; and, $\frac{d\mathrm{N}}{dn}$ being discovered in any one case, (as, for instance, when Laplace inferred it from the observed declination-correction,) is applicable to the other cases, (as, for instance, when Laplace applied the value so found to correct the first value of the mass of the Moon.) And this holds for any port under any circumstances whatever; it even holds, so far as we can see, for the heights of tide as distinguished from the time of tide; and from these two classes of phænomena (supposing observation to be perfect) the correct mass of the Moon ought equally to be inferred, though the laws of the two classes are, in the first inspection, discordant. But this law does not in the same manner bring under our management the rules of diurnal tides to be inferred from semidiurnal, or *vice versâ;* the difference between n and $2n$ being too great to permit us to confine ourselves to the two first terms of Taylor's theorem. A similar law however would connect the diurnal tide with the slow variations of diurnal tide and the alteration to be made in the Moon's mass as applying to diurnal tide; and thus, theoretically speaking, the Moon's mass might be inferred from the parallax-corrections of diurnal tides in the same manner in which Laplace has found it from declination-corrections of semidiurnal tide.

CONCLUSION.—ON THE PRESENT DESIDERATA IN THE THEORY AND OBSERVATIONS OF TIDES.

(586.) If we advert to the different parts of this extensive subject in the same order in which we have treated them in the preceding Essay, we shall find the following to be the most important points requiring attention.

(587.) A subject of very great importance is, the more general solution of Laplace's equation in (96.), to the extent mentioned in (119.), so as to enable us to apply the general theory to seas limited by shore-boundaries. A great point would be gained if this could be done on any assumption whatever as to the depth of the sea.

(588.) The value of Laplace's theory is lost in a great measure, because the solutions hitherto attempted apply only to those cases in which $i=n$ exactly (100.), or $i=2n$ exactly (107.). Thus the difference in the specific action of the Sun and Moon, depending on the difference of their angular velocities, is entirely lost. It would be highly important to obtain solutions on the supposition, that i differs from n or from $2n$ by a small quantity whose square may be neglected.

(589.) Laplace's theory would be much more valuable if it were extended so far as to include the effects of friction. The methods of (315.), &c., would probably apply with sufficient accuracy.

(590.) The additions to the theory, indicated in the three last articles, would be exceedingly valuable, even if quite independent. If they could be treated in combination, their value would be very greatly increased.

(591.) In the theory of waves, the most important point by far is the theory of river-tides, in which the extent of vertical oscillation bears a sensible proportion to the depth; which we have partially treated in (192.), &c. The following extensions would very much increase its value; it is apprehended that they would introduce more of labour than of difficulty.

(592.) The investigations of (218.) and (260.) must be extended so as to include the terms depending on the vertical oscillation, at least to the third order; observations showing that those terms are not only sensible but important. This investigation, if properly conducted, will include the extension of the investigation of (309.).

(593.) The effect of friction must be introduced in combination with these investigations.

(594.) The investigation must, if possible, be effected for the case where the vertical oscillation is very great; as, for instance, where the low water leaves very small depth on the bottom. In this case it is hopeless to attempt a converging series, and an independent and finite method must be tried. Much would be gained if this could be effected in the simplest case, as for a rectangular channel, of uniform section, without friction.

(595.) In regard to observations, it is very desirable that simultaneous observations at short intervals should be made on different points of some long tidal river, or some deep estuary, for examination of the change of the wave. These observations should be discussed as is mentioned in (479.). It is particularly desirable that these observations should be made in very high spring tides and in very low neap tides, to discover the laws of alteration of the various constants as depending on the range of the tide.

(596.) As a special locality, we may point out the various channels near the Isle of Wight as most particularly requiring attention. It would be very useful that simultaneous observations of a few tides should be made at two or more points on Southampton water, two or more on the Solent, one or two on the eastern side, as at and beyond Portsmouth, and one or two on the west side of Hurst Point.

(597.) In regard to the reduction of long series of tide-observations as applicable to particular ports, we shall only call the reader's attention to the following points.

(598.) It will probably be found, from the inquiries, theoretical and experimental, to which we have alluded above, that the elevation of high water in rivers or bays requires a certain multiplier to make its fluctuation of range comparable proportionably with the fluctuation of range on the coast, and that the depression of low water in like manner requires a multiplier different from the former. Much confusion would be removed by ascertaining these multipliers and applying them at once to the observations.

Tides and Waves.

Correction of time, depending on range of tide.

(599.) It will probably also be found that the time of high water requires a correction depending on the whole vertical range, to make it comparable with that of the sea; and that the time of low water requires a different correction. These should be ascertained, if possible, and applied. It would, perhaps, be best to assume that such a correction is needed, and to determine its quantity from the observations themselves in such a manner that the epochs of highest tides and mean lunitidal intervals shall synchronize. And in like manner, for the corrections to the heights, it might be best to determine the factors, so that the mean height shall be uniform, and that the first proportion of the Moon's mass to the Sun's, inferred from the semimenstrual inequality of heights, shall be the same as that given by the semimenstrual inequality of times.

Correction of height.

Methods for diurnal tide.

(600.) In the places where the diurnal tide, though sensible, is small, its effect in height at the time of high or low water may be considered independent of its effect on the time of the high or low water, and *vice versâ*. The best way of disengaging it, numerically, would probably be, to calculate a small approximate table of second differences of the heights, and, subtracting from each observation of height the mean of the preceding and following heights, to apply that computed second difference. But where the diurnal tide is very large, the effect on height is not independent of the effect on time. In this case we see no method so clear and easy as to calculate beforehand a few tables of the values of $\cos\theta + a\cos(2\theta + b)$ with different values of a and b; the result will enable the experimenter to judge how much the real epoch of high semidiurnal tide differs from the time of highest water, and what is the real epoch of diurnal tide. The same will apply to the times.

Methods for general inequalities.

(601.) The whole of the inequalities should then be treated with reference to the theory of (451.), and so as to include the terms pointed out in (550.) and (554.). For these it will not be sufficient to class together all observations at which the declination was the same; before this is done, the whole must be divided into two categories, namely, those of declinations increasing and of declinations diminishing, which are to be afterwards subdivided by absolute declinations. In like manner, as regards parallax, all the observations must be divided into the two categories of parallax increasing and parallax diminishing; which are to be afterwards subdivided by absolute parallax. The whole of these elements are to be taken for an epoch anterior by a quantity equal to the age of the tide. From the discussion of these inequalities in time as well as in height, the mass of the Moon is to be inferred by the process sketched in (555.); and the agreement of the different values of the mass will be the proof of agreement of theory and observation.

(602.) The best method of starting in these reductions cannot be the subject of general rule; the age of the tide however should be determined as early as possible. When the lunar parallax correction is ascertained, that part of it which applies uniformly in the same age of the Moon (depending on variation) should be subtracted from all the observations, or rather from the means of the groups, and then only can the semimenstrual inequality be found exactly. Each inequality, when determined, should be subtracted from the observations before investigating a new one.

(603.) The same methods should be used for diurnal inequality, where it is conspicuous. But, as north declinations and south declinations are not now to be confounded, it will be advantageous to express the places of the Sun and Moon by north-polar-distances instead of declinations.

Points to be noticed in the tide-observations in the Pacific Ocean.

(604.) In regard to the tracing of cotidal lines, the principal defect, in marine localities which otherwise are well known, is in the Pacific Ocean generally. The attention of those who are interested in defining these lines should be particularly directed to the devising of means for rendering the tide even coarsely sensible, in places where its range is small, where it is partly masked by day-breezes and night-breezes, and where the water is held in a state somewhat different from that of the open sea by the rings of coral reef which surround so many of the islands.

Conclusion.

Referen to the si plest fu of tide-function for dra ing coti lines.

(605.) In some smaller seas scrupulous attention should also be given to the distinction between the actual time of high water and the time when the simple sine expressing the sea-tide reaches its maximum. It is not unlikely that in this way some part of an apparent anomaly which Mr. Whewell has remarked to the east of the Isle of Wight may be removed.

INDEX TO THE ESSAY ON TIDES AND WAVES.

Introduction.

Section I.—Ordinary Phænomena of Tides.

Section II.—Equilibrium-Theory of Tides.

Conclusion.—On the present Desiderata in regard to Tides.

ARCHITECTURE.

PART I.

THE ANCIENT ARCHITECTURE OF GREECE, EGYPT, AND PERSIA.

CHAPTER I.

The Origin of Architecture.

practice building gan with first So-ties.

If we pass over the time when there existed no implement capable of excavating a rock, or felling a tree, and when the human savage, who drew his subsistence from the Earth or waters, retired for the night to the shelter of some natural cave or hollow tree, we shall come to a period when the practice of building began in the World, and this was, probably, as early as the formation of the first Societies. As soon as a number of individuals or families had united themselves together for the purposes of defence, or of more effectually obtaining the means of support, habitations, larger and more commodious than those afforded by Nature, would be required.

The means resorted to by different Tribes of people to procure the necessary protection from the inclemency of the weather, may be reasonably supposed to vary according to the mode by which each people obtained its subsistence, to the materials for building which happened to be found in the places occupied, and, perhaps, to some peculiarities of character with which each people might be endowed.

ts and es were bably the habita-ns.

A pastoral nation, of which each family must change its place of abode as often as its flocks consume the productions of the Earth about the station it occupies, will have little inducement to erect permanent buildings; and, in a region nearly level, tents, or at most, light timber-huts, which can either be removed at pleasure, or abandoned without loss, will, probably, be the only dwellings it finds necessary to construct.

Nearly the same thing may be said of a people inhabiting a mountainous country, or the sea-coast, and seeking its support from hunting or fishing; for the families or communities which pursue those modes of living, being thinly scattered over an extensive territory, will, in most cases, find it convenient to fix their abodes in caves formed by Nature or Art in the rocks.

what cir-stances might be-an Art.

But when men applied themselves to the cultivation of the ground, in a region where an ungrateful soil compelled them to the constant performance of a regular succession of labours in order to acquire the means of subsistence, being necessarily attached to one spot, perhaps for life, it is conceivable that their dwellings would be of a permanent nature; and, consequently, it is among such a people that, through successive improvements, the practice of building may be expected to rise to the dignity of an Art. This would take place when, in process of time, men had learned to give to their buildings such internal arrangements as were suited to the purpose for which they were intended; to make the exterior forms characteristic of those purposes; and to establish the fit proportions which the several parts of an edifice should bear to each other, in order to fulfil the above conditions, and to render the whole capable of producing an effect which might be pleasing to the eye. Now the Art of Architecture is a collection of rules for constructing buildings conformably to these principles.

The prototype of Architectural works unknown.

As this Art must have had its origin in some very simple and rude construction, and as its early progress must have been made by insensible steps, neither the primitive form of a building nor the successive improvements it underwent were likely to excite such notice at the time they were made, as to cause the memory of them to be preserved. It is therefore hardly to be expected that any Tradition, still less that any Historical document should remain, concerning either the one or the other, of a date anterior to the establishment of a considerable number of general principles of construction. Afterwards, these becoming objects of study for persons who were called upon to exercise Architecture as a profession, would necessarily lead to an inquiry whether they were founded upon any original model, and what that model might have been.

Probable form of the first houses.

Vitruvius, who wrote on the Art, in the time of Augustus, or of one of his immediate successors, has, in the Ist Chapter of his IId Book, indulged his own fancy, or recorded that of some more ancient Philosopher, respecting the origin of the Arts and Sciences, and particularly that of the Art of building. Having given a fabulous account of the origin of fire, he goes on to state that, by the comfort men derived from it, they were induced to form themselves into Societies, and erect buildings to shelter themselves from the severity of the climate. Such buildings, he thinks, would resemble the huts constructed by men who occupy the lowest grade in Society; and, to give an idea of that primitive style, he describes the mode of building practised by the Colchians, a people who probably were then in the same rude state as are now the inhabitants of the Islands in the South Seas.

He says, it consisted in fixing trees upright in the ground, side by side, so as to include the space to be inhabited; the distance between the rows of trees equalling the length of the trees intended for the covering. The roof was laid over the tops of the upright trees, and above these, other upright trees were placed, in a manner similar to those below. Thus the building was raised to the height required. A roof was formed at the top, he says, by raising beams across from the four angles, so as to unite in a point; the sides and roof were filled up with boughs, and the interstices were stopped by chips and clay.

It is, however, by no means necessary to suppose that the square or rectangular form which Vitruvius describes is the only one which would be affected by the earliest people for their houses; indeed, it is probable that a circular form would as often be adopted, if it were not the original construction; and this is so much the more likely to be the case as it is less artificial, and as the practice exists among those people who approach the nearest to the state of Nature. The conical form is that which is actually given to their huts by the natives of the Southern extremity of the American Continent, and a cylindrical form of wall with a conical roof is very generally adopted in the interior of Africa.

Tombs of masonry are probably more ancient than dwellings of the same material.

The inquiry into the nature of the earliest edifices seems to lead us to the discovery that, before Man had provided any thing better than a frail tenement of wood to shelter him, when living, from the summer's heat and winter's cold, he had bestowed incredible pains in the endeavour to form an eternal building of stone which was to receive him when dead.

A pile of stones, or a mound of earth, was certainly the first monument erected to commemorate some event, to mark the grave of some person who had been of importance during his life, or to serve as a general receptacle for the bodies of men slain in battle: such are the monumental Barrows of earth or stones which abound in Europe, from the Steppes of Tartary to the Highlands of Scotland, and which have been discovered even in North America. The more artificial Pyramids, which have been erected in so many different parts of the World, are works, in all probability, intended for similar purposes, and their construction displays the next step in the Art of building.

Origin of the pyramidal form of tombs.

The pyramidal or conical form, which was universally given to these monumental masses, is naturally enough derived from the form which earth assumes when thrown loosely in a heap, such as that which would necessarily be made over a grave when the excavation was filled up after the body had been deposited; or, we may add, from the form assumed by stones piled loosely on the ground as a monumental mark; and, accordingly, we may consider the adoption of that form as an argument in favour of the propensity of Man to imitate, in his artificial constructions, the appearance of some natural object, or some primitive work.

Tombs excavated in rocks.

In Countries abounding with mountains and rocks, natural excavations would often be found capable of serving as receptacles for the dead; and when these were wanting, artificial excavations might be made with less labour than it would require to erect a Pyramid. It is therefore probable that both these species of sepulchre are of equal antiquity, and were employed for the same purpose, according to circumstances. Excavations, which have been used as sepulchres, abound in Egypt, Persia, India, and Europe, and even in the Island of Teneriffe in the Atlantic Ocean. An account of the disposition of the chambers and galleries in the principal places where such sepulchres have been formed, is given under CATACOMB, in our *Miscellaneous Division*.

Pyramids and caverns were probably used also for other purposes.

But though the Pyramids and Catacombs were, generally speaking, intended to contain the bodies of the dead, there is sufficient reason to believe that in some cases they must have been used as Temples, or at least, that some part of each was appropriated to the purposes of Religion, or to the residence of its Ministers; the latter destination is inferred from the testimony of Herodotus, who on that account was not permitted to see the interior of the Labyrinth in Egypt. It is possible also that such works may have occasionally served as retreats for the inhabitants of a Country from the pursuit of an invading enemy, or as secure places to contain the treasures of the Sovereign or of the State. For some or all of these purposes, Pyramids or caverns seem to have been the necessary accompaniments of most cities of the ancient World.

Egypti Pyrami

At the earliest period of Society in Egypt, the rocks of Thebais seem to have presented an indestructible asylum for the dead, who were deposited in extensive excavations made in those natural masses of stone; but when the seat of the Empire was removed to Memphis, near the Delta, those masses were not so abundant, and it became necessary to erect artificial buildings, containing chambers for the same purposes; such masses are the Pyramids, which still exist in that part of the Country, and form a distinguished feature in an Egyptian scene.

The three principal Pyramids of Egypt are supposed to have been erected by Cheops, by his brother Cephrenes, and his son Mycerinus, who were successively Kings of that Country. But so little dependence can be placed upon the early History of Egypt that it is impossible to say whether we are to refer their reigns to a period previous or posterior to that of the Trojan war. Those Pyramids are situated along the Nile, near Cairo, probably not far from the place where the ancient Memphis once stood, and they are built of granite upon a nucleus of natural sandstone.

At a short distance Southward from the great Pyramids is the town of Saccara, in the neighbourhood of which are several Pyramids, some constructed of stone, others of brick, and one is described as formed of heaps of pebble-stones cemented together. The exterior of the latter is composed of six stages, each terminating at top in a horizontal surface 11 feet broad, and the vertical distance from stage to stage is 25 feet. Between the stages, the faces of the Pyramid are oblique to the horizon, so that the whole has the appearance of several frusta of Pyramids placed one on another.

In Upper Egypt the Pyramids seem to have been less general than in the country about Cairo, probably because the natural rocks were more abundant in the former district than in the latter; but M. Caillaud, and subsequently Mr. Burckhardt, observed great numbers in Nubia, at the distance of more than one hundred leagues beyond the cataracts of the Nile. They are described as bearing considerable resemblance to those of Egypt, both in their general form and in the character of their sculpture, but they are much smaller, the greatest not being above 50 feet high. They are disposed in groups of twelve or fifteen together, and within the mass of each is formed a sepulchral chamber, to which there is an entrance through a Temple built against the face of the Pyramid.

Anci Pyra of As

The custom of erecting Pyramids must have been very general throughout Asia. The Tower of Babel was, not improbably, a work of a similar nature, and that which was called the Tower of Jupiter Belus, in the centre of one of the divisions of Babylon, was certainly so. According to the description given by Herodotus, (*Clio*, sect. 181.) the base of this Tower was a square, each side of which was a furlong in extent. The building consisted of eight different portions in pyramidal forms, one above another; the whole height was one furlong, and as the portions are stated to have been built in regular succession, perhaps they were all of equal height, *viz.* about 80 feet. The ascent from the ground was by an inclined plane which passed eight times about the Tower, and formed the divisions just mentioned; in each of the divisions were constructed Temples, consisting of apartments whose roofs were supported by pillars, and in the upper Temple was a magnificent couch of gold. It is probable also, that this Temple was used as an Observatory, and that from it the Chaldean Astronomers made the celestial observations, of which a few have been transmitted to our times. Here, then, we have an example of a Pyramid which does not seem to have been used as a tomb.

In his account of the Retreat of the Ten thousand Greeks from Persia, Xenophon mentions the arrival of his army at an uninhabited city, which he calls Larissa, situated on the Tigris; and he says, that close to the city there stood a Pyramid of stone, 100 feet square and 200 feet high, into which the inhabitants of the neighbouring villages retired after the defeat of the Persians. (*Anabasis*, book iii.) Bochart supposes this city to be the Resen stated by Moses (*Gen.* x. 12.) to have been built by Ashur; and if so, there is a probability that this Pyramid was one of the most ancient in the World. It seems to have contained chambers, and therefore must have been intended either for a tomb like those of Egypt, or for a place of worship, like the Tower of Belus. Its proportions, however, differ considerably from those of the Egyptian Pyramids, inasmuch as its height appears to have been double the length of each side of its base, whereas the heights of the latter are scarcely equal to the lengths of their sides.

is of

In the earliest times, Barrows of a conical or pyramidal form seem to have been commonly raised as funereal monuments in Greece. In the XXIIId Book of the *Iliad*, Homer states that the Tomb of Patroclus was made by heaping earth over his grave; and, from the circumstance that the foundations are said to have been laid deep, we infer that the Pyramid was reveted with masonry. Pausanias mentions (*Argolica*, c. 15.) a sepulchre of Opheltes, at Nemea, about which were several altars, and the whole of which was surrounded by a stone wall; and he speaks of a pyramidal structure between Argos and Epidauros which was built over the graves of the combatants who fell in the quarrel of Prætus and Acrisius. These monuments, perhaps, resembled that pyramidal Tower which still exists near Argos, on the road to Tripolizza, and which is described in the *Supplement to the Antiquities of Athens* originally published by Stuart and Revett. Its plan is rectangular; at the foot the length is 44 feet, and breadth 31 feet 4 inches; the height of the part yet standing is 9 feet 2 inches, and at that level the length is 34 feet, and breadth 24 feet 3 inches. How the building was terminated above is unknown, all the upper part having been destroyed, but in the interior there is a chamber, now roofless, about 20 feet long and 17 feet 6 inches wide. On one face of the Pyramid is an entrance covered by horizontal courses of stones which project beyond each other till they meet at top, and form a triangular head. A passage from this entrance leads nearly to the opposite face of the Pyramid, and at the extremity on one side has been the doorway of the apartment.

It is a remarkable circumstance that Pyramids did not, subsequently, become prominent objects in Greece, as they did in Egypt, and perhaps we may consider this as a proof of the independent origin of the Architecture of the former Country; the prevalence of a more complex and refined style of building, in later times, probably caused simple Pyramids to be disregarded, and such as once existed to be destroyed.

Pyramids are not confined to the ancient continent.

The pyramidal form of Sepulchral monuments, or Religious edifices, does not appear to have been confined to the ancient continent; we find the same form affected by the inhabitants of parts of the World which are separated from it, in opposite directions, by the Atlantic and Indian Oceans: we allude to the Pyramids existing in Mexico at the time of the invasion of that Country by the Spaniards, and in the Islands of the South Seas at the time of their discovery, and perhaps at the present day. On reading the descriptions of these works we cannot avoid being struck with their resemblance to the Pyramids of the Babylonians and Egyptians.

Dr. Robertson states, on the authority of the Spanish writers, in the VIIth Book of his *History of America*, that the great Temple of Mexico was a solid mass of earth, of a square form, and having part of its superficies reveted with stone. Each side of the base was 90 feet long, and it diminished gradually upward till it terminated in a quadrangle 30 feet long each way; on the top of this square was a Temple containing two altars, on which the victims were sacrificed. And he thinks it probable that all the other Temples of Mexico resembled this exactly. Whether it was intended as a place of burial, or not, does not appear, but the *morai* which Captain Cook saw at Taheite in his first voyage was certainly an elevation for that purpose. He says it consists of an enormous pile of stonework 270 feet long, 90 feet wide, and from 40 to 50 feet high, in the form of a Pyramid, with a flight of steps on each side. The foundation consists of rock stones, the steps are of coral, and the upper part of round pebbles; the rock and coral stones are squared neatly, and the whole is compact and firm, which, considering it was constructed before the natives possessed iron tools, or cement, must have been a work of prodigious labour. This forms one side of a court, whose length and breadth are nearly equal, and the court, which is surrounded by a wall, is paved with flat stones.

Having described what are the most simple constructions, and what were the kind of works first executed by Man, we proceed to exhibit the probable origin of edifices of a more artificial character.

CHAPTER II.

The supposed Prototype of a Systematic Style of Building.

Comparison of an original hut of timber with the form of an ancient Temple.

We may collect from what is said by Vitruvius in the IId Chapter of his IVth Book, that, at a period as early as his time, the analysis of the forms of buildings had led to the hypothesis that they are all derived from some mode of construction employed in the infancy of Society; and consequently that the most superb edifices are but grand imitations of the system of timbers forming the framework of a simple cottage. It is indeed easy to conceive that whatever might be the forms of the primitive dwellings of the inhabitants of any Country, that form would be copied when a more substantial material than timber was employed, or a more extensive edifice than a hut was to be constructed. If, then, we admit that the first habitations of any people were of timber, and in whatever Country this material abounds it is probable enough that such would be the case, the hypothesis will be justified by showing the correspondence between the construction of a timber-hut and the general disposition of the members of a stone edifice, which may be supposed to have been erected by the people of such a Country at a time when the Arts and Sciences were extensively cultivated among them.

This conformity we purpose now to trace, taking for our example a building similar to some of those erected in Greece or Rome at the time of its greatest national splendour. Such a comparison will afford an opportunity of showing the situations and uses of the principal members which enter into the composition of almost every building of importance, whether ancient or modern, and, therefore, will facilitate the comprehension of the more particular descriptions which will be, hereafter, given.

It may first, however, be observed that Architecture was, probably, brought to considerable perfection in edifices of timber before stone was employed; because no traces remain of any buildings, executed in the latter material, whose forms indicate a series of approximations to the perfect state of the systems or Orders exhibited in the most ancient of the existing edifices; and it cannot be said that such examples may have formerly existed but are now destroyed, because it is reasonable to believe that such works, being the oldest and rudest, would be constructed in a more substantial manner than the others; and, therefore, would be better able to resist the ravages of time.

The best notion we can form of the construction of the hut is, that a number of posts would be placed vertically on the ground, so as to enclose an area in the form of a square or parallelogram; along the tops of these would be placed a horizontal beam on each of the four sides, and over these would be laid other horizontal beams, parallel to one of the sides of the building, in order to support the material which was to serve for the roof. But, as the flat covering which we have here supposed, would not, in a Country subject to heavy rains and snows, afford a sufficient protection to the interior, an inclining roof supported by beams placed obliquely above the vertical posts would, very early, be substituted for the flat one. Now the Temples of the Greeks and Romans were generally rectangular, accompanied and, often, surrounded by columns, and covered by roofs inclining on both sides from a ridge over the middle of the building and parallel to its length. This construction bears, certainly, great resemblance to the hut just described; but, in order to get a more complete idea of the correspondence of the copy with its supposed original, we must compare them together more particularly, first exhibiting the principal members and, afterwards, the minor parts in detail.

The origin of the columns and entablature.

The trunks of trees placed vertically in the ground are supposed to be represented by the columns in the finished building. (Pl. i. fig. 1.) Over the tops of these trunks, on each face of the primitive hut, was placed a beam horizontally, and this, in the copy, is what has the name of *epistylium* or *architrave*. Above the architrave may be supposed to come the transtra or horizontal timbers, which, stretching over the enclosed space, in a direction parallel to either face of the building, support the roof. These being placed at certain distances from each other, and their extremities appearing immediately over the face of the architrave, were represented in the copy by rectangular divisions which, from the manner of ornamenting them, bear the name of *triglyphs*. The notches cut in the architrave to receive the extremities of those beams were called by the Greeks *opæ*, and, hence, the intervals of the beams have the name of *metopes*. The whole space occupied by the triglyphs and metopes was called, by the same people, *zophorus*: in later times it has been called the *frize*, because it is generally ornamented with sculpture.

From this description of the timbers above the architrave, it will be immediately perceived that the triglyphs, which represent the extremities of those timbers, should only appear on two opposite faces of the building; yet, in every ancient example of a rectangular building where triglyphs are employed, they are formed in a similar manner on each of the four faces; unless, therefore, we suppose the timbers to be disposed in two directions, at right angles to each other, and to be framed together so that the lower and upper surfaces may be in the same plane respectively, this must be considered as a departure from strict conformity with the original model; and then the triglyphs placed on the two faces which are parallel to the directions of the beams must be supposed to have been intended, only, to give a certain similarity of ornament to all the fronts of the edifice. It is not, however, in every building that a representation is made of the ends of the beams immediately above the architrave; for, in some, the frize is ornamented in a different manner, or left quite plain, as if copied from a model in which the ends of those beams were covered by a smooth board.

Above these transverse beams may be supposed to have been placed other horizontal beams of smaller dimensions, closer together, and at right angles to them. The extremities of these latter beams, or joists, may extend beyond the face of the architrave and frize and support the planks or still smaller timbers, which either constitute the covering itself of the roof, or serve as a bed for the materials employed for the covering. The reason of extending the joists and covering of the roof beyond the face of the architrave, is, that the rain-water which falls on the roof, may, thereby, be thrown beyond the posts or columns, or beyond the walls of the building, if, in the intervals of the posts, walls are constructed. The projecting parts of the lower joists just mentioned, being imitated in stone buildings executed according to some of the systems or Orders, become what are called *modillons*, and the extremities of the upper course represent, perhaps, what are called *dentels*. Each of these species of projections, like the triglyphs, can, properly speaking, only appear on two fronts of any quadrangular building, unless each course consists of timbers framed at right angles to each other, as above described; but as this method is not adopted in practice, and as we find that the modillons and dentels are exhibited on every face of such buildings, we must suppose this to be a measure adopted, as before, for the sake of obtaining a similarity of ornament on every side.

The courses of modillons and dentels, together with the beams upon which those courses appear to rest, and the part of the roof above them, form what was sometimes, by the Ancients, called the *corona*, but, in modern Architecture, is called the *cornice;* and the name of corona is occasionally by Vitruvius, and always by the moderns, confined to the projecting member immediately above the modillons. The whole system of horizontal beams above the columns, comprehending the architrave, frize, and cornice, was called by the general name of *epistylium*, but in later times, the *entablature.*

When an inclining roof was to be made, (see pl. i. fig. 2.) beams, called by Vitruvius *cantherii*, and by the present Architects, *rafters*, were disposed in two planes declining each way from the columen, or ridge of the roof, which ridge extended longitudinally above the middle of the area enclosed by the building: the upper extremities of the rafters were attached to this ridge, and the lower extremities rested upon the entablature vertically over the extremities of the horizontal beams in the frize. Above these rafters were placed small timbers, called by Vitruvius *templa*, by the moderns *purlines*, in horizontal positions, and parallel to the ridge of the roof; and, over them, a second tier of rafters, smaller than the former, and projecting, at their lower extremities, beyond the face of the architrave or frize on the flanks of the building. These last rafters, in some cases, carry the tiles or other materials which cover the sloping roof; and if we may suppose them to be placed so that one rafter may be over each triglyph and metope, the projecting extremities, being imitated in the copy, will constitute what, in one of the Orders, are called *mutules*, whose inferior surfaces are in a plane parallel to the inclining surface of the roof in which they are placed. And though these also can only, with propriety, exist upon the two lateral fronts of any building, yet it has been, universally, the practice to depart so far from the model as to repeat them upon the front and rear faces of a complete edifice. The extremities of the purlines, appearing in front and rear of a building, may have suggested the idea of forming modillons in each of the inclining sides of the roof, which in some of the Orders is done; but, in practice, a deviation is made from the character of the model by placing such modillons closer together than the purlines really would be, and by forming their side faces in vertical planes instead of perpendicular to the directions of the rafters.

The desire of ornamenting the inclining extremities of the roof in a manner similar to the horizontal cornice has led, in some Orders, to the employment of dentels also in those situations; as if the inclining roof had been formed by two tiers of purlines, in alternate order with the rafters, under its external covering.

In the above developement of the Vitruvian hypothesis, it is not intended to assert that artists can, in any case, bind themselves to produce a perfect correspondence of all the members in the buildings they construct, with those of any model; but, merely, to exhibit a simple structure, the parts of which may have served as prototypes of the members we find occasionally employed in the most complex edifices.

The roof of a building, when formed by two inclined planes, was, by the Ancients, called by the general name *fastigium*. The triangular extremity of such a roof is called a *pediment*, and the space included within the horizontal and inclined cornices of the pediment had, and still retains, the name of *tympanum.*

The principal members of a finished edifice have now been compared with those of the simple hut; if we descend to the minuter parts and ornaments, we shall find that many of them may be traced to objects necessarily connected with the same prototype, and from which it is possible they may have been derived; others, by their nature, are incompatible with such an origin, and, therefore, must be considered either as imitations of some natural objects, or as improvements which would easily suggest themselves when the members were executed in a different material.

The base of a column.

It is supposed that, originally, the trunks of trees, which served as posts, might have been planted immediately upon the ground; but experience would soon show that the bottoms of the posts were liable to be destroyed by its humidity, or that the weight of the edifice would force them into it, and thus endanger the safety of the whole. An endeavour would, perhaps, be made to remedy these evils, by placing a tile or flat stone under the bottom of the post to keep it from the ground, and, by presenting a greater surface underneath, to prevent it from sinking; from this probably originated what has been since called the *plinth.* The bottom of the post being liable to split by the weight above it, may be supposed to have been protected by a hoop or cord surrounding it; and, from this, some have derived the torus and other ornaments placed above the plinth, which, with the latter, form the *base* of the column.

The capital.

Now it might happen that the tops of the posts were not exactly situated in a horizontal plane, from the inequality of the ground, or of the lengths of the posts; and, in such a case, the architrave which was placed upon them, might not touch every one. In order to remedy this, it may be supposed that flat tiles, or stones, would be placed above the posts, having their thicknesses so regulated that the under surface of the architrave, when in a horizontal position, might rest upon each. If this opinion is well founded, one of these tiles may be represented by the abacus of the column in the finished building; and ropes surrounding the tops of the posts, like those in the base, might have been the origin of the echinus, the astragal, and some other of the ornaments, which constitute what is now called the *capital* of the column. The column may, therefore, be considered as formed of three parts or members, *viz.* the base, the body or shaft, and the capital.

It must be owned, however, that bases and capitals are not, universally, the accompaniments of columns; in some edifices, we find columns without bases, in others, we find them without capitals, and there are some columns without either bases or capitals; neither do all capitals of columns resemble ropes or rings, on the contrary we find, in this member, a very great diversity of form, and the talents of artists have been particularly exerted to give it all the beauty of which it is susceptible.

Some columns have their upper extremities adorned with spiral curves, or volutes, projecting beyond the surface of the shaft, and the opinions concerning the origin of these ornaments have been various. Vitruvius asserts that they are imitations of the curls of hair about a woman's head; but later inquirers think they were derived from the curling leaves of plants, or from the horns of animals slain in sacrifice; with which a capricious taste might, on festival days, have decorated the columns of a Temple. It is difficult to say which of these ideas is the most just, and, perhaps, none of them deserve much consideration.

In other columns we find the capitals consist of two or more rows of leaves surrounding the shaft, at its upper extremity, so as to resemble very much the foliage of a plant growing round the side of a cylindrical or bell-shaped vessel. And, according to Vitruvius, it was from the casual observation of such an object, near Corinth, that the idea was first taken. This account of the origin of that particular species of capital has, however, been much controverted; and it is alleged that the representation of foliage, similarly disposed, adorned the tops of Egyptian columns before the time at which the Grecian capital is said to have been invented. However this may be, there is certainly nothing improbable in the supposition that this kind of capital, as well as that last mentioned, was derived from some such appearances.

Lastly, we find that the summits of columns are, sometimes, sculptured to represent the head of a man or woman, or the figures of animals; and we, therefore, conclude that no general type has been followed in designing this member; and that artists, in different circumstances, have chosen such forms as their tastes indicated, in order to obtain a pleasing effect.

The shaft

The shaft of the column is frequently furrowed longitudinally in channels, and various opinions have been started respecting the origin of this practice. If we listen to Vitruvius, he informs us that they were made to represent the folds of a woman's dress; and by some persons they have been supposed to represent the natural inequalities which are found in the bodies of certain trees. But it is conceivable that the stone column might be cut longitudinally in a number of plane faces preparatory to giving it the curved form, and it might easily happen, that some artist, in search of novelty, would chisel out the spaces between the angular ridges, perhaps to increase the effect of his work by the play of light and shade it would produce; and, hence, the channels may have originated. This opinion is rendered more probable by the fact that pillars of a prismatic form are found in some of the Architectural edifices of Egypt and India.

Another opinion has been started by Mr. Mitford (*Principles of Design in Architecture*, let. 7.) which, from its singularity, must not be omitted. He supposes the channellings to have been purposely made to serve as rests for the spears of the warriors, who might deposit them there previous to their entrance into the building; and he founds his opinion upon a passage in the Ist Book of the *Odyssey*, where it is said that Minerva placed her spear by the tall column within the spear-holder, in which were many others. This spear-holder he supposes to mean, one of the channels of the column; and he observes that, in the columns of one of the Temples in Ionia, (that of Minerva Polias at Priene,) the upper surface of one of the mouldings of the base has a horizontal groove surrounding the column, which seems intended to serve as a footing to receive the spears. It is urged, however, in opposition to this theory by Lord Aberdeen, (*Principles of Beauty in Grecian Architecture*, p. 114.) that the place where the spears were deposited was a large receptacle, expressly formed for the purpose, in or near the column, or in the wall of the building, where they might be more conveniently deposited than round the columns; in which situation, his lordship thinks, they must cause an impediment to the passage, and be liable to fall down. Without, however, assenting to the opinion that the channels of columns were originally made for this purpose, we may observe that it would be easy to secure the spears in their places, and prevent any impediment to the communication, by having fillets or cords to surround the column at top and bottom; and by placing the spears in an upright position in the interval of the cord and the concave surfaces of the channels. It may be added that horizontal grooves, similar to those in the bases of the columns of the Temple at Priene, are found in the bases of columns existing in some of the Gothic Cathedrals of Europe; the latter grooves certainly could not have been intended as rests for spears, and they may have been cut, both in these and in the Asiatic columns, merely for ornament. See Wild, *Lincoln Cathedral*, plate xiii.

The trunks of trees are not of equal thickness throughout their length, and this circumstance has been copied in the columns of buildings; which artists have, almost at all times, made to diminish in diameter toward the top, though they are far from being agreed, either upon the precise quantity of the diminution, or upon the form which should be assumed by a section of the column, taken in the direction of its axis.

Origin o
pilasters

In concluding the account of the origin of columns, it may be proper to observe that, occasionally, artists have employed some in the form of square prisms or frusta of Pyramids, to which the name of pilasters is given; and if it is necessary to look for the primitive type of this member also, it may easily be conceived to exist in such posts as were made by cutting the trunks of trees into one or other of those forms.

Origin o
triglyph
and gutt
the enta
blature.

Lastly, the essential ornaments of the members in the entablature of an edifice may have been derived from natural circumstances, which could not fail to afford subjects for imitation. The rain which fell upon the sloping roof would descend from its projecting extremity, would flow across the entablature, and along the columns, and would appear in drops on the under surfaces of the projecting members. This has been supposed to be represented by what are called the *guttæ*, or drops, suspended below the mutules, by the channels cut, as if for the passage of water, in the extremities of the beams which lie across the architrave, and by the guttæ which are formed below the triglyphs. It is not impossible, also, that the channellings of the columns might have been made to represent the courses of rain-water down the shaft. On the other hand, some persons consider the guttæ in the Grecian buildings as imitations of the heads of nails, which may have been driven to attach the members in which they are found to the parts of the edifice above them.

Forms
probabl
uses of
mouldi

The ornamental members about the columns and entablature of a building, which are called by the general name of *mouldings*, project beyond the surface to which they are applied, and their exterior surfaces are either curved or plane, but their particular forms and combinations have been made to depend on our perceptions of beauty, and, perhaps, on the fitness of the members for the purposes to which they are subservient. In plate ii. may be seen the forms of the different mouldings which are employed in both the Greek and Roman Architecture, either to surround the columns, or to extend along the entablature.

We have said that the principal mouldings about the columns, *viz.* the torus, astragal, and echinus, were, probably, derived from the means employed to strengthen and secure the shafts. The same reason, however, cannot be given for all the mouldings which occur either in the columns or in the entablature of the building; and, in the absence of all positive information on this subject, we are reduced to form the best conjectures which the doubtful light of ancient practice will afford. It is probable, then, that it would occur to the first builders of permanent stone edifices, that some small projecting member should mark the separation between any two of the principal parts, as between the architrave and frize; and, for this purpose, a simple *fillet* or *listel*, whose section is a square or rectangle, would serve. But, subsequently, the too frequent repetition of square mouldings, in one and the same edifice or Order, appearing disagreeable, men would naturally be led to vary the surfaces of such mouldings by giving a simple or compound curvature to their sections. Hence would arise the *torus*, *astragal*, *echinus*, *cavetto*, the two kinds of *cymatia*, and that which has been called the *bird's-beak* moulding. These mouldings being introduced, the next step taken to increase the embellishments of the Order, would be, to combine two or more convex mouldings together; and this would require the intervention of a simple fillet or a concave curved moulding, in order to prevent confusion. Such is, no doubt, the origin of the *scotia*, which is generally placed between two tori, or astragals; and, in this way, the system of mouldings constituting the base of a column is formed.

In many ancient examples, (though the practice was not universal,) we find the echinus and the cima reversa employed where a weight is to be sustained, no doubt because their form renders them fit for that purpose. The torus and astragal are well adapted for strengthening the shafts of columns, for which purpose they are used in the bases and capitals. The cavetto and the cima recta were chiefly employed to form a finish at the summit of an edifice, perhaps because their upper extremity, terminating in a thin edge, would render them improper for the purposes of support; while the same members are of importance in throwing off the rain-water, which would flow down the face of the building if it were not for the concave form of their under-surfaces. The bird's-beak moulding is that which most frequently occurs in the Greek edifices; its form is such as to permit it to be used either as a support or as a crowning member, and, accordingly, we find it employed in both circumstances, though most commonly for the former.

All the mouldings above-mentioned afford a field for the chisel of the sculptor, and the last step in the embellishment of an edifice would be, to give them the highest possible degree of ornament. The subjects chosen for this purpose are, sometimes, the figures of animals, but, generally, the leaves of plants, of which Nature presents an inexhaustible variety of beautiful specimens. The meandering ornaments and scrolls so frequently exhibited on ancient edifices are supposed to have been derived from imitations of the ruffled surface of water.

The hypothesis of Vitruvius concerning the primitive model of an edifice, and the opinion that this model was first copied in Greece, were, perhaps, universally acquiesced in till the remains of the Architectural works of the Egyptians became known in Europe. Since that time many artists, being struck with the enormous quantity of masonry employed in the walls of the Temples of Egypt, and with their ponderous roofs, supported by numerous short and massive columns, arranged in close order, have inclined to an opinion that the primitive types of those buildings were the rocks in which the first inhabitants of that Country formed their dwellings or tombs, by excavation; while, from an opinion of the superior antiquity of some of the Egyptian edifices, and from certain resemblances in the ornaments of these edifices to those of the Temples of Greece, they have concluded that the Grecian style of building is but a derivation from the Egyptian, and has no claim to originality.

Probability that the prototype of the Egyptian buildings is a hut.

There is nothing improbable in the opinion that different Tribes of men should have adopted different modes of construction for their original dwellings; and, therefore, we are far from thinking that a timber-house, of the kind before mentioned, was the origin of all the different styles of Architecture which have prevailed in the World. But, with respect to that of Egypt, the huts of the present inhabitants of that Country, which are composed of mud and reeds, built in the form of frusta of Pyramids, and which, probably, resemble those of their remotest ancestors, present, also, so great a similarity of form to the vast masses of masonry placed at the entrances to their ancient Temples, that hardly a doubt can remain concerning the original model from whence the forms of those masses have been derived. It may, perhaps, also be unnecessary to have recourse to a caverned rock for the model of the Egyptian columnar edifices, since a building which, in a burning climate, would be required only to afford shelter from the sun, and a free circulation of air, must, necessarily, consist of a number of pillars supporting a roof. Even some of the tombs that have been excavated in the rocks afford indications of a style drawn from the construction of a building raised from the ground. Above the columns which support the roof is an abacus, sometimes surmounting a capital ornamented with leaves sculptured in the stone; over the abaci is a horizontal band of stone, plain or ornamented, similar to an architrave; and, over all, in front is a projecting cornice, whose inferior surface is, sometimes, sculptured in imitation of reeds, as if disposed there horizontally for the support of the materials forming a roof.

Uncertainty of the opinion that the Grecian style is derived from the Egyptian.

The resemblances said to exist between the Egyptian and Grecian buildings, if we leave out those parts which must, necessarily, be common to all edifices, are found in the capitals of some of the columns employed in both Countries, and in a sort of frize on the faces of some of the Temples in Egypt, on which frize are sculptured, at intervals, in vertical planes, clusters of three reeds constituting an ornament which has been likened to the triglyphs in the entablatures of the buildings of Greece, and from which M. de Pau supposes the latter to have been derived. But these can hardly be considered as affording sufficient ground for establishing a dependence of one style on another; since, without any inter-communication, both people might have invented ornaments which resemble each other so faintly. And the impossibility of fixing the dates of any of the Egyptian buildings, puts it out of our power to ascertain whether those buildings in which the resemblances occur, were, or were not erected before the Greeks acquired an influence in the affairs of Egypt; after this had taken place, it is as likely that the Egyptians copied some of their ornaments from the Greeks, as that the latter should have copied from them.

Possibility of dispensing with an original model.

We have said enough, perhaps, to show that the Vitruvian hypothesis is deserving of some consideration, since it may be made the basis of an elegant system, an adherence to which might operate as a guard against any considerable deviation from propriety and good taste in the execution of a complex edifice. But it must not be understood that this hypothesis alone is capable of guiding an artist in his constructions, or of restraining the excesses of a capricious fancy; since the nature of the building to be raised, and our perceptions of beauty may be, together, sufficient to obtain these ends. In forming a portico, for example, we have to support a roof by means which may leave one or more of the sides open to the air. The roof must, therefore, be borne on columns, and between the breadth and height of these, certain proportions must subsist, which experience would soon determine for the best. The entablature might be, originally, one plain mass of stone, but it would be subsequently found more pleasing to divide its exterior surface, horizontally, into two or more parts by projecting mouldings, and to ornament the faciæ in various ways, which would produce an agreeable play of light and shadow; and lastly, the capitals of the columns may have been, originally, simple blocks broader than the shafts in order to increase the points of support under the entablature; and these would soon, by the taste of artists, be brought to the graceful forms they have since exhibited.

Supposed origin of the Chinese Architecture.

One nation only, *viz.* the Chinese, is considered as having adopted a mode of building derived from the forms of the tents in use among a pastoral people. But from the lightness of construction, which is the characteristic of that style, the buildings are not of long duration; therefore, the specimens which that Country affords are, all, of comparatively recent date; and it will be better to defer the consideration of them till we come to the period in which that style was made known to the people of Europe.

CHAPTER III.

The Invention of Architecture among the Greeks

Seats of the first Empires.

Almost as soon after the Noachian Deluge as Society could be formed, we read that Nimrod and Ashur built the cities of Babylon and Nineveh, and founded Empires in the regions of Chaldea and Assyria, along the courses of the Euphrates and Tigris. From these territories proceeded colonies to Africa, Europe, and, probably, to the more Eastern parts of Asia, all which places, in process of time, became the seats of powerful Monarchies, and the sea-coast of Syria must have been soon covered with populous cities, which, in the time of Moses and Joshua, that is, within 500 years from the Flood, were of so much importance as to be surrounded by walls, which, from their loftiness, are described as reaching to heaven. In the plains of Assyria, stone being sparingly distributed by the hand of Nature, the material employed in building was chiefly brick; and the perishable quality of this material, together with the frequent wars which desolated a territory situated between the powerful Monarchies of Egypt and Persia, will account for the entire disappearance of all the earlier Architectural works raised in that part of the World.

Situations of Babylon, Nineveh, and Ecbatana.

The city of Babylon was situated in the Delta formed by the Euphrates and the Tigris, about the thirty-second degree of North latitude. It was brought to the highest degree of its perfection by Nebuchadnezzar about six hundred years before the Christian Era; but its splendour must have been of short duration, as it was taken by Cyrus about sixty years after the death of that Monarch, and, from that time, it gradually declined. What its ancient condition was we have no means of knowing, except by the description of Herodotus. He says (*Clio*, sect. 181.) it was situated on each side of the Euphrates, and the whole formed a square, each side of which was fifteen miles long; it was divided by twenty-five parallel streets, running from North to South, and by as many, also parallel to each other, from East to West. The walls were 387 feet high, and 87 feet thick, all built of brick, and there was a quay of the same material along each side of the river, which was crossed by a bridge, formed by laying great horizontal stones over the tops of piers, built in the bed of the river. In the centre of each division was a circular space surrounded by a wall; in one of these stood the Royal Palace, whose walls were adorned with sculpture, and the Temple of Jupiter Belus occupied the other.

The ruins of this celebrated city have been lately visited by several European travellers; according to Mr. Rich, they extend on both sides of the Euphrates between Mohawil and Hellah, 48 miles from Bagdad, and consist of immense masses of brickwork, buried under earth which has been accumulating over them for Ages. The bricks obtained from these heaps bear inscriptions which have been the subjects of many learned discussions; and, recently, a large statue of a lion has been discovered among the ruins; but, as yet, it is impossible to trace the line of the ancient walls, or to ascertain, with certainty, the site of the Tower of Belus.

The city of Nineveh was of equal antiquity and, probably, of equal magnitude with the city of Babylon; it is, now, entirely destroyed; but it is supposed to have been situated on the Tigris, in about the thirty-sixth degree of North latitude, near the spot on which the city of Mosul now stands.

Ecbatana, the Capital of the Median Kings, was also a city of great magnitude, and surrounded by seven walls, rising gradually each above the next towards the interior; this, also, has been destroyed; but it is supposed to have been situated in the North of Persia, near the present town of Hamadan, in about the thirty-fourth degree of North latitude.

The Egyptian Thebes, situated near the Southern extremity of that Empire, is the most ancient city of whose buildings any remains subsist at the present time. The period of its foundation ascends, probably, to the same antiquity as that of Babylon and Nineveh. It was the first seat of the Egyptian Government, but, at an early period of the History of the World, that seat was transferred to Memphis, near the Northern extremity of the Empire. From this time its importance declined; but the imperishable nature of the materials, the dryness of the climate, and the immensity of the masses, have preserved the buildings through all the vicissitudes of three thousand years. Memphis, less fortunately situated, by being nearer the line of communication between Asia and Africa, has been more subject to the destructive caprices of Man, and has disappeared from the face of the Earth, so that its situation is entirely unknown. The Pyramids, however, which were in its vicinity, still exist.

About fifteen hundred years before the Christian Era, colonies from Syria extended themselves to the Countries bordering the Archipelago, and brought the Science of Legislation, and the Art of building to those uncivilized lands. From this time we may, perhaps, date the origin of the principal cities of Greece, though the existing remains of their purest Architecture belonged to edifices erected a thousand years later. The cities of Asia Minor, Sicily, and Italy were probably founded between the years 1000 and 700 before Christ; and, both in these and in the cities of Greece, are displayed the first monuments of a school of Architecture which, subsequently, prevailed throughout the civilized World, till the Arts and Sciences fell with the Roman Empire, and which, after a long sleep, revived in the XVth century; since that time it has extended itself over Europe, and, till very lately, it formed, exclusively, the style of the artists of this quarter of the World.

In Syria, the city of Jerusalem is yet known by its ancient name; its prosperity was at the highest point in the days of Solomon, about nine hundred and ninety years before Christ; at which time it contained a splendid Temple dedicated to the true God. The cities of Balbec and Palmyra, in the same part of Asia, must have been considerable at a very early period; but the ruins at present existing on their site, and those more recently discovered near the Jordan, belong to the time of the Roman power in that region.

Persepolis, situated further Eastward, still presents some ruins, the date of which is referred to the time of Cambyses, though the city itself is probably much more ancient.

In India, two cities of great antiquity once existed, viz. Canouge and Palibothra,* (if these names were not both given to the same place.) The former was situated on the Ganges, according both to Strabo and Arrian; who add, also, that its form was quadrangular, its length 80 stadia, perhaps about 8 miles, and its breadth 15 stadia, or 1½ mile. According to the Poem *Mahabbarit*, it was founded about one thousand years before Christ, but we know nothing of its buildings.

Since the Architecture of Egypt is commonly considered as more ancient than that of Greece, it would seem that we ought to proceed, immediately, to exhibit the character of the former in the remains of the ancient Temples and Tombs of that Country. We prefer, however, to begin with the Architecture of Greece, because, in the latter Country, from a few simple and cognizable principles, the Art grew up into a perfect system, which has stood the test of more than twenty-five centuries; and, with some exceptions and modifications, constitutes the Architecture of Europe at the present day. With this, as a standard, we are accustomed to compare both the Egyptian and Roman styles of Architecture; and without an accurate knowledge of the dispositions and proportions of the different members which compose the Grecian system, the others cannot be conveniently described, nor easily understood.

Cadmus probably first induced the people of Greece to build their habitations near each other, and to surround them by walls for the purposes of defence; and thus their earliest cities were formed. Near Argos are still to be seen the remains of the walls of Tirynthus, which, probably, formed a military post or citadel for the protection of that part of the Country. The construction of these walls must be referred to a very early date, though the precise time is unknown; according, however, to the testimony of Strabo and Pausanias, they were erected at a period which must have preceded the Trojan war, and by a people who had emigrated from Lycia. In common with several other works of a similar nature yet remaining in Greece, they were by the people considered as a work of the Cyclopes; a Tribe which is supposed to have arrived there from Thrace, and to have founded colonies in the Country. The stones of which the walls are composed are rudely shaped and placed together; and passing through the wall there is a gallery formed of stones laid in horizontal courses, but projecting over each other, so that the sides approach together at the top, and a vertical section of the gallery is of a triangular form.

The Treasury of Atreus at Mycenæ.

In those times the lawless character of the people, or the danger of being surprised by invading enemies, rendered it necessary to construct strong places for the purpose of securing the wealth of the Prince or of the State. The earliest of these buildings seems to have been erected at Orchomenos by Minyas, a King in Bœotia; and it is described by Pausanias (*Bœotica*, c. 38.) as one of the most wonderful productions of Grecian Art. But the most interesting to us, because it remains in a tolerable state of preservation, is the subterranean chamber at Mycenæ, which is called the Treasury of Atreus. This also is mentioned by Pausanias. (*Argolica*, c. 17.) The entrance to the chamber is by a passage 20 feet 6 inches wide, between two parallel walls, the remains of which are about 50 feet long; this passage is open to the sky; and, at its extremity, is the entrance, which forms a gallery 18 feet long and 8 feet wide, covered by flat stones; but having above them a triangular arch, if it may be so called, consisting of horizontal courses of stones, like those in the gallery at Tirynthus before described, and probably intended to lessen the pressure of the horizontal ceiling of the gallery. At the extremity of this gallery is the chamber, which is of a circular form, and 48 feet 6 inches diameter; the walls are formed of circular courses of stones laid horizontally on each other; each course projecting towards the interior, beyond the course below, till they meet in an apex over the centre; thus producing a resemblance to the inside of a dome. The height of the chamber is 45 feet; and a section taken vertically through the centre forms nearly a parabola, or rather two segments of circles rising perpendicularly from the pavement and meeting nearly in a point at the top. The interior projections of the stones have been cut to form a smooth surface, but there is a little irregularity in one part, probably caused by some accidental displacement of the materials. The whole of the internal surface appears to have been lined with plates of bronze.

On one side of the circular apartment is a square chamber 27 feet long and 23 feet wide; and between the chambers is a communication through a narrow passage formed in a manner similar to the gallery before mentioned. There are several subterranean chambers, similar to this, near the same place, and the Treasury at Orchomenos, mentioned above, appears from Pausanias to have been of similar form; many similar buildings also exist in Egypt, Sicily, and Italy.

About the chamber at Mycenæ are scattered many heterogeneous enrichments which appear to have belonged to the building; and from these Mr. Donaldson has given, in the *Supplement* to Stuart's *Antiquities of Athens*, a design for the restoration of the façade at the entrance of the building. The exterior of the wall, which is shown in pl. i. fig. 3., appears to have been faced with red, white, and green marbles, embellished with zig zags and scrolls; a species of ornament which is frequent on the fragments of ceramic vases found

---

* See Col. Francklin's learned *Inquiry concerning the Site* of this City.

about the same place; and the holes for the cramps by which the marbles were attached to the wall are still visible. On each side of the door-way, he supposes a column to have been placed, the form and ornaments of which he has made out from a base and part of a shaft discovered among the ruins. See pl. i. fig. 4.

Walls of Mycenæ.

On that side of Mycenæ which is opposite the Treasury of Atreus, remain what appear to be parts of the ancient walls of the city, and which, according to popular tradition, formed part of the Palace of Agamemnon. The entrance is by an aperture similar to that of the Treasury of Atreus, being formed by two vertical jambs and a horizontal lintel, rudely executed. Above this is a piece of sculpture representing two lions, each about ten feet high; one on each side of a short column, with their fore feet placed on a sort of pedestal. From these figures, the aperture has obtained the name of the Gate of the Lions. This gateway is mentioned by Pausanias, (*Argolica*, c. 17.) who also states that in his day it was reported to be a work of the Cyclopes.

The supposed origin of Temples.

The notices we have of the earliest Temples in Greece or Asia are so few and unsatisfactory that what can be said of them may be delivered in a few words. The Sacerdotal office, which at first was possessed by the father of each family, became, in some Countries, by the establishment of a Monarchical Government, vested in the Prince; and where this happened, there is reason to believe that some division of the Regal Palace was set apart for the offices of Religion. But when, subsequently, a regular Order of Priests was formed, it would no doubt be found convenient to have places expressly appointed for performing the sacrifices; and therefore Temples would be erected.

Before the time of Homer there were few Temples in Greece. Those he mentions are of Minerva at Athens, Apollo at Delphi, and Neptune at Ægæ. He often represents sacrifices performed on altars in the open air; and it is plain from the terms which he employs that the Fanes of Minerva and of Apollo were roofless. That Temples existed on the Asiatic coast before his time is certain, for Hecuba is described by him as leading a procession of matrons to the Temple of Minerva in the city of Troy, in order to propitiate the Goddess.

The Palaces of Priam

From the description, in the *Iliad*, of King Priam's Palace, we may obtain some idea of the public buildings in that part of Asia about Homer's time. This edifice is stated by him to have been built of stone, and to have consisted of a court surrounded by apartments; of which there were fifty on one side for his sons, and twelve opposite them for his daughters and their husbands; besides these, there were the apartments occupied by the Monarch himself.

and Ulysses.

From what we can collect, in the *Odyssey*, of the Palace of Ulysses, its plan does not seem to have been very different from that of King Priam's Palace. It appears to have consisted of an αὐλὴ, which, from the derivation of the word, may be concluded to be a court without a roof; this was surrounded by the apartments, some of which must have been formed with a lower and an upper story; for Penelope occupied the upper rooms in one part of the house, and the armoury was up stairs in another part. But it is probable that in some places the house might have consisted only of a ground-floor; for Minerva, in the shape of a bird, placed herself upon a rafter or beam, and beheld from it the destruction of the suitors; therefore, there could have been no ceiling in this part between the pavement of the room, which was on the ground-floor, and the roof; the latter was, probably, formed of rafters resting on the walls, and meeting in a ridge or point at top. Columns are mentioned by Homer, as having a place in this building; but it is remarked by Lord Aberdeen, that he makes no allusion to their beauty; it is therefore probable that they were nothing more than wooden posts; and as a cable was stretched between them and the wall, for the purpose of executing the guilty attendants of Penelope, (*Odyssey*, book xxii.) we may infer that they surrounded the central part of the aula, or court, at a distance from the walls. Mr. Gwilt, in an interesting Essay prefixed to his edition of Sir William Chambers's *Architecture*, infers, from the epithet sonorous, applied by Homer to the 'Αιθούσα, or passage between the columns and the walls, that it was covered by a roof.

It has been observed that the *Odyssey* was composed at a later period than the *Iliad;* and therefore the description just given may not apply correctly to the style of building employed at the time of the Trojan war. It is not, however, likely that the interval between the times of composing the two Works was considerable, and it is evident that the character of the building is such as prevailed among the Greeks at a very early period, which is all that it is necessary to show.

In the buildings consisting of open courts surrounded by apartments, we see also the first examples of a ground-plan, which has been ever since practised very generally for the dwellings both of Princes and private individuals of rank, in the whole extent of Europe and Asia; from Spain to China.

Flat an
ridge r
in use i
time of
Homer.

The roofs of houses in the Homeric times were sometimes formed by two or more inclined planes, meeting in a ridge or point above; as we have seen reason to believe from the description of the Palace of Ulysses, and as may be shown from a passage in the *Iliad*, in which two men wrestling are compared to two beams in the roof of a house. But it is also evident that in some cases the roofs were flat; of which the Palace of Circe affords an example, since Elpenor, one of the companions of Ulysses, was killed by falling from it.

Flat r
were g
ral in t
East a
that ti

At a time more ancient than that of Homer's heroes, we learn that the houses in the East were built with flat roofs; for, in the Book of *Deuteronomy*, the people of Israel are commanded to surround the roofs of their houses by a rail or parapet, to prevent any person from falling off. And since, in all Ages, in that part of the World, there has been little variety of fashion in houses, furniture, and dress, and the manners and customs of the people are nearly the same now as in the time of Moses, we may safely conclude that manner of building was then, as it is at present, general both in Syria and Egypt. To these terraces there was an ascent by steps on the outside of the house, and the fineness of the climate permitted the inhabitants to use them for the purpose of repose as well as of exercise.

The A
tectur
Greec
known
the lo
migrat

From the war of Troy till the time of the Ionian migration, a period of about a century and a half, little is known of the state of Architecture in Greece. Vitruvius, indeed, says, (chap. i. book iv.) that a Temple, dedicated to Juno, was erected at Argos during the reign of Dorus, the son of Hellenus, which must have been more than twelve hundred years before Christ: he states that it was built according to the Order, since called the Doric, and he asserts that the same Order was, subsequently, used in the other cities of Greece. He admits that the proportions of the Order, meaning, no doubt, the relations between the dimensions of the different parts of the columns and entablatures, were not then reduced to any system; we must, therefore, suppose that the Greeks, at that time, had no fixed principles to guide them in the construction of their buildings.

Whatever progress the Greeks might have made in civilization and Art during that period, it seems certain that it was arrested by the return of the Heraclidæ to Peloponnesus. This people, driving from their dwellings the inhabitants of a considerable part of the Country, and maintaining a sanguinary warfare with those who remained, so much unsettled the minds of men that no leisure could be found for cultivating the Arts of Peace.

neral ions Doric first hed

While the political affairs of Greece were in this perturbed state, a Body of adventurers from it, under the command of Ion, the son of Xuthus, colonized that part of Asia which was before inhabited by the Carians and Leleges. Then it was, as Vitruvius asserts, that the Temple of Apollo Panionios was erected by the colonists in a manner resembling the Temples of Greece. These persons, being ignorant of the proportions which the columns should have, in order to support the roof, conceived the idea of making them correspond to the dimensions of the figure of a man; the height of which is about six times its breadth. They, accordingly, made the diameter of the column, at its foot, equal to one-sixth of its whole length; and the system, or Order, which received those proportions, they are said to have called the Doric, because it had been first used in the cities of the Dorians; by which name, at that time, probably, all the Greeks who lived to the North of the Gulf of Corinth were called; and, perhaps, also, to distinguish it from another system or Order which, Vitruvius says, was invented or used by Ion himself, and, on that account, called the Ionic Order.

In establishing the proportions of this latter Order, Vitruvius asserts, that the inventor copied the dimensions of the figure of a matron, which is, in general, more slender than that of a man; and he gave to the diameter of this kind of column, at its base, one-eighth of its whole length, by which it assumes a more graceful appearance than the other. Vitruvius goes on to state that the ornamental parts about the Ionic column were intended for resemblances to different parts of the dress of a woman. Thus the mouldings of the base were intended to represent the shoe; the volutes of the capital, to represent tresses of hair curling on the right and left of the head; and the channels of the shafts, to represent the folds of the garments.

If we may give credit again to Vitruvius, a third Order was subsequently invented, by a sculptor named Callimachus, who is said to have lived about the end of the Peloponnesian war. This Order was, afterward, called the Corinthian, and it has been supposed that the artist, wishing to give to his columns more delicacy than was possessed by those of the Ionic Order, adopted the proportions observed in the figures of young women. Vitruvius, however, does not determine what part of the whole length of the column is equal to the diameter, and, in all probability, the practice of different artists was very various. The circumstance from which the capital of this Order originated, has already been alluded to, and the following tale concerning it is stated by Vitruvius from report. He says that a young woman of Corinth, being just marriageable, was seized with a disorder, and died; after her interment, her nurse collected in a basket the toys which pleased her when alive, placed the whole over her grave, and covered them with a tile. The basket happened to be placed over the root of an acanthus, which, afterwards, grew up round its exterior, and curled under the angles of the tile. This being observed by Callimachus, he took from it the idea of the capital of a column; and, whatever we may think of this story, there is certainly no improbability in the supposition that the ornament in question was derived from the appearance of some plant encircling a vase.

The Greeks invented an Architecture founded on proportions.

When we contemplate the account which Vitruvius has given of the origin of these Orders, we cannot avoid recognising, in some parts of it, the liveliness of imagination which has always characterised the Greeks; and, while we suffer ourselves to be amused by the circumstances he relates, we are cautious of considering them as entitled to implicit confidence.

It will, however, be hardly fair to refuse our assent entirely to the general facts, whatever we may think of the particular circumstances; for, among a people so exquisitely refined as the ancient Greeks, it is highly probable that an imitation of natural objects would be adopted, both for the purposes of ornament, and to establish a system of proportions, by which the magnitudes and dispositions of the members of their edifices might be determined. This imitation was at first, no doubt, rude, but by the liberty which that people took of altering the proportions according to the dictates of an improving taste, their Architecture finally acquired that degree of perfection in which it has been transmitted to the present times.

The Egyptian Architecture was not reduced to a system.

The architectural works of the Egyptians, as well as those of the Greeks, bear the marks of a very remote period; and, if we consider only the probable ages of some particular edifices, the claim of even superior antiquity may, by some, be decided in favour of the former people; but, if we consider Architecture as an Art founded on a system of proportions, we think there can be little doubt that the Greeks are really the inventors of that Art; since, as is observed by a French writer, among the other people, there is not found any expression of the characters of edifices by those variations in the proportions which constitute the different Orders of Architecture. The Egyptians employed columns in their buildings at a period, at least, as early as those of the oldest recorded in the descriptions of Greece; and, long before the time of the supposed invention of the Corinthian capital, there existed columns in Egypt, the heads of which were ornamented with sculptured leaves of the palm or lotus. But in the Grecian edifices, the principal ornaments are always, respectively, made to accompany one particular Order, which differs in the proportions of its parts from another Order; while, of the Egyptian works, there is nothing, in the proportions, by which we may distinguish either the columns or entablature of a building in which certain ornaments exist, from those in which they do not so.

Opinion that the Greeks might have modified the Egyptian Architecture

The intercourse between Egypt and Greece became general about the year 679 before Christ, when the 1st Psammeticus entered into an alliance with the Greeks, in order to be supported by them on his throne. And it is an opinion, entertained by some persons, that the existing examples of Egypt were executed, or restored, by Grecian artists at the time that this intercourse subsisted between the two Countries. We are far, however, from thinking that this opinion is well founded, because, on account of the extreme veneration entertained by the Egyptians for every object connected with their Religion, they never suffered any but their Priests, or persons subordinate to them, to perform any of the services required about their sacred edifices; it is not likely, therefore, that foreigners would be allowed to change the style of their Architecture.

CHAPTER IV.

Description of the Grecian Doric Temples.

Temples are, in general, the most ancient buildings remaining.

In Greece, as well as in Egypt, nearly all the most ancient specimens of regular Architecture, yet remaining, are the Temples which were consecrated to the Gods. These, being constructed with great solidity, and not subject to the mutations which affect buildings intended for domestic purposes, might be expected to survive all such edifices; and, as they possess, at the same time, a simplicity of character which causes their form to approach very near to what is supposed to have been that of the primitive model, it will be proper, in describing the Grecian buildings, to begin with the Temples. This we purpose to do after having stated the different denominations which, according to Vitruvius, were assigned to them, on account of the disposition and number of the columns employed.

General plan of the ancient Temples.

The Greek Temples were, almost universally, rectangular, only one or two examples remaining of a circular or polygonal form, though, no doubt, many such existed formerly. These, however, were small, in some cases the building consisted merely of a row of columns, disposed on the circumference of a circle, and covered by a roof; in others, a space was enclosed by a cylindrical wall, covered by a roof, which projected beyond the wall, and was supported by a circular range of columns. These Temples were said to be *monopteral.*

The plan of the generality of the rectangular Temples in Greece and her colonies was a simple parallelogram, a form which also prevailed in the Temples of Egypt. In some of the smaller Temples a row of columns was placed in front; but, in most cases, there was a row both in front and rear. And the superior Temples were, generally, surrounded by one, or even two ranges of columns. The Temple was divided into two or more parts; in the front, and, sometimes, in the rear face was formed a porch; beyond this, or between the two, was the *naos*, or body of the building, into which the worshippers were admitted; and, at one extremity, separated from it by a wall, was, sometimes, an apartment called *opisthodomus*, to contain the treasures of the Temple or of the State, and into which the Priest, or the chief Magistrates only, were allowed to enter. The porch in front was called *pronaos*, and that in the rear, *posticos*. The interior of the naos was without ornament, and, generally, received its light from the door only, or, perhaps, from openings formed in the roof; though, in some cases, windows were formed in the walls.

The roofs of the rectangular Temples were formed in two inclined planes, extending from front to rear, meeting in a ridge over the middle, and forming a triangular pediment at each extremity. Above the walls, at the angles of the building, are generally placed *acroteria*, or pedestals, which rise through the roof to about the level of the centre of the tympanum. On the upper surface of each of these pedestals a square place is sunk, probably for the reception of some figure which might be intended to ornament the roof.

The simplest form of the rectangular Temple was that in which the two side walls were carried out from the naos, to form the porch before mentioned, at one or both extremities of the building. These projecting walls were terminated on the front, or on both faces of the building, by pilasters, which, thus situated, were called *antæ;* and, hence, this kind of Temple was said to be *in antis.* Between the pilasters in front were placed two or more columns which, with the pilasters, supported the entablature.

Distinct of Temp accordin the posi of the column

When columns were placed at one extremity of the building, in advance of the line joining the antæ, the Temple was said to be *prostyle;* the entablature was placed over the front columns, and returned on the right and left as far as the antæ, or, perhaps, quite along the sides of the building. If columns were placed, in a similar way, at both extremities of the building, it was said to be *amphiprostyle.*

A Temple having columns entirely surrounding the walls was called *peripteral;* in which kind of Temple a space equal to an intercolumniation, that is, to the distance between two columns, is supposed by Vitruvius to be left between the columns and each of the side walls of the naos; to which spaces the Greeks gave the name of *pteromata.* When the exterior of a Temple was not surrounded by a peristyle or colonnade, the Temple was said to be *apteral.*

A Temple was of the kind called *dipteral*, when it had two ranges of columns resting on the pavement, and entirely surrounding the naos. When there were two rows of columns in front and rear, and only a single row on each flank, the temple was said to be *pseudodipteral.* In this case, a space equal to the extent of two intercolumniations existed between each of the side walls and the columns.

A Temple was called *Hypæthral* when it had a row of columns in the interior at some distance from each of the four walls. The space between the walls and the columns may, in some cases, have been covered by a roof, but the central space enclosed by the columns had none. Hypæthral Temples being those of the greatest magnitude, had, generally, a double range of columns surrounding the naos on the exterior; and they are supposed by some to have been mostly, if not always, dedicated to Jupiter; but this is very doubtful.

Distinct of Tem accordin the inte lumniati

Vitruvius, in the IId Chapter of his IIId Book, distinguishes Temples according to the magnitudes of the intervals of the columns; thus a Temple is said to be *pycnostyle* when the interval between the nearest sides of the columns is equal to once and a half the diameter of the column. It is said to be *systyle*, when that interval is equal to two diameters. But he considers both these kinds as inconvenient, because persons entering the Temple arm in arm cannot pass between the columns.

The next kind is called *eustyle*, in which the intervals were equal to two diameters and a quarter, or two and a half, except one interval, *viz.* that in the middle of the front and rear faces, which was a little greater. This kind he considers as uniting beauty, convenience, and strength.

Another kind was called *diastyle*, in which the intercolumniation is equal to three diameters; he considers this as, in general, too wide, since the architrave, if made of stone, was liable to break.

Lastly, the kind called *aræostyle* has the columns placed at considerable, but undetermined intervals from each other; the entablature is supposed to be formed of timber, and, where this disposition is employed, the whole edifice is made low and broad.

It may also be observed, that Temples were distinguished according to the number of columns they had in front; thus we read of *tetrastyle*, *hexastyle*, *octastyle*, and *decastyle* Temples, which denominations were, respectively, applied to them according as they had four, six, eight, or ten columns in front.

We proceed next to give a concise description of some of the principal Temples in Greece and its ancient colonies, and to state their general dimensions, in order to afford data for determining the characters and proportions of the several Orders of Architecture employed in the edifices of those Countries. And, as the existing specimens of the Doric Order are the most ancient, we begin with them. The dimensions are expressed in English feet, decimally divided, for the sake of comparing them together with facility; in the VIIth Chapter is given a general Table, in the same measure, of the dimensions of the columns and entablatures; and in plates iii., iv., and v., are elevations of the same columns, showing the proportions of their several members. In the plates, the lines of numbers marked H, express the heights of the members individually, and those marked P, their projections from the axis of the column. Agreeably to the general practice, the module, or lower diameter of the shaft of each column, is supposed to be divided into sixty equal parts, called minutes, and the integers in the lines of numbers are of that denomination.

Probably, one of the earliest Temples the remains of which are still to be seen is that at Corinth. It is of the Doric Order, and the proportions of the members of its columns seem to show that it must have been erected before Architecture had acquired that perfection which distinguished the Athenian buildings of the time of Pericles. The disposition of the columns which are yet standing have led the authors of the *Antiquities of Athens* to believe that the Temple must have been of the kind called peripteral and hexastyle. Its form seems to have been rectangular, and, measuring on the exterior of all the columns, it must have been about 160 feet long and 109 feet wide. The columns are 23.7 feet high, from the foot of the shaft to the top of the capital, and the diameter, at bottom, is 5.83 feet; consequently, the whole height of the column is equal to 4.06 diameters, which makes the ratio of the diameter to that height greater in this than in any other of the Greek examples. The diminution, or difference of the diameters at the top and bottom of the shaft, is nearly equal to one-quarter of the lower diameter, and the difference of the two semidiameters is $\frac{1}{30}$ of the height of the shaft.

The capital consists of an abacus and echinus with three rectangular fillets surrounding the column under the latter member. A little below the fillets are three channels cut round the column, forming a separation between the main body of the shaft and what is called the *hypotrachelion*, or that part immediately below the capital. The shaft, which consists of but one block of stone, is cut longitudinally by twenty channels or flutes, each of which forms, on the plan, a segment of a circle whose radius is equal to the breadth of the channel. These channels extend from the foot of the column to the fillets under the echinus.

The frize and cornice are entirely gone, but part of the architrave remains; the height of this member of the entablature is 4.722 feet, or about one-fifth of the height of the column, and its face is in a vertical plane, which, if produced downward, would fall a little within the foot of the column. The distance between the centres of the columns is 13.5 feet, and the intercolumniation, or distance between the nearest sides, is 7.67 feet, or nearly 1⅓ diameter.

The Temple at Ægina.

The Temple of Jupiter Panhellenius at Ægina seems to be of equal antiquity, though it is impossible to assign a date to either. It is, however, observed by Lord Aberdeen that, as the State of Ægina fell into obscurity almost immediately after the Persian invasion of Greece, it is unlikely that such a building would have been erected subsequently to that period. The Temple, which was of a rectangular form, of the Doric Order, and peripteral, was 90.5 feet long and 41.5 feet wide, measuring on a line circumscribing all the columns. According to Dr. Chandler, it had six columns at each extremity and twelve on each flank, including the extreme columns, with two columns between the antæ. The Temple itself was divided into three parts, forming a pronaos, naos, and posticos, and is supposed to have been hypæthral, as three columns are yet to be seen which must have belonged to the interior. The height of each of the exterior columns is 15.796 feet, and the diameter, at bottom, is 2.927 feet, so that the whole height of the column is equal to 5.397 times its diameter; the difference of the two diameters is nearly equal to one-quarter of the lower diameter, and the difference of the semidiameters is $\frac{1}{38}$ of the height of the shaft. The architraves and frizes of the entablature remain, but the cornice is wanting; the height of each of the former members is nearly equal to 2.5 feet, or to one-sixth of the height of the column.

When the Greeks colonized Sicily, about 650 years before Christ, they carried with them the principles of their Architecture; and within a period of 250 years, during which time the States they founded enjoyed an independent existence, several Temples of the Doric Order were erected, the ruins of which yet subsist. To this island, therefore, we must look for other specimens of that Order, whose execution may be referred to an early Age.

The great Temple at Selinus.

The ruins of Selinus occupy two hills and the valley between them. On the Eastern hill are the remains of three Temples lying nearly in one direction, *viz.* from North to South; of these the first appears to have been one of the largest of the sacred structures of antiquity, and is, therefore, supposed to have been dedicated to Jupiter Olympius. It was octastyle, with seventeen columns on each flank, pseudodipteral, and probably hypæthral. The plan was rectangular, and the building was raised on a *stereobata*, or basement, the sides of which were formed in three steps surrounding the whole. Its length was 331 feet and breadth 161 feet, measured on the upper step and on a line circumscribing all the exterior columns. The breadth of the body of the Temple within the walls was 67.25 feet, and its length was probably about three times its breadth. The pronaos and posticos were, each, about 65 feet long; the walls of both were terminated by antæ pilasters, between which were two columns; and before the pronaos was a portico having four columns in front, with one between each of the extreme columns and the antæ. Three entrances conducted from the pronaos to the cella which was divided into three parts, longitudinally, by two rows of Doric columns, eleven in each row, at the distance of 20 feet from the walls.

The height of the columns surrounding the Temple is 48.583 feet, including the capital, and the diameter at the bottom of the shaft is 10.625 feet, so that the height of the column is equal to about 4.5 diameters; the difference of the upper and lower diameter is $\frac{1}{3.5}$ of the latter, and the difference of the semidiameters is $\frac{1}{30.28}$ of the length of the shaft; a greater diminution than is found in any other example with which we are acquainted. The flutings on the shaft are shallow, and there is a narrow, longitudinal fillet between them; and a narrow groove is cut round the shaft immediately below the fillets of the echinus. The faces of the architrave and of the metopes in the frize are in a vertical plane, which, if produced, would fall about the middle of the face of the shaft; and the faces of the triglyphs project beyond that of the frize. A plain course of stone lies above the corona, and the entablature is crowned by a pediment the inclining sides of which are also formed of two plain courses of masonry.

The heights of the architrave and frize are, nearly, equal to each other, and that of the cornice is about one-half of each. The height of the whole entablature is 21.76 feet, which is about $\frac{1}{2.23}$ of the height of the column.

The central Temple is 200 feet Southward of the former, and the third is 154 feet Southward of the last; both of them are hexastyle and peripteral, but the former has fourteen columns on each flank, and the latter, fifteen. The pronaos, or vestibule, of the central Temple seems to have been enclosed by bronze gates or doors, as the grooves in which they turned are still visible.

On the Western hill, which is supposed to have been the Acropolis, are the remains of a wall, nearly a mile in circuit, and enclosing a space covered with the ruins of buildings, among which, the remains of three Temples have been made out. All the six Temples are of the Doric Order, built of limestone covered with fine plaster, and several members of their entablatures have been painted. The Architecture and sculpture of these Temples have been beautifully illustrated by Messrs. Angell and Evans in their recent publication on the sculptured metopes in the ruins of Selinus.

The Temple at Ægesta.

At Ægesta, or Segesta, are the remains of a Temple 190 feet long and 76.7 feet wide, measured on the upper step as before. This was hexastyle, amphiprostyle, and peripteral, with fourteen columns on each flank, and two columns between the antæ both of the pronaos and posticos. Each column is 30.096 feet high, and the bottom diameter is 6.6 feet; consequently the height of the column is equal to 4.56 diameters. The shafts of these columns are entirely plain, and a groove is cut round them at the foot, either to produce a dark shadow, or to serve for the reception of bronze ornaments which might be occasionally fixed on. The height of the whole entablature is 14.77 feet, which is $\frac{1}{2.04}$ of the height of the columns; the faces of the architrave and of the metopes in the frize are in a plane, which, if produced, would pass through the middle of the front of the shaft; and the faces of the triglyphs project beyond that of the frize. In the vertical face of each step on the four sides of the stereobata is a row of small blocks of stone, and a horizontal groove is cut along the bottom of the same face.

The Te
of Mine
at Syra

The Temple of Minerva at Syracuse is 182 feet long and 74 feet wide, measured also on the upper step, and has the same characters as the Temple last mentioned; the height of the columns surrounding it is 28.667 feet, including the capital, and the bottom diameter is 6.503 feet.

The columns of this Temple are remarkable for standing on a plinth, which is not the case in any other example of the Grecian Doric Order. The columns of the pronaos are still further remarkable in being thicker than those which surround the building, in having an astragal under the echinus, and a base, consisting of two astragals on a low plinth, with a fillet above; circumstances which have led to an opinion, that though this Temple is, undoubtedly, one of the most ancient in Sicily, these columns must have been set up subsequently to the construction of the rest of the building.

Templ
Agrig

At Agrigentum are the remains of two Temples, nearly similar to each other, and nearly of the same size, of which one is dedicated to Juno Lucina, and the other to Concord. Both are hexastyle, peripteral, and amphiprostyle, with thirteen columns in each flank. The length of the Temple of Juno is 124 feet, and its breadth 57 feet, measuring on the upper step. The height of the columns is 20.833 feet, and their lower diameter is 4.508 feet; the architrave and frize remain, but the cornice is wanting. In the stereobata of this Temple is a doorway leading to a subterranean gallery, communicating with the interior of the edifice.

The Temple of Concord is smaller than the other, its length being 93.75 feet, and breadth 31 feet. An entablature surrounds the walls of the cella, in the frise of which are triglyphs, and the cornice above them is crowned by a cavetto. But the most remarkable circumstance is, that there are no mouldings on the horizontal corona, nor on the sloping sides of the pediment. The height of the columns is 21.51 feet, and the lower diameter 6.42 feet.

At the same place was, formerly, a Temple dedicated to Jupiter, which must have been of vast magnitude; according to Diodorus it was 340 feet long, 60 feet broad, (probably 160 feet,) and 120 feet high. Instead of having pteromata, or walks, round the exterior of the body of the Temple, the walls seem to have been built between the exterior columns, so that half of each column projected beyond the face of the wall. The semicircumference of each column was equal to 20 feet, and the flutings were so large that a man could stand in one.

The T
at P

At Pæstum, on the Gulf of Salerno, in Italy, are the remains of two Temples of the Doric order, which, though, in their general features, resembling the style of the Sicilian Temples, yet, in some points, appear to approach the forms which characterised the later examples of the Grecian school. The author of the *Antiquities of Magna Græcia* even supposes that they may be of an Age subsequent to the Roman conquest of the Country; the Roman style, he observes, seeming to predominate over the borrowed features of the Grecian. A certain sentiment, however, which is perceptible in the designs, and the quality of the workmanship, affords indubitable proof that they are of a very ancient date; and we endeavour to account for the variations found in their style from that of other buildings of high antiquity, by supposing the artists of a Grecian colony to have been influenced by a capricious taste, which may have led them to deviate from the general practice of their masters in the mother Country.

The first is an hypæthral edifice 195 feet long, and 79 feet broad, measured on the top of the stylobata which supports it; it is hexastyle and peripteral, with fourteen columns on each flank, and in the thickness of the wall between the naos and pronaos, are steps formed for the purpose of ascending to the roof, or to the upper gallery of the naos; this gallery was supported by fourteen columns in the interior, seven on each side, at 8 feet from the walls, and above these is a plain entablature which supports an upper tier of columns of the same Order. Those of the exterior peristyle are 29.952 feet high, including the capitals, and the bottom diameter is 7.66 feet. The extreme triglyphs on each face are placed at the angles of the frize, as in all the ancient Grecian examples; but they project in front of the frize, which, as well as the architrave, is in a vertical plane passing through the face of the hypotrachelion. There are also triglyphs on the walls of the body of the Temple, and the ceiling of the pteromata coincided with the under surface of the inclining roof. The sides of the pediment are plain, and without an *epitithedas* or crowning moulding.

The second Temple is hexastyle and peripteral with thirteen columns in each flank; its length is 107.33 feet, and its breadth 47 feet, measured on the upper step. The pronaos is open on three sides, with four columns in front, and one on each side between those front columns and the pilasters of the naos; but the posticos is closed by a wall in front, as if intended to serve for an opisthodomus or sanctuary. The height of the columns is 20.354 feet, and the bottom diameter is 4.244 feet.

Instead of the annulets under the echinus, which, in almost every instance, occur in the Grecian Doric examples, there is here formed, at the top of the shaft, a sort of scotia; on the concave surface of which is sculptured round the column, a row of leaves whose tops incline forward, as if pressed down by the weight of the capital which they support; the echinus being placed immediately above them like a vase on the top of a plant. The face of the architrave is vertically over the middle of the shaft, and the extreme triglyphs have their centres corresponding with the axes of the columns; whereas, in every other ancient Grecian example, one of the vertical sides is in coincidence with the angle of the frize. This Temple is further remarkable for having no mutules in the cornice, and for the soffit of the corona being formed into rectangular *lacunaria*, or sunk panels, three deep.

The columns of the pronaos are shorter than those of the peristyles, and they have small bases, consisting of an astragal and fillet. There are triglyphs in the entablature of the pronaos, and the top of its cornice is on a level with the under side of the architrave of the peristyle.

At the same place are the ruins of what has been taken for a third Temple, and in the *Antiquities of Magna Græcia* it is described as such; we are, however, informed by artists who have recently visited this spot, that there are no traces of the walls of a cella to be found within the peristyle; and it is therefore probable that the edifice has been merely an open portico. On this account we think it right to give the description in another place.

As we endeavour to describe the Grecian Doric Temples according to their antiquity, we are brought, in the next place, to those of Athens, which are universally considered as affording the best specimens of the Architecture of the Grecian school. A full description of these celebrated buildings is contained in Stuart's *Antiquities of Athens*, and particularly in an augmented edition of that Work, with a supplementary volume, just published. In this Work, the joint production of several distinguished Architects, numerous mistakes, into which the author had fallen, are corrected, and the subjects are enriched with copious and learned notes.

The Temple of Theseus at Athens.

The most ancient, perhaps, of the Athenian Temples, is that which was dedicated to Theseus, and which is thought to have been erected a few years after the battle of Marathon, when the ashes of that hero were brought by Cimon to Athens.

This Temple, like the others, is of a rectangular form, of the kind called peripteral, amphiprostyle, and hexastyle, and has thirteen columns on each flank, including, as usual, the columns at the angles. Its extreme length is 104.244 feet, and its width 45.28 feet, measuring on lines circumscribing the exteriors of all the columns. The whole length of the side walls of the Temple is 74.06 feet, and the breadth between the exteriors of these walls is 25.78 feet. The side walls extend beyond the naos at each extremity of the Temple, forming a pronaos whose depth is 16.4 feet, and a posticos whose depth is 12.49 feet. These walls are terminated by antæ pilasters at the extremities, and between the pilasters, both of the front and rear, are two columns. The whole building is elevated on a stereobata, or general basis, to the top of which there is an ascent by two steps surrounding it.

The columns are fluted, as usual, and are without bases; their height is 18.735 feet, and the diameter at bottom is 3.304 feet. The height of the whole entablature is 6.846 feet, that is $\frac{1}{2.7}$ of the height of the column; the face of the architrave is in a vertical plane passing nearly through the circumference of the shaft at its foot, and those of the triglyphs are in the same plane.

The intercolumniations of this Temple are equal to 1.6 diameters, except those between every two outer columns on each side, which are rather less; and the breadth of the pteromata is 6.45 feet. The antæ pilasters are 3.19 feet broad; they have both capitals and bases, but their shafts have no diminution; the capitals do not resemble those of the columns, but consist of an abacus, under which is a bird's-beak moulding and an astragal; the base consists of an inverted cymatium above a low plinth.

The soffit, or ceiling between the front columns and the pronaos, is in a horizontal plane which passes a little above the top of the corona of the front columns; and the entablature over the front of the pronaos is continued to the interior face of the entablature of the flank columns. Seven rectangular projections below the ceiling, like beams of stone, each 1.575 feet broad, and 3.1 feet from each other, are placed in horizontal positions, extending from the front of the pronaos to the interior face of the entablature of the front columns, as if to support the ceiling above them. Their lower surfaces are on a level with the top of the frize; and between every two are sixteen lacunaria, or sunk panels, of a square form, disposed in two rows, to ornament the ceiling. The general ceiling of the interior is on the same level as that in front of the pronaos; but, below it, in horizontal positions, and in the direction of the breadth of the Temple, are other projections like beams of stone; the intervals between every two of which are ornamented with two rows of lacunaria similar to those before mentioned.

On the metopes of the Eastern front are sculptures representing the labours of Hercules. On the frize over the antæ of the pronaos, where there are no triglyphs, is the representation of some battle, probably that of Marathon, and over the antæ of the posticos are sculptured the combats of the Centaurs and Lapithæ. The whole building was covered by a pediment roof which is now destroyed. A plan and elevation of this Temple is given in pl. i. figs. 5 and 6.

The Temple of Minerva Parthenon at Athens.

When Pericles became possessed of the supreme authority at Athens, his own elegant taste, and perhaps the necessity of gratifying a people vain of their importance, led him to embellish the city with the most splendid edifices Art could construct. Phidias was then in the full enjoyment of the most exalted reputation, and, under his direction, the Temple of Minerva Parthenon, on the site of the more ancient Hecatompedon, was built by Ictinus.

The present Temple is of a rectangular form, its length is 228.7 feet, and breadth 100.8 feet, measured on a line circumscribing all the exterior columns. It is peripteral, hypæthral, and octastyle, having eight columns in front and seventeen on each flank, including the columns at the angles. The length of the body of the Temple between the exterior of the front and rear walls is 158.6 feet, and its breadth between the exterior and the side walls is 70.22 feet; the thickness of the front and rear walls is 6.658 feet, and of the side walls is 3.858 feet. The body of the Temple is divided into two unequal parts by a wall 2.917 feet thick; and there were doors of communication between them, the traces of which are still to be seen near the wall on each side: one of these divisions was 43.8 feet long, and the other 98.6 feet; the former was the opisthodomus or Treasury of the Temple, or, as some suppose, the public Treasury of the State; it was covered by a ceiling, and was divided into three parts by two rows of columns, two in each row; it had no windows in the walls, consequently it could only have received its light from the doors, unless there were windows in the roof. Mr. Stuart has, by mistake, placed six columns in this division of the Temple; but that there were only four is evident from the disposition of the circles on the floor which mark the places where they stood. The other division was a court enclosed by the four walls, and having its central part open to the sky. In the interior was a peristyle, probably of Ionic columns, at the distance of 14 feet from the walls on each of the four sides of the building, and the passage left between the columns and the walls was, probably, covered by a roof. On three sides of the Temple the pavement of this passage is sunk in the middle below that of the court; on the higher level, next to the interior of the court, are yet remaining the marks where the interior ranges of columns stood; and on the side of this division, which is furthest from the entrance, are seen the foundations of the pedestal which supported the statue of the Goddess; this pedestal appears to have been about 20 feet square.

The side walls were carried out five feet beyond the walls of the front and rear faces, and were terminated by antæ pilasters. There are no columns between the antæ, as in the Temple of Theseus, but there is a row of six columns parallel to the front and rear of the building at the distance of seven feet from the faces of the antæ. Between these columns and those of the front and rear faces is a space 12 feet broad, but the breadth of the pteromata, or spaces between the side walls and the columns of the flanks, is only 9 feet. The ceiling of the pteromata was level with the under part of the corona in front, and fragments of its soffit have lately been discovered, from which it seems to have resembled that of the Temple of Theseus, and to have been ornamented with lacunaria. Above the stones of this soffit came the masonry of the roof.

The whole Temple and the surrounding columns stood on a stereobata, or general basis, to the upper surface of which was an ascent by three steps; the walls of the Temple stood on another basis, the upper surface of which was the pavement of the interior, and to this was an ascent by two steps from the pavement of the pteromata.

All the columns are of the Doric Order; the height of those surrounding the Temple is 35.903 feet including the capital, and, except the four columns at the angles, their lower diameter is 6.15 feet. The columns at the angles of the edifice are rather thicker than the others, their lower diameters being 6.29 feet, and the shafts of all the columns are fluted with shallow channels which meet each other in longitudinal edges. The whole entablature is 11.192 feet high; that is, $\frac{1}{3.2}$ of the height of the column, and the faces of the triglyphs are in the same plane as that of the architrave. The antæ pilasters resemble those of the Temple of Theseus.

The columns and walls of the Temple incline, at top, towards the centre, so that the whole building assumes the form of a frustum of a pyramid. By accurate measurements, lately made, it appears that the faces of the abaci of the columns are vertical; those of the architrave and frize incline inward at top, but the parts which remain of the cornice incline outward, and the foot of the architrave is in a vertical plane passing through the circumference of the foot of the shaft. All the metopes are enriched with sculpture representing the combats of the Centaurs and Lapithæ, and on the frize of the wall enclosing the body of the Temple, which has no triglyphs, was sculptured a Panathenaic procession. The two pediments were, also, filled with exquisite sculpture; that on the Eastern pediment represented Jupiter receiving Minerva in an assembly of the Gods, and that on the Western pediment expressed the contest of Minerva and Neptune. The epitithedas, or crowning moulding of the pediment, which is in the form of an echinus, is terminated at each lower extremity by a lion's head which is not perpendicular to the faces of the walls, but inclined towards the opposite extremity of the building.

The roof of the Temple was covered with flat marble plates, the lateral junctions of which formed a number of parallel lines extending down the sloping sides of the roof: from the general ridge of the building to the tops of the flank walls, and along the top of the cornice on each flank was a row of fleurons, or honeysuckle ornaments at certain distances from each other but not always

itec-
re.

corresponding with the extremities of the lines above mentioned.

The shafts of the columns, instead of being exactly frusta of cones, have a certain entasis or swell, so that a longitudinal section through the axis is bounded on each side, not by a right line, but by a curve concave towards the axis. This form, which was long supposed to be peculiar to the Roman columns, was first observed, by Messrs. Allason and Cockerell, to exist in a Grecian example, in the columns of this Temple, and it has been subsequently ascertained that a similar entasis exists in other examples of the Grecian Doric Order. The curvature of the section appears to be continuous from the top to the bottom of the shaft, as if it were part of a circle of very large radius, the centre of which is in a horizontal line passing through the foot of the axis. In general, however, the deviation of the shaft from a conical form is scarcely perceptible to the eye; and it, therefore, easily escaped the notice of previous travellers.

The appearance of this Temple must have been extremely brilliant from the paintings with which it was adorned. The abaci of the capitals of the columns, the tenia or fillet of the architrave, and the capitals of the triglyphs and metopes were all embellished with a painted fretwork, and the regulæ under the triglyphs with inverted palmettes and honeysuckles. In the sloping sides of the pediments the epitithedas and the mouldings below it, also the bird's-beak in the bed moulding, were painted with oves. On the architrave of the principal front, under every metope, were bronze shields or circular plates attached by metal cramps, and, between them, are as many holes to which metal ornaments or inscriptions were attached, so that the stonework could hardly have been seen. On the other three sides there were circular plates over each column only. Between the columns of the hexastyle or inner portico is a marble sill, in which was, at one time, inserted a metal railing.

Beneath the marble steps surrounding the present Temple are seen the substructions of the ancient Hecatompedon, consisting of a rusticated basement of freestone. And below the interior of the Temple have been found many fragments, among which are parts of an Ionic architrave having three faciæ, a proof that this Order had been employed before the time of the erection of the present Temple. In the walls of the Acropolis are immense fragments of a Doric entablature, executed in freestone, nearly similar to that of the Parthenon, and frusta of columns, all of which are supposed to have belonged to the Hecatompedon. These ancient columns have channels, cut at top and bottom only, about 10 inches long, the rest of the shaft being plain. Besides these splendid examples of the Doric Order, there exists in the Agora at Athens, a tetrastyle portico of the same Order, executed in the ancient manner; but it is supposed, by Stuart, to have been part of a Temple dedicated to Rome and Augustus.

at

At Bassa, near Phigalia, in the Peloponnesus, are the remains of a peripteral Temple dedicated to Apollo Epicurius, of the Doric Order, with six columns in front and fifteen on each flank. This Temple, the length of which is 121.3 feet, and breadth 43.5 feet, measured between the centres of the extreme columns, is remarkable both from its position and construction; instead of lying in a direction nearly East and West, as is usual with the Grecian Temples, it lies nearly North and South, and from the interior faces of the walls of the cella project five piers on each side, to the extremities of which half columns of the Ionic Order were attached; all these piers are perpendicular to the faces of the walls, except that at one extremity of the cella there is one on each side which stands obliquely with respect to those faces; and between these two is an isolated column of the Corinthian Order. The time of its construction is unknown, and the employment of Ionic and Corinthian columns in the interior would lead us to suspect that that part of the building may have been erected subsequently to the peristyle, which bears marks of the best Age of Architecture in Greece; but the masonry of the whole Temple is so united together as to leave no doubt that all the parts are of equal antiquity.

Part I.

Rhamnus,

At Rhamnus, in Attica, are the remains of two Temples of the Doric Order, one of which, dedicated to Nemesis, was peripteral and hexastyle, with twelve columns on each flank. All the columns are fluted at top and bottom only, the rest of the shaft being plain, and the soffits of the ceiling of the pteromata and porches are ornamented with lacunaria. Nearly in contact with this, is the apteral Temple of Themis, which consists of a cella and one porch only, with two columns of the Doric Order between the antæ. The columns are of a soft, porous stone, but the walls are of marble, the blocks of which are polygonal prisms of unequal sides. These, together with the Temples of Minerva at Sunium and of Jupiter at Nemea, between Argos and Corinth, appear to have been built in the time of Pericles. They were all of the Doric Order, and each had six columns in front, but their dimensions cannot now be ascertained.

and Delos.

In the Island of Delos are some remains of what is supposed to have been a Temple of Apollo. It is of the Doric Order, but at what time erected is unknown; it possesses, however, some peculiarities of form which lead to an opinion that it was at a late period of the Grecian school.

The height of its columns is 18.72 feet, and the lower diameter is 3.092 feet; consequently the height of the column is about six diameters. The height of the entablature is 5.875 feet, or about $\frac{1}{3.2}$ of the height of the column.

The shaft is plain, except near the top and bottom, where the circumference is cut in channels about one foot long, as in the columns of the Hecatompedon: the plain part is rather larger in diameter than that which is fluted, and the echinus in the capital is nearly in the form of an inverted frustum of a cone. The face of the architrave is in a vertical plane which, if produced downward, would intersect the shaft in about the middle of its length, and the faces of the metopes coincide with that of the architrave.

Temple at Cora.

At Cora, in the Ecclesiastical States, are the remains of a Doric Temple supposed to have been dedicated to Hercules, and to have been built while the South of Italy was under the dominion of the Grecian Colonists; but, perhaps, not long before the Romans obtained possession of the Country. The columns of this Temple are eight diameters high, and consequently the Order is much lighter than that employed in the buildings of Greece or Sicily; the shaft is of a polygonal form up to one-third of the height, and the remainder is channelled; the base consists of a simple torus without a plinth, and the capital is formed by an abacus placed over a moulding, the vertical section of which has the form of a quadrant of a circle instead of an echinus. There are triglyphs in the frize, but, between every two columns, there are three of these ornaments, whereas the earlier Greeks introduced but one or two.

Herculaneum and Pompeii were, originally, towns built by colonists from Greece, and the style of Architecture in those places is decidedly Grecian; the buildings are mostly of the Doric Order, and the proportions employed in the columns and their entablatures are nearly the same as those of the Order at Cora. The lightness of the shafts and the forms of the capitals of the columns above-mentioned seem to afford ground to believe that the Orders employed at all these places are intermediate links connecting those of the ancient Greeks with the Orders afterwards adopted in Roman buildings.

CHAPTER V.

Description of the Grecian Ionic and Corinthian Temples.

We have seen that, according to Vitruvius, the Ionic Order originated in Asia Minor, and that the first Temple built in that style was in honour of Diana. However this may be, it is certain that the Order prevailed chiefly in the Asiatic States of Greece, and it was not till long after its invention that it was much employed in Europe.

The triple Temple at Athens.

There existed in Athens, at an early period, a Temple dedicated to Minerva Polias and to Erectheus, which is supposed to have been partly destroyed at the time of the Persian invasion; and, from a passage in Xenophon it seems that the destruction was completed by a subsequent fire in the XCIIId Olympiad, or about 408 years before Christ. The present Temple appears to have been erected upon the ruins of the old one, by Philocles, of Acharnæ, probably during the Peloponnesian war: it is threefold, dedicated to Minerva Polias, to Erectheus, and to Pandrosus; and it is considered as the best example of the Ionic Order that has ever been executed.

The body of the present building is of a rectangular form, 74.52 feet long, and 38.39 feet broad, measured on the exterior of the upper step; this was divided into two parts by a wall perpendicular to the length of the Temple; the division at the Eastern end was that dedicated to Erectheus, and the division at the Western end, to Minerva Polias. A projection was made on the Southern side close to the Western extremity, which formed the small Temple appropriated to Pandrosus, and a corresponding projection was made at the Western extremity on the Northern side, in order to serve as a common porch to the two last-mentioned Temples.

The pavement of the Temple of Erectheus is elevated about two feet above the general level of the ground on the Eastern and Southern sides of the building, and it is ascended by three steps which extend along those sides. On the Western and Northern sides of the spot occupied by this Temple the ground falls abruptly, so that the pavement of the Temples of Minerva Polias, of Pandrosus, and of the Northern portico is about nine feet lower than that of the former Temple.

In front of the Temple of Erectheus is a portico of six Ionic columns, the centres of which are 6.425 feet from the face of the wall. At the Western, or opposite extremity of the building, are four half columns of the same Order, projecting from the wall, but their lower extremities are 3.15 feet below the level of those of the columns at the Eastern end, and about 13.75 feet above the ground on this side. On the interior side of this Western wall are four pilasters placed exactly at the backs of the columns, and between the columns and pilasters are three windows which give light to the passage leading to the Temple of Pandrosus. One general roof, with sloping sides, served for the whole of the double Temple of Erectheus and Minerva Polias.

The Northern portico is 34 feet long from East to West, and 20 feet wide, but the Western flank projects 7.5 feet beyond the Western end of the whole building. It has four columns in front, with one on each flank between the front columns and the pilasters which are attached to the wall of the building. This portico was covered by a pediment roof, and the top of the cornice of the portico was on a level with the under surface of the architrave of the main building. A doorway opposite the centre of the portico leads to the passage before mentioned, which may be considered as a pronaos to the Temple of Minerva Polias, and which was separated from that Temple by a wall. At the opposite side of this pronaos was a doorway leading to the small Temple of Pandrosus, whose length is 19 feet from East to West, and breadth is 11.5 feet; the Western flank coinciding with the Western end of the main building. It consists of a flat roof, supported in front by four female figures, which, in such a situation, are denominated *Caryatides*; and there is one on each side between the front figures and the pilasters, which are attached to the wall of the Temple of Minerva. The figures are 7.087 feet high, and stand upon a *podium*, or low wall, which encloses the area of the Temple. The height of this podium is 5.683 feet, and it stands on three steps, which elevate the pavement about 2.37 feet above the ground. The entablature of this Temple is 2.963 feet high, and the top of its cornice is on a level with the middle of the architrave of the portico of Minerva Polias. The soffit, or ceiling, is ornamented with square, sunk panels, three deep, the sides of which are in the form of inverted steps.

The departure from the general simplicity of the Grecian Temples which we observe in this edifice, seems to have been rendered necessary by the nature of the ground and the disposition of the neighbouring buildings; which anciently, perhaps, approached very near the Temple, and prevented the view of it except from three points, where as many streets led to the site it occupies. Opposite each of these three openings a portico was formed, seemingly with the design of affording a grand termination to the view on approaching the Temple along the street. The manner in which the masonry of the three porticos is connected with the body of the building proves that the whole edifice was erected, as it is now, at one time.

In the portico of the Temple of Minerva Polias, the columns are 25.822 feet high, of which the base occupies 1.108 feet, and the capital 1.954 feet, measuring from the astragal below the volutes to the top of the abacus. The diameter of the shaft at bottom is 2.786 feet, so that the height of the whole column is equal to 9.27 diameters; the difference of the upper and lower diameters is $\frac{1}{5.6}$ of the latter, and the difference of the semi-diameters is $\frac{1}{9\frac{2}{3}}$ of the length of the shaft.

The capital consists of a sculptured echinus, and on two sides it has volutes, the faces of which, on each of those sides respectively, are in a plane parallel to the front of the portico; above these is a square abacus, the sides of which are cut in mouldings. The base is of the kind iec- e.

called *Attic;* that is, it consists of two tori with a scotia and fillets between them; the lower torus is plain, and the upper is sculptured with an ornament called a *guilloche.* None of the bases of the columns of either Temple have plinths. The shaft is fluted or cut in twenty-four channels, which do not join in a single edge as is the case with almost every Doric column, but have a narrow fillet or flat surface between every two; in order, no doubt, to render them less liable to be broken when, as in the present case, the channels are deeply cut in the shaft.

The taste of the Greeks for ornamenting their Architectural works was displayed to great advantage in this Temple; for, between the spiral mouldings in the volutes of the capitals are cut channels, which were once filled with gilt bronze ornaments or mouldings in similar curves; and ornaments of the same material were placed in the angles between the curves of the volutes and the top of the shaft, in front, which must have considerably increased the effect of the sculpture. Glass eyes of various colours were also fixed between the curves which form the guilloche in the capital.

The height of the entablature is 5.513 feet, which is $\frac{1}{4.7}$ of the height of the column, and the intercolumniations are equal to 3.5 diameters.

The antæ pilasters, which are placed at the extremities of the walls, have bases similar to those of the columns, but the tori are fluted horizontally; the capitals have no volutes, but the hypotrachelion and an echinus moulding above it correspond with those in the capitals of the columns, and are similarly ornamented; above the echinus is a cymatium which supports the abacus. The heights of the pilasters are equal to those of the columns, but their breadths are less than the diameters of the latter, being equal to 2.4 feet, and their shafts have no diminution.

The architrave of each of the three buildings is divided horizontally into three faciæ, every one of which projects a little way over the one below it; and Mr. Mitford thinks this is the oldest Temple existing in which such a division was made, but we have shown that a similar architrave must have formed part of some Temple more ancient than the Parthenon itself. The frizes of the Temples of Erectheus and of Minerva Polias are plain, and the corona has its under surface excavated. In the Temple of Pandrosus there are dentels, which rest immediately upon the architrave, and seem intended to supersede the triglyphs of the Doric Order.

The columns of the Temple of Erectheus are similar to those of Minerva Polias, but on a smaller scale; their height is 22.554 feet, and the lower diameter of the shaft is 2.317 feet. The capitals of the columns of both Temples are very much alike, but the bases of the former are less elegant than those of the latter; the lower torus being smaller, and the upper one channelled horizontally, which gives the base a confused appearance. The execution of the portico of this Temple does not appear to have been performed by the same hand as that of Minerva Polias, and is much more coarse; the volutes are tame, and the sculptures rude. Fig. 1. pl. vi. is a general plan of the triple Temple; figs. 2 and 3 are elevations of the hexastyle portico, or that of the Temple of Erectheus, and of the front of the Temple of Pandrosus. Fig. 1. pl. vii. is an elevation of one of the columns of the tetrastyle portico, or that of Minerva Polias.

Part I.

Temple on the Ilyssus.

A specimen of the Ionic Order, which united considerable beauty with simplicity, was that found in an apteral Temple, the remains of which lately existed on the South bank of the Ilyssus near Athens. This Temple was supposed by Mr. Stuart to have been built in honour of the hero Panops; the date of its erection is unknown, but, probably, it was about the time of the Peloponnesian war. It was of a rectangular form, and amphiprostyle, with four columns both in front and rear. Its whole length was 41.623 feet, its breadth 19.532 feet, and the body of the Temple was divided into two parts by a wall separating the naos from the pronaos. The height of the columns was 14.693 feet, and the diameter of the columns, at the bottom of the shaft, was 1.783 feet. The height of the entablature was 3.606 feet, or about one-fourth of the height of the column, and the frize was adorned with sculpture.

The bases of these columns were of the Attic kind, but deficient in elegance; the scotia was high and shallow, and the upper torus fluted horizontally. The extremities of the side walls were terminated by pilasters, the bases of which were similar to those of the columns; except that the lower torus was smaller; the capitals resembled those on the pilasters of the Erectheum, but the mouldings were quite plain; like all the Greek antæ, the breadths of these were rather less than the diameter of the columns, and the shaft had no diminution. It is much to be lamented that this building, which was in good preservation in Stuart's time, is now entirely destroyed, and that not a vestige remains of the ruins.

Ionic Temples in Asia.

The famous Temple of Diana at Ephesus was of the Ionic Order, but we only know that it was 425 feet long, and 220 feet broad, that the columns were 60 feet high, and that it was of the kind called dipteral, having two rows of columns along each flank. This Temple was designed by Ctesiphon, and burned by Eratostratus three hundred and thirty-six years before Christ. It was the wonder of Asia, and is said to have been four hundred years in building, though all the Greek cities of Asia contributed to the expense.

Soon after the Persian invasion of Greece, it is probable that the Temple of Bacchus was constructed at Teos. Vitruvius shows that it was built by Hermogenes, that it was of the Ionic Order, with eight columns in front, and that it was of the kind called pseudodipteral. He further adds, that this Architect was the inventor of that style of building, by leaving out the interior of the two ranges of columns which surround the dipteral Temples, in order to afford spacious walks between the columns and the walls. This building is now completely in ruins, so that no vestige of the plan can be discovered; but, from the fragments which remain, the form and dimensions of the columns and architrave have been fully ascertained. A description of them is given in the *Ionian Antiquities.*

The once magnificent Temple of Apollo Didymeus near Miletus, was of the same Order, and is supposed to have been built about three hundred and eighty years before Christ. It is almost entirely destroyed, but travellers have succeeded in ascertaining that the extent of the Western front was nearly 163 feet, and it appears to have been of the kind called dipteral. The columns of the interior range are fluted through the whole length of the shaft, but those of the exterior range, only to about two feet below the capital; from which circumstance it seems probable that the Temple was never finished.

The Temple of Minerva Polias at Priene appears, by an inscription, to have been dedicated by Alexander the Great, probably on being rebuilt after it had been destroyed by Xerxes. The authors of the *Ionian Antiquities* show, from the ruins, that the Temple has been peripteral, and surrounded by a *peribolus* or enclosing wall. The eyes or centres of the volutes appear to have been bored, as if for the convenience of fixing festoons, and the faciæ of the entablature incline forward at top, both on the exterior and interior of the colonnade. This is the last existing specimen of the Grecian Ionic Order whose age can be depended on; and the ruined state of this and the preceding Temple renders it impossible to show the proportions of the column and entablature, the bases and capitals of some of the columns being all that remain entire.

At what time the Corinthian Order may have come in use.

We have mentioned the circumstance which is said to have given rise to the invention of the Corinthian Order; and, though the story is doubtful, and there is reason to believe that the capital of this Order had been employed at an earlier period, yet it is probable that it might not have come much into use till the time of Callimachus; that is, towards the conclusion of the Peloponnesian war. About that time, it appears that the hypæthral Temple of Minerva at Tegea was built by Scopas, an Architect of Paros, the interior of which, according to Pausanias, was adorned with columns of the Corinthian Order. Unfortunately this superb building, as well as the city itself, is completely destroyed, and the ruins, if any remain, are so deeply buried, that it is not likely any information can ever, now, be obtained concerning it.

The Temple of the Winds at Athens.

No example of this Order remains, of a truly Grecian origin, which can be called a Temple; unless we are allowed to consider as such, the edifice at Athens built by Andronicus Cyrrhestes, an Astronomer of that city, in honour of the eight principal Winds. It is the general opinion that this building was erected about the time of Alexander the Great, though the character of the mouldings and sculpture has, by some, been thought to indicate the Age of Hadrian. This Temple, or Tower, is of an octagonal form, having four of its sides made to face the four cardinal points of the horizon, and the others, to face the four intermediate points. The length of each side, on the exterior, is 10.8 feet, and both on the North-Eastern and North-Western faces is a doorway, with a porch in front, having a pediment roof, supported by two columns of an Order which some have been pleased to call Corinthian, but which others have proposed to call the Attic Order; and attached to the wall, on the Southern side of the building, is a tower in the form of a segment, equal to three-quarters of a cylinder, the diameter of which is 9.7 feet on the exterior. The general pavement is raised on three steps, each one foot high, and in the centre is a well with small channels cut about it, probably to serve the purpose of a *clypsedra*, or water-dial; being, perhaps, supplied with water from the circular building before mentioned.

Each external face of the building is quite plain up to the height of 29 feet from the top of the steps; at this height is a moulding which surrounds the building, and, above it, upon the different faces, are sculptured the figures of the eight Winds. The walls terminate in a general entablature, consisting of an architrave, frize, and cornice, which together are equal in height to 4.229 feet, and the top of the cornice is 7.937 feet above the moulding before mentioned. The diameter of the Temple is less at top than at bottom, so that it has the appearance of a frustum of a pyramid; and the whole is covered with a pyramidal roof 4.375 feet high, consisting of one block of marble resting on the walls and having its exterior cut in the form of tiles. Above this, according to Vitruvius, was a brazen Triton, holding a rod in his right hand, and capable of turning with the wind so as to point toward the figure of the Wind at that time blowing.

In the interior of the building, are three cornices along the periphery of the wall, and projecting from it. The lower one is 5.68 feet from the pavement, and consists of one plain facia with a moulding at the top. The middle one is 8.637 feet above the former; it consists of sundry mouldings, and is supported by modillons which project from the wall, and have their under surfaces cut in the form of a scroll or curve of contrary flexure; in the soffit of this cornice are panels of a trapezoidal form sunk between the modillons; and between the mouldings on the front of the cornice is a row of dentels. The third cornice is 11.475 feet above the last, and quite plain; this supports eight small columns resembling those of the Doric Order, and these support the internal cornice of the whole building.

Mr. Stuart observes that the capitals he has given to the columns of the porches were found about the building, but he doubts whether they ever belonged to it; however, as such capitals are abundant in Athens, and other parts of Greece, they may serve as specimens of an Order which approaches very near the Corinthian. Each capital consists of a row of lotus leaves surrounding the vase, and reaching from bottom to top; about these, at bottom, is another row, about half the height of the former, and consisting of clusters of leaves, resembling those of the olive. An elevation and plan of these buildings are given in plate vi. figs. 4 and 5, and an elevation of one of the columns in plate vii. fig. 5.

The T
of Ju
Olym
Athen

One of the most superb Temples of antiquity was that of Jupiter Olympius at Athens, which was begun in the time of Pisistratus. The work, however, was interrupted by his death, and by the troubles in which the State was, subsequently, involved; and it appears from what Vitruvius says, in the Proem to the VIIth Book, that it was finished by Cossutius, a Roman Architect, in the time of Antiochus, that is, about 400 years afterward: but as the Emperor Hadrian is also said to have finished the same building, it is probable that some of the ornamental parts were not added till the time of that Monarch.

The columns of this Temple are of the Corinthian Order, 6 feet in diameter and 60 feet high, of Pentelic marble, with Attic bases and fluted shafts, but, as they were probably put up by Cossutius, they cannot be considered as specimens of the Grecian style. The Temple was rectangular, dipteral, hypæthral, and decastyle, having ten columns in front and twenty-one on each flank. The body of the Temple, measured on the exterior, was 259 feet long and 96 feet wide, and was divided into two parts by a wall; one of these divisions was covered by a roof; the central part of the other was open to the sky, and was surrounded by an interior peristyle. The side walls of the Temple were continued beyond those of the front and rear, and were terminated by a column at each end. Between these were four other columns, and there were three rows of columns beyond them, at both extremities of the Temple. The whole length of the Temple was 354 feet; its width 171 feet, measured on lines circumscribing all the exterior columns, and it was surrounded by a peribolus or enclosure, of a rectangular form, 679 feet long and 463 feet wide.

Many other examples of this Order might, perhaps, at one time, have existed in Greece, but it is highly probable that the columns were transported to Italy by the Romans when they became possessed of the Country.

CHAPTER VI.

Description of the Civil Edifices of Greece.

The *Propylea*, or entrances of the Grecian cities, were, usually, adorned with Architectural embellishments; and those of Athens and Eleusis have been particularly remarkable for their grandeur. We, therefore, think it may be acceptable to give a short description of these buildings.

The Propyleum of Athens is situated on the Western side of the Acropolis, on an ascending ground, commanding an extensive view towards the Gulf of Corinth, and lying in a direction from West to East. On account of the form of the ground, the horizontal pavement is divided into three parts; and steps, extending across the entrance from North to South, afford an ascent from one level to the next. On approaching the Western front of the building there is, according to Stuart, an ascent to the first pavement by a flight of steps about 80 feet long, with a pedestal or pillar of masonry on each side of them; but it has been since observed that the one on the Southern side of the steps, certainly, never existed; for its place is occupied by the substructure of a small Temple, which is now thought to be that of Victory, without wings; and the existence of even the steps themselves is uncertain, as the spot on which they were supposed to have been placed, has been long occupied by a Turkish battery. The upper part of the pedestal on the Northern side of the ascent is, decidedly, of Roman construction; but, from its appearance, it is possible that the lower part may have been more ancient.

The pavement before mentioned is of a rectangular form, about 78 feet long from North to South, and 40 feet wide. On the Eastern side, three steps, extending the whole length of the pavement, led to the next platform, which is three feet higher than the other, and on this is the body of the building. The plan of this is a rectangle, 66.5 feet wide from North to South, and 42.25 feet long, within the walls which enclose it on the Northern, Southern, and Eastern sides; it has a magnificent portico of six Doric columns before the open entrance on the West, which makes the whole length of the building equal to 54 feet from the front of the columns to the interior of the Eastern wall. This part was, originally, covered by a roof, which, together with the cornice of the portico, is now destroyed. The architrave and frize remain, and we find that the metopes of the latter were adorned with sculpture.

The interior of the building is divided into three passages, directed from West to East, by two rows of columns, two in each row, (Mr. Stuart places three in each row, but this is a mistake,) and, from the fragments which have been found in the walls, it appears that the columns were of the Ionic Order, that their capitals resembled those in the Temple of Erectheus, and that they had Attic bases. Within this portico may be seen vestiges of an inclined plane, with traces of ruts cut in the rock, to enable the cars to ascend towards the citadel.

The foot of the Eastern wall is elevated above the pavement of the building, and there is an ascent to it by five steps leading to the third pavement, which is five feet higher than the former. In this wall are five doorways which lead to the interior of the Acropolis, through another portico of six Doric columns, which forms the Eastern extremity of the whole building. About the three centre doorways are false lintels and jambs; and above them were cornices, supported on consoles, of which some indications remain on the walls, together with various holes for the insertion of metallic ornaments. The length of this portico, from North to South, is the same as that on the Western front, and its depth, from East to West, is 26.5 feet, not including the thickness of the wall just mentioned, which separates it from the principal building. This portico also was covered by a roof with a pediment facing the East, but the roof was higher than that of the rest of the edifice. At the foot of the columns of the Eastern portico is one low step descending towards the citadel, in order, probably, to prevent the rain water, from it, running down into the Propyleum.

On the right and left of the first, or Western platform, is a building of the Doric Order with three steps in front, which are placed on a blue marble band, considerably elevated above the platform. That on the left was divided into two parts by a wall, from West to East, in which was a door and two windows. In front of its pronaos are three Doric columns between antæ, and the sides of the windows on the interior are ornamented with short pilasters. The length of the whole is 55.75 feet from North to South, and the width is 41 feet, on the exterior of its walls.

This is supposed, by Mr. Stuart, to have been the Temple of Victory without wings, but, by later travellers it is considered as a simple chamber. Mr. Stuart also supposes that there was a building similar to it on the Southern side of the platform, and he considers this as the saloon which was decorated with the paintings of Polygnotus; but, it is evident that it could not have had the same length as the opposite chamber, unless its extremity had been raised on substructions carried out from the rock, of which no indications appear. There is not even any vestige of a wall on the Western front of the Southern building, and it is probable that no such wall existed. Both these wings seem to have been crowned by pediments, as a fragment of one has been found under that on the Northern side; and it has been supposed that there were small colonnades on that side of the two wings of the Propyleum, which faces the citadel. The wings undoubtedly formed part of the original structure, as the masonry of both is inserted in that of the central building.

The columns of the Western portico are 28.667 feet high, of which the capital occupies 2.304 feet, and the upper diameter is 3.917 feet. The columns of the Eastern portico are 28.798 feet high, to the top of the capital, which is in a horizontal plane, coinciding with the ceiling of the principal building, or a little above the top of the architrave of the Western front. The pedestals of the columns within the Propyleum are 5.25 feet high, which brings the foot of their bases on a level with the pavement of the Eastern portico. The columns are 27.167 feet high, including the bases and capitals, and the tops of the capitals are on a level with the top of the architrave of the Western front; their upper diameter is 2.858 feet, and their shafts are fluted.

The height of that which is called, by Stuart, the Temple of Victory, and of the building on the opposite wing is 25.596 feet from the pavement to the top of the cornice. The columns are 19.196 feet high; and the upper diameter 2.729 feet, and the height of the entablature is 6.397 feet. The antæ pilasters of these two buildings are 3.027 feet broad, and their shafts are without diminution.

Under the present Propyleum have been found the substructions of a more ancient entrance to the Acropolis. But in front, where the inequalities of the rock must have rendered it necessary to form additional works for the purpose of carrying the roadway, no remains of any such works exist; it is, therefore, probable that they have been removed at some succeeding time. In the Northern wall, under the right wing, are the appearances of what some persons have supposed to be a triple entrance. It is, however, probable that they are but the intervals between buttresses supporting the wall of the building on this side; for, besides being too narrow, the sides of the buttresses are left in steps, and have not been made smooth, as the sides of gates would have been. A low, continuous wall is carried out from the ends of the steps in front of the Northern wing of the Propyleum, nearly as far as the pedestal; but Mr. Stuart is wrong in making a gateway through it, for no such thing appears.

This superb edifice was constructed by Mnesicles between the years 437 and 432 before Christ, and during the time that Pericles possessed the Government of Athens.

The Propyleum of Eleusis.

The Propyleum of Eleusis is now totally destroyed, but from the account published in the *Unedited Antiquities of Athens*, it appears to have been, in some respects, similar to that which has been just described, being formed by two lateral walls, 60 feet asunder and 50 feet long, with a hexastyle portico of Doric columns both on the Northern and Southern fronts. There were five portals in a transverse wall, which led to the interior of the town, and, between the Northern front and the wall, was a double row of Ionic columns, three in each row. These columns resembled those of the Temple on the Ilyssus, and had Attic bases, of which the upper torus was fluted horizontally; the tops of the abaci were on the same level as the tops of the architraves in the entablatures of the porticos.

After passing through the Propyleum, there was found a peribolus, in the form of an irregular pentagon, enclosing a Temple of Ceres. The entrance to this enclosure was by a smaller Propyleum, or vestibule, about 48 feet in length, and as much in width; in the interior extremity of which were three portals formed by the side walls and by two intermediate piers; and in the middle of this vestibule, opposite the pilasters by which the piers are terminated, were two Ionic columns, similar to those of the Temple on the Ilyssus, with plain Attic bases, and an entablature only ornamented with dentels in the cornice.

The Temple of Ceres was nearly a square on the plan, and the length of each side was equal to 180 feet, exclusive of the portico, which was on the Western front, and consisted of a single row of twelve Doric columns, with shafts quite plain, except very short flutes at top and bottom. In the interior of the Temple were two double rows of columns, in directions parallel to that of the portico, which is contrary to the general practice of the Greeks. When this ruin was measured, a fragment of one column alone retained its original position; the places of the others were ascertained by the holes in the pavement, which were intended to receive the plugs connecting it with the lower part of the shaft; a situation in which plugs are rarely found, though they are frequently found at every joint of the stones in a column. This pavement, being below the level of that in the portico, seems to indicate that it belonged to a crypt or subterranean chamber. Plutarch speaks of lower columns in the interior of this Temple, and, hence, it is probable that there must have been a double range, one above the other.

A little in front of the grand Propyleum was a Temple of Diana, consisting of a naos and pronaos, with no other columns than two between the antæ. The Temple was of a rectangular form; its cella 24.5 feet long and 16 feet wide, and the ascent to the pavement was by five steps. The columns were of the Doric Order and fluted, and the triglyphs returned quite round the flanks. In other Grecian Temples the roof terminates in *stillicida*, or dripping eaves, but in this, the cymatium, or upper moulding of the pediment cornice, was continued along the flanks, and a channel was hollowed in it, for the purpose of collecting the rain from the roof; which was then discharged by the lions' heads sculptured at intervals along that moulding.

The external appearance of the dwelling-houses of the ancient Greeks seems to have been very simple, the Republican spirit of that people not permitting any of the Nobles to have their residences superior to those of the generality of the citizens; and it being thought highly indecorous to attempt, in the habitations of individuals, to rival the Temples of the Gods. Nothing remains, in Greece, of this class of buildings at the present day, and the only account we have of them is that which Vitruvius gives us, in the Xth Chapter of his VIth Book, where the internal disposition is said to have been made in the following manner.

The house was divided into two principal parts; one, called *andronitidis*, contained the apartments appropriated to the male part of the family, and the other, called *gynæconitis*, contained those appropriated to the women; the latter occupied the Southern, and the former the Northern side of the building. The entrance is described as a narrow passage on the Southern side, and having a stable and servants' room situated, one to the left and the other to the right hand of it. After getting through the passage, there was found an open quadrangle, the Southern side of which consisted of the apartments just mentioned; on the right and left hand were the *thalami*, or chambers. This quadrangle constituted, generally, an interior peristylium, being surrounded by columns within the walls, on the four sides. A long passage on the exterior of the thalami, and on the Eastern and Western sides of the building, separated them from other apartments, which, being destined for the reception of strangers, were called *xenodochia;* and these passages, from their situations between the *aulæ*, or courts, were called *mesaulæ*. On the Northern side of the peristylium was a covered space, opposite to the entrance, called *prostas*, which served as a porch, and had, on each side, an apartment, of which one was called *thalamus*, and the other *antithalamus*. At the extremity of the prostas was a passage leading to a vestibule, and from thence to a peristylium larger than the former. On either side of this passage were the *œci*, or apartments in which the mistress of the family dwelt. On one side of the vestibule was a dining-room, or *triclinium*, so called, probably, from its containing a triple couch for the company at meals; and, on the other, a painted room, or room for pictures, called *pinacotheca*. The peristyle last mentioned formed the centre of the men's apartments; on the Eastern side of it were the libraries, and on the Western side the *exedræ*, or places for study, conversation, and exercise. The Northern side was occupied by the *œci*, or apartments for the master of the family, and a vestibule in its centre led to a portico, which formed the exterior of the building towards the North.

From the dwelling-houses of the Greeks we may proceed to describe, in a few words, the disposition of the parts of their Theatres. The form of these buildings on the exterior was nearly semicircular; they were generally situated on one side of a hill, and the seats of the spectators occupied its declivity; or if a solid rock served for the basis of a Theatre, the seats were formed by cutting its mass in the shape of steps; of which kind of Theatre there are several still in existence, but reduced to heaps of ruins.

These seats, or steps, were divided at intervals by broad flat surfaces, or landing-places, concentric with the steps; these were by the Greeks called *diazomata;* and at the top of the steps was a colonnade, within which also were steps, serving as seats for spectators. Vitruvius prescribes that the upper edges of all the steps and diazomata should be in one right line, and he says that under the steps, in various parts of the building, were left vacuities, in which were put *echeia*, or brazen vessels, in order to increase the effect of the voices of the performers.

The curve formed by the lowest range of seats, or steps, was exactly equal to three-quarters of a circle, and within this curved line was a level space, which the Greeks called the *orchestra*, on which the dances were performed.

Beyond the chord line which limited the orchestra, was a level stage, raised about 10 or 12 feet above the orchestra, on which the actors performed their parts; this was called the *logeion*, and it was terminated by the *scena*, or wall against which the scenes were exhibited. Its length was nearly equal to the internal diameter of the Theatre, and its depth was limited by the circumference of the circle formed by completing the curve of the lower step surrounding the orchestra.

The height of the scena depended upon the magnitude of the Theatre, and it is described by Vitruvius as equal to that of the colonnade on the top of the seats. Three doors were formed through it, of which the central one was for those performers who represented the citizens, and the other two for such as personated strangers; an arrangement which accorded with that prescribed for the entrances of private houses.

The colonnade at the top of the steps was roofed over, but the rest of the Theatre was without cover, except that a great piece of cloth was occasionally drawn over, to protect the spectators from the heat of the sun, or from a shower of rain. If a heavy rain took place, it was necessary to suspend the performance, and the spectators retired to a covered portico behind the scena. Among the Ancients, the Theatrical representations took place by daylight.

The dramatic performances in the Greek Theatre were of three kinds; *viz.* Tragedy, Comedy, and Satire, and to each of these a particular kind of decoration was adapted. For Tragedy, the scene represented Palaces and Temples, of magnificent forms; for Comedy, streets with private dwelling-houses; and for Satire, were painted all the circumstances of a rural prospect. And to exhibit these different subjects, when required, there were placed, in vertical positions, in front of the wall of the scena, triangular prisms of wood, called *periactoi*, because they turned on axes: on each side of these was a painting, representing some part of one of the scenes which it was intended to exhibit, and when the parts relating to one subject were, by the revolution of the periactoi, brought into a plane surface, the scene was complete.

Gardens and promenades were made about the Theatres, for the entertainment of the company before and after the performance.

The nature of the Greek Theatre can be learned only from the description of Vitruvius; as no building of that kind exists entire in Greece, of an Age earlier than that of the Roman conquest. The plate, representing a plan of a Greek Theatre, which is given with this Work, is taken from the edition of Vitruvius, published by Mr. Wilkins: see pl. viii.

According to Suidas, a Theatre of wood was erected at Athens about 498 years before Christ, for the purpose of exhibiting a Drama of Pratinus, and the timbers gave way during the representation. After this, the Athenians erected one of stone, which was finished by Lycurgus, the Orator, about 170 years afterward. This was probably that called the Theatre of Bacchus, the ruins of which are yet to be seen at the South-Western angle of the Acropolis. It is formed by a semicircular excavation of the rock, from the inclining sides of which the seats of the spectators were cut, which, consequently, were supported by the rock itself. A semicircular wall is carried round the upper part of the excavation, and is strengthened by buttresses on the exterior of the Theatre. This wall, which probably formed the back of the colonnade above the seats, is 248 feet in diameter, and 7.8 feet thick, and has rectangular recesses made in it, with vaulted tops. The lower part of the wall of the scena remains in the gorge of the excavation, with part of the staircases at each extremity. This contains some semicircular-headed arches; but both it and the semicircular wall are of later date than the original Theatre, and probably were the work of Herodes Atticus.

The Odeon of Pericles.

The Odeon was a building similar to a Theatre, and intended for the exhibition of Musical performances. Pausanias describes one, which was erected at Athens by Pericles; and the authors of the *Antiquities* of that city suppose that a semicircular excavation in the rock of the Acropolis, below the South-Eastern angle, is the place in which it stood. It must have resembled a Theatre in form, but probably it had no scena, and in the gorge of the building might be a portico or colonnade. Pausanias says the roof was like the tent of Xerxes, which may imply that it was of a conical form. The colonnade was adorned with the prows and sterns, and the timbers of the roof were formed of the masts of the vessels which had been taken from the Persians.

Remains of Greek Theatres in Europe.

In the Supplement to Stuart's *Athens* is given the present state of the few Greek Theatres the destruction of which is not so complete as to prevent any trace of their plan from being discovered. Of those situated in Europe, besides the Theatre of Bacchus beforementioned, we select the following. At Cheronea are the remains of some, the seats of which appear to have been partly cut in the rock, and in which the diazomata are visible. In one at Argos, the lower range of seats coincides with the circumference of the semicircle, but from the appearance of the ground, it is probable that the two upper ranges were flanked by two walls perpendicular to the scena, and touching the back of the diazomatæ above the first range. Two flights of steps are observable, considerably distant from each other, for the purpose of ascending from the lower to the upper ranges of seats; and there were, probably, two others close to the external walls. On the banks of the Alpheus, at Megalopolis, has been a Theatre, which was erected on one side of an artificial mound.

Ruins of several Theatres are still to be seen in various parts of Asia Minor, and those which are in the best state of preservation are at Stratonicea, Miletus, and Laodicea; representations of which are given in the IId Volume of the *Ionian Antiquities.* In the walls are several semicircular-headed arches, formed by voussoirs, but not the smallest information can be obtained of the date of their construction; and, no doubt, they were erected at the time during which the Romans had possession of that part of the World. In one of the Theatres at Scythopolis, in Syria, Mr. Bankes has discovered a complete example of the echeic chambers under the seats, with a gallery of communication, affording access to each chamber, for the purpose of arranging and modulating the vases.

The Choragic Monument of Lysicrates.

When an individual among the Greeks gave a theatrical or musical entertainment, in which the performers contended with each other for the prize of superior skill, it seems to have been customary to erect a monument in honour of those who gained the victory. The person who gave the entertainment was called Choragus, and the edifice was called a Choragic Monument. The most splendid of these is that which was erected by Lysicrates, about 330 years before Christ, and vulgarly known as the Lantern of Demosthenes. It has a square basement, or pedestal, 12.654 feet high, and each side of which is 9.541 feet long; above this are three circular steps, which support a cylindrical building, 7 feet diameter on the exterior, and 11.25 feet high; this consists of six pieces of marble in the form of portions of a cylinder, cut by planes passing through the axis, and placed together on the pedestal, so as to form an entire cylinder with its axis in a vertical position; but, at each of the six places of junction, a column is introduced in such a way that half of it appears to project beyond the face of the cylindrical wall. This wall is quite plain to within 1.6 feet of the top, where there is sculptured a row of tripods surrounding the building. The columns are of the same height as the cylinder, *viz.* 11.25 feet, including the bases and capitals, and that height is equal to 9.64 diameters.

The columns may be said to be of the Corinthian Order; their shafts are fluted, and the longitudinal fillets that separate the channels, end at top in points of leaves. The base of each column consists of two tori with a scotia between them, and is connected with the pedestal by a congé, or inverted cavetto; the upper torus is in the form of an inverted echinus. The capital is separated from the shaft by a groove surrounding the column, and consists of elegant foliage, disposed about a cylindrical block, which seems to be a continuation of the shaft of the column; a small row of plain leaves, resembling those of the lotus, surrounds it at bottom, and above these is a taller row, composed of clusters of leaves resembling those of the nettle. From the middle leaf in front rise two stems, each of which afterwards divides into two others; of these one pair diverges to the right and left, and curls under the angles of the abacus, the other forms double volutes in front of the capital. The groove which separates the shaft from the capital of the column, seems to leave the lower course of foliage unsupported, and gives the column an unfinished appearance; but if, as is probable, the groove was intended to contain a metallic moulding or row of ornaments encircling the column, that objection is removed: we may observe, however, that though the column is, undoubtedly, in itself, highly elegant, yet the cutting of the capitals by the wall of the building must have always produced a disagreeable effect when the columns were viewed in flank.

The architrave is divided horizontally into three faciæ, and the frize is sculptured with figures representing the story of Bacchus and the Tyrrhenian pirates; in the cornice is a row of dentels resting upon the frize, and the entablature is crowned with a row of plain knobs instead of a cymatium. This kind of ornament above the cornice seems to have been very common in the ancient Temples, if we may judge from the many medals on which it is represented, though scarcely any example of it occurs, except in this building.

The frize and architrave are each formed of one block of marble, cut in the form of a ring; these are crowned by the roof, which is a solid piece of marble, approaching to a conical form on the exterior, and the interior is excavated in the form of a segment of a sphere. The whole roof, or *tholus*, rests upon the cylindrical wall, like that of the Temple of the Winds; the exterior is sculptured to represent a thatch, or covering of laurel leaves, and from the centre rises a tall flower, on which formerly stood a tripod. The tops of the leaves of the tholus approach nearer to a horizontal plane toward the top than they do toward the foot, which gives to the external surface the appearance of a curve of contrary flexure. There is no entrance to the building, nor is there any aperture to give light to the interior. See pl. vi. fig. 6.

Next to the Theatrical buildings of the Greeks it will be proper to show the disposition of the edifices which served for the public promenades and Baths of the citizens; for the Schools of Philosophers; and those in which instructions in gymnastic exercises were given, and the public combats of the athletæ were held. These *Palæstræ* and *Gymnasia* were essential to every Grecian city, for the small States of that Country being perpetually at war with each other, and their towns frequently in danger of a siege, such public institutions enabled the young people to study the Arts, and to practise the exercises which were to qualify them for the defence of the community to which they belonged. Little more of them is now to be known than what may be obtained from a general description given by Vitruvius, (v. 11.) which we have already extracted in our *Miscellaneous Division*, under GYMNASIUM, and which need not, therefore, be repeated here.

At Epidaurus, traces may be seen of a vast system of edifices, containing Temples, Baths, Xysti, and Theatres for the accommodation of persons visiting the Temple of Æsculapius for the recovery of their health. Similar edifices exist in ruins at Ephesus, Laodicea, Alexandria, Troas, and at many other places in Asia; and at Præneste, in Italy.

A very ancient edifice, probably a Palæstra, formerly existed at Thoricus, on the South-Eastern coast of Attica. It was of a rectangular form, 104.67 feet long, and 48 feet wide, and consisted of a space enclosed by columns, but without walls; the columns stood on a general basement formed in steps on each side, and were of the Doric Order, fluted at top and bottom only, but no part of the entablature remains. The number of columns in front of the building was seven, from which it is inferred that the building could not have been a Temple; since then there must have been a column opposite the doorway, contrary to the practice of the Ancients, and to every notion of convenience; the number in flank was fourteen. The height of the columns is 17.441 feet, and the lower diameter 3.317 feet.

In the Island of Delos also appears to have been a Palæstra, which, from the name of Philip of Macedon inscribed on the architrave, was probably erected in the time of that Monarch, though its form and the occasion of its erection are both unknown. The columns are of the Doric Order, and their style is lighter than that of any other known example of the Order. The height of the column is 19.305 feet, and the lower diameter is 2.958 feet; consequently, the height is equal to 6.5 times the diameter, and the height of the entablature is 4.912 feet, or $\frac{1}{3.9}$ of that of the column.

The face of the architrave is in a vertical plane, which, if produced, would fall about the middle of the length of the column in front; the faces of the metopes are in the same plane, and those of the triglyphs project about two inches in front, as is the case in the frize of the Temple of Apollo, in the same Island. The echinus in the capital has nearly the form of an inverted frustum of a cone.

This must be considered as the latest example of what may be called the Grecian Doric; that Order, soon after this time, ceased to be employed in Greece, and instead of it was substituted the Corinthian.

The remains of a building coming under the denomination of a Palæstra are still to be seen at Athens. The authors of the *Antiquities of Athens* call it the Stoa, and they suppose it to be that which Pausanias calls Poikile, and from which the followers of Zeno had the name of Stoics; but from the indications of a Roman style observed in it, the conductors of the recent edition of that Work, think it may have been one of the buildings erected by Hadrian.

It is a rectangular enclosure, 376 feet long and 252 feet broad; and in the middle of one of the shorter sides is an entrance gate, elevated on a stereobata, to the top of which there is an ascent by six steps. This portico, which is 34 feet long and 21 feet broad, has four Corinthian columns in front, and is covered by a pediment roof. The whole extent of this side of the enclosure is also ornamented with Corinthian columns detached from the wall, and standing on pedestals as high as the top of the stereobata; and the entablature of the wall is broken vertically, so as to project from the wall over each column. The two lateral walls of the quadrangle are extended about 16 feet beyond the line of that front, and each extremity is ornamented with a Corinthian pilaster. About the middle of each of the lateral walls was formed a projection towards the exterior, of about the same dimensions as the portico beforementioned, and, like it, intended probably for an entrance; and nearly midway between each of these projections and the two end walls of the enclosure, was formed a semicircular recess, 33 feet in diameter, which perhaps was intended as an exedra, or retired place for conversation.

There are traces, quite round the interior of the quadrangle, of a peristyle or colonnade, consisting of a double row of columns at about 23 feet from the walls; and near the middle of the quadrangle are some old foundations, but it is impossible to determine to what they have belonged.

Peristyle at Pæstum.

At Pæstum, in Italy, are the remains of a peristyle which, as has been said, was formerly considered to be part of a pseudodipteral Temple, but the destination of which is now thought to have been very different. The columns stood upon a rectangular basement, 177 feet long and 75 feet wide, with each side formed in steps like those surrounding a Temple. In front were nine Doric columns, a circumstance which, one would think, might have led to a suspicion that the building could not have been a Temple, since one of the columns must have been opposite the entrance. The peristyle has eighteen columns in each flank, and there is a row of columns along the middle of the interior, and parallel to the flanks, probably for the support of a general roof, which, as there was no cella, would require such support from the impossibility of getting materials long enough to extend across the breadth of the edifice. A work thus constructed may, with great probability, be supposed to have been intended for the performance of gymnastic exercises, for the delivery of Philosophical lectures, or it may have served as a market-place.

The height of the columns is 20.965 feet, and the diameter at bottom is 4.709 feet; but the sides of the shaft are remarkably curved; at one-third of the height the diminution is $\frac{1}{20}$ of the lower diameter; at two-thirds the diminution is $\frac{1}{12}$, and at the top of the shaft is $\frac{1}{8.04}$. Where the antæ of a Temple would be, there are here two pilasters which present some peculiarities. They are 20 feet high, including the capital, the height of which is 3 feet; the breadths at top and bottom are nearly equal to the upper and lower diameters of the columns, and the sides are curved in a similar manner. A plain fillet separates the shaft from the capital, which has the form of a cavetto, projecting at top and resembling that which crowns Egyptian buildings; it is covered by a square abacus, and has a small ornament suspended from each angle.

The peristyle was crowned by an entablature, of which the face of the architrave, if produced, would fall a little within the foot of the column; and a large moulding, now destroyed, separated this member from the frize. The exterior of the frize is in a vertical plane, which falls a little within the hypotrachelion, and there are no triglyphs. The cornice is entirely lost.

It is right to observe here, that, in modern Architecture, the name of *Portico* is given only to the columns and roof placed before a doorway; but the Romans applied the term, generally, to any system of columns supporting a roof. Thus the colonnade surrounding a building on the exterior, or any court in the interior, was called, indifferently, peristyle or porticus.

CHAPTER VII.

The Principles of Grecian Architecture.

The reason of adopting proportions in the formation of Temples.

It seems to have been the intention of the ancient Architects that the lengths, breadths, and heights of Temples, as well as the dimensions of all their members, should constantly bear certain proportions to each other; so that all such buildings might be constructed according to a system founded on the established relations between the parts of which they were composed. This is what is signified by Vitruvius, in the Ist Chapter of the IIId Book; and the reason given by this writer for adopting such a system of proportions in sacred edifices is, that the different parts of the human figure bear also certain proportions to each other, which are nearly constant; and he means to infer that because Nature has thought fit to use proportions in the formation of her noblest creature, proportions should also be used in those edifices which, being appropriated to the worship of the Deity, ought to be of the most perfect construction.

The relations between the several members of the Grecian Orders will be presently exhibited from the existing examples of those Orders; we purpose here only to show what relations, if any, subsisted in the general elements of the Temples themselves.

The proportion between the length and breadth of Temples.

In the IVth Chapter of the IVth Book, Vitruvius, speaking of rectangular Temples surrounded by columns, states that the length of the Temple should be double its breadth; and, as he mentions afterward the proportions of the cella and pronaos, his meaning probably is, that that proportion should subsist between the two sides of a parallelogram which pass through the centres of the surrounding columns, or which circumscribe the bottoms of all their shafts.

But though there is an approximation to this proportion in all the Greek examples, it cannot be said that it holds good precisely in any one of them. In the Temple of Jupiter, at Selinus, the length is to the breadth in the ratio of 2.05 to 1; in the Temple of Theseus, these terms are to one another as 2.3 to 1; and from a mean of the six best examples of the Doric Order in Greece and Sicily, the proportion between the length and breadth is as 2.21 to 1.

Distribution of the columns in front and flank.

In order to give to the flank and front of a Temple the proportions he requires, measuring on lines passing through the centres of the columns of the peristyle, Vitruvius directs that the number of intercolumniations on each flank should be double the number on each face; which, if all the diameters of the columns and the intervals between them were respectively equal, would be quite correct; but in the Greek Temples these two conditions do not take place; and as the central intercolumniation is made wider than the others, in order to afford sufficient space for persons who are to enter the door, while those of the flanks are nearly all equal; it follows, that by this rule the length of the Temple would be found less than twice its breadth. In order, perhaps, to approach nearer to the required ratio, the Temples of Jupiter, at Selinus and at Ægina, have the number of columns in flank exactly double the number in front, and, in fact, in those examples, the length is to the breadth as 2.1 to 1, which is nearly the proportion prescribed by Vitruvius.

But in the later examples of the Doric Order, the Greek Architects seem to have intended to increase the ratio of the length to the breadth, by adopting a rule nearly as simple as that of Vitruvius; for we find in the Temples of Theseus and of Minerva Parthenon, at Athens, and in those of Juno Lucina and of Concord, at Agrigentum, the number of intercolumniations in flank is double the number of columns in front, or which is the same thing, the number of columns in flank is one more than double the number in front; and in these examples, the lengths of the Temples are to their breadths nearly in the ratio of 2.3 to 1. The proportion is still higher in the two smaller Temples at Selinus, and in that at Ægesta, which have the number of columns in flank greater, by two, than double the number in front. Perhaps the Greeks were led into this deviation from the simplicity of the first rule, by some idea of the beautiful appearance afforded by a long line of flank columns, when viewed by an eye situated near one extremity of the building.

The g proport were strictly tered

We should be cautious of adopting, too literally, the opinion often asserted of the perfection of that system of proportions which prevails in the Grecian Architecture. It has been alleged that the magnitude of any one member being given, the form of the whole building, and the distribution of all its parts were determined from it by invariable rules; but this must be understood with some limitation, for the whole practice of the Greeks shows that, in their Architectural works, they used their discretion, and indulged in considerable liberty. It may, however, be safely affirmed, that when a Greek Temple of any given Order was to be built, it was only necessary to decide upon three arbitrary points; *viz.* the diameter of the column, the number of columns in front, and the species of intercolumniation; then every part of the edifice might be determined by established proportions, with a few modifications depending upon local or other circumstances.

Vitruvius seems to consider that a particular number of columns was necessary in front of each of the different species of Temples; *viz.* six for peripteral, eight for pseudodipteral, and ten for hypæthral Temples; but this rule has not been adhered to in practice; the latter kind of Temples, for example, have sometimes ten, sometimes eight, and, occasionally, only six columns in front. On contemplating the forms of the Greek Temples, we cannot avoid perceiving that they possess a great and noble simplicity of character; every member appears to have its use, and the horizontal lines of the stereobata and entablature, being unbroken, permit the length and breadth of the edifice to be appreciated at once by the eye.

Dime of the cian colu

The Orders, or systems of Architecture, are distinguished by the forms of the columns, and of the entablature above them; and from the account that has been given of the most celebrated buildings of Greece, we shall be able to draw some conclusions respecting the general features of the Orders employed in that Country; and obtain a knowledge, not of the proportions which are to be invariably adhered to in the construction of an Order, but of those from which a deviation may be permitted, only within certain limits, which are authorized by these examples.

The following Table, formed from the Works referred to in the preceding account, exhibits, in one view, the dimensions, in English feet, of the columns and entablatures belonging to the principal examples of the Grecian Doric Order, and will be useful in enabling us to ascertain the characteristic proportions of that Order

sec-
e.

in particular. The height of the architrave is measured to the top of the fillet between it and the frize; the height of the frize is measured to the top of the capital of the triglyph, and the height of the cornice to the top of the corona; the height of the epitithedas is not included.

Names of Edifices.	Height of shaft.	Height of capital.	Bottom diam.	Upper diam.	Height of architr.	Height of frize.	Height of cornice.	Height of entablat.
Temple at Corinth..................	21.335	2.365	5.83	4.34	4.722	....	....	....

pro-
of
cian
rder.

In all the examples of the Grecian Doric Order that have been given, we may observe that the style is extremely heavy. The height of the columns, including the capitals, is, except in one or two instances, only from four times to five and a half times the diameter at bottom. The capital is equal in height to about half the lower diameter, and the height of the entablature, not including the epitithedas, is about one-third of the height of the column, or about one-fourth of the whole height of the Order; that is, of the column and entablature together: the heights of the architrave and frize are nearly equal to each other, and that of the cornice is about half the height of either of the others, or one-fifth of the whole entablature. The members of the whole Order are large, and are composed of few parts, as if it was intended that the buildings should be seen to advantage from a considerable distance, where the effect of small ornaments would have been lost.

de-
of
mn.

The more particular characters of this Order may be expressed as follows: the columns have no bases, and this rule may be considered as without exception, if we omit two or three of the examples in Italy and Sicily: perhaps, the edifice, being raised on a platform the sides of which were formed in steps, these served as a general base for the whole system of columns, and a particular base for each was thought unnecessary. The shafts are cut longitudinally, by twenty *striæ*, or channels, every two of which, in almost every case, unite in an edge; the transverse section of a channel is frequently circular, but, in some cases, as in the Temple of Apollo, and in the Portico of Philip, they are elliptical. This channelling, however, was not universally adopted, for in several examples which have been described, the channels exist only very near the capital and at the foot of the column, the rest of the shaft being plain. The abacus is, in every example, of a square form, with vertical sides; the echinus, though beautifully curved in the vertical direction, is nearly an inverted frustum of a cone, but rounded abruptly at the upper extremity; the lower extremity is surrounded by three or four annulets projecting from it, having their upper and lower surfaces either horizontal or inclined upward from their outer extremities, and having their exterior faces either vertical or parallel to a tangent drawn to the echinus from its foot. At a short distance below the echinus is cut one or more horizontal grooves, generally rectangular, round the column, making a separation between the hypotrachelion and the rest of the shaft. By a mean of several examples, the projection of the face of the abacus, from the axis of the column, is equal to 0.565 of a diameter of the column.

A remarkable circumstance in some of the Grecian Temples in Sicily and Italy deserves to be mentioned; *viz.* that the diameter of the column at the hypotrachelion, is considerably contracted, and the echinus seems to rest on the top of a row of leaves which crowns the shaft. It is difficult to account for this caprice, which can hardly be reconciled with any principle of good taste, as it destroys that appearance of strength which should be the inseparable quality of a column.

Diminution
of the
shaft.

The shafts of the Grecian columns have been shown to diminish, invariably, from bottom to top; a practice supposed to have been drawn from the law observed by Nature in the formation of the bodies of trees. Now, if columns were to be viewed from an infinite distance, there is no reason why short and tall columns, of one and the same Order, when employed for the support of buildings of similar forms, should not themselves be similar bodies; in which case the upper and lower diameters would always bear a constant ratio to each other, or to the length of the shaft; but on account of the apparent diminution of objects, when elevated above the eye, it is evident that this constant ratio ought not to subsist if the apparent forms of all columns, of the same Order, are to be similar when the eye is situated at the same distance from a lofty as from a short column, and in, or near a horizontal plane passing through its foot; and it is also evident, that the difference of the upper and lower diameters should be less as the height of the column increases, on account of the greater diminution which the upper part of the taller object will experience. It is for this reason Vitruvius recommends that the upper diameter, which he makes equal to five-sixths of the lower, when the column is not more than fifteen feet high, should be seven-eighths of the lower, when the column is fifty feet high. In these extreme cases, the differences of the upper and lower diameters are one-sixth and one-eighth of the latter respectively; and if we assume the mean height of the shaft of a Doric column to be 4.5 diameters, the differences of the semi-diameters at top and bottom will be $\frac{1}{54}$ and $\frac{1}{72}$ of the lengths of the shafts respectively

But, whatever propriety there may be in these rules, and Vitruvius professes to follow those given by the Grecian Architects, it does not appear that, in practice, the latter paid much attention to them; for, of sixteen examples of the Grecian Doric Order which we have compared together, we find that the difference between the upper and lower diameters of the shaft varies from one-fifth to one-third of the lower diameter, and the mean of all was one-fourth nearly. But as this mode of expressing the diminution does not indicate, what seems to be the most important point, *viz.* the obliquity of the side of the shaft to the axis, supposing the former to be rectilinear, which is nearly the case; we have compared the excess of the lower above the upper semidiameter with the length of the shaft, and we have found that, when the columns were between fifteen and twenty feet high, the diminutions were from $\frac{1}{38}$ to $\frac{1}{70}$ of the height of the shaft, and the mean was $\frac{1}{50.8}$; when they were between twenty and thirty feet high, the diminutions were from $\frac{1}{25}$ to $\frac{1}{50}$, and the mean was $\frac{1}{37}$; and, when between thirty and fifty feet high, (leaving out one example in which the diminution was only $\frac{1}{16.5}$.) the diminutions were from $\frac{1}{34}$ to $\frac{1}{65}$, and the mean was $\frac{1}{48.6}$; from all which it appears, that nearly the same diminution was given to the highest as to the lowest columns; of the intermediate columns, two, whose heights were equal, differed in their diminutions as much as $\frac{1}{22.6}$ and $\frac{1}{38.8}$. Either, then, no Optical principle was adhered to in giving the diminutions, or they must have been regulated by the situations of points of sight which we have it not now in our power to ascertain. The variation of the diminution on account of the point of sight being very near the column is, however, of little consequence; for as is observed by Sir William Chambers, the nearness of the object renders the image thereof indistinct, and, consequently, any small alteration imperceptible.

Form of the shaft.

It has been said that the outline of a section of the shaft, passing through the axis, is a curve concave towards the axis. This form is alluded to by Vitruvius when he describes the column as having a swell, or entasis, in some part of its length. His Commentators, however, are not agreed whether he means that the middle part of the shaft should be greater in diameter than the bottom, or whether the section should diminish from bottom to top, so that each side may be in a curvilinear direction, presenting its concavity to the axis, which would give the appearance of a swell. Palladio felicitates himself upon the former idea, but the measurements of all the ancient examples have confirmed the general opinion, which is in favour of the latter. The only argument, if it may be called one, which could be offered in support of the other is, that a timber column compressed by a weight, acting in the direction of its length, would swell out near the middle before breaking, and it is conceivable that some observation of this fact may have suggested the idea of giving to columns a similar swell, to men who were bent upon copying Nature even in her deformities; but, to give such an appearance as an ornament is, evidently, one of the greatest abuses of principle into which a depraved taste can fall, and, except something like it which occurs in a few of the Egyptian examples, it was reserved for an Age later than that of the Greeks to incur the reproach of such deviations from propriety.

The curvature of the outline of the shaft is supposed to have been given from some refined perception which the Greeks might have had on the subject of the apparent diminution of objects on account of their height above the eye; and Vitruvius seems to think that it was intended to correct that apparent diminution in some way or other. The Roman author does not explain himself upon this subject, but modern artists, who entertain the same opinion, found it on the circumstance, that the sides of the shafts of columns which are, accurately, either cylindrical or conical, from some cause with which we are not well acquainted, assume, to the eye, the form of curves whose convexity is toward the axis; this appearance conveying an idea of weakness, the Ancients might have attempted to remedy it by giving them a convex form on the exterior, in order to make them appear conical. If we suppose that the Greeks had this notion, it must be owned that they did not always confine themselves to the mere correction of the concave figure; for they made the shafts of some of their columns, as those in the Temples at Pæstum, to curve so much as to appear very sensibly convex; and this inclines us to favour another opinion, which is, that the curvature of the profile was merely an imitation of the forms of certain trees.

The apparent concavity of the conical shaft of a column is a fact of general observation, but it is at variance with the form determined by the rules of perspective, and no satisfactory reason has yet been assigned for it. The opinion at present received is, that it may be the result of an erroneous judgment which the mind makes of relative magnitude, when bodies of different sizes are presented, at the same time, to the eye: thus the entablature and stylobata of a building produce perceptions of magnitude which cause the smaller object between them, *viz.* the shaft of the column, to appear less than it is in reality. This explanation is liable to some objections, and we venture to suggest the following, which has the advantage of being less Metaphysical. When we direct the axis of the eye to the middle of a tall column, the organ accommodates itself to the distance of that part of the object in order to obtain distinctness of vision, and then the oblique pencils of light from the upper and lower parts of the column, do not so accurately converge on the retina; hence arises a certain degree of obscurity, which always produces a perception of greater magnitude than would be produced by the same object if seen more distinctly. The same explanation may serve to account for the well-known fact, that the top of an undiminished pilaster appears so much broader than the body of its shaft; to which, in this case, may be added some prejudice in the mind, caused by our more frequently contemplating other objects, as trees, which taper towards their upper extremities.

Appar diamet colum the ang buildi

Vitruvius, in the IId Chapter of the IIId Book, considers that the diameters of columns at the angles of buildings appear smaller than those of the intermediate columns in the peristyle, on account, as he says, of their being more surrounded by the air; that is, probably, on account of the columns, in one case, being seen against a bright ground, and, in the other case, against the walls of the building, which being behind the colonnade are generally in shadow: and, in order to compensate for this Optical diminution, he recommends the former columns to be made thicker than the latter by $\frac{1}{50}$ of a diameter. This rule is, no doubt, drawn from the general practice of the Greek artists, who in the Temples of Theseus and in the Parthenon have made the columns at the angles to exceed in diameter the intermediate columns by $\frac{1}{28}$ and $\frac{1}{44}$ of a diameter respectively. Vitruvius also directs that the columns between the antæ before the pronaos should be less in diameter than those of the peristyle, or colonnade surrounding the Temple, for a similar reason. But there is a difference of opinion among modern artists concerning the apparent magnitudes of columns which are seen against a bright ground; to some eyes they appear larger than those seen against a dark ground, though the former is considered as the more general case, and these opposite deceptions admit of explanation from Optical principles. Both opinions may be confirmed by the practice of the Ancients, since, though it was generally the case, they did not always make the angular columns thicker than the others; and in the Temple of Minerva at Syracuse, the columns of the pronaos, which must have been seen against a dark ground, are thicker than those which surround the Temple, contrary to the precept of Vitruvius, and to what we observe in many other buildings.

Other reasons may be offered to justify these rules of Vitruvius; first the angular columns should be thicker than the others in order to give them more strength, where greater strength is required; secondly, the columns between the antæ should be more slender than those of the peristyle, not only because they have less weight to support, but also, because they will thereby have a greater apparent distance in perspective. It may be observed here that these interior columns were, by the Ancients, placed not exactly opposite those of that part of the peristyle which was in front, in order that they might not be entirely concealed by the latter.

The architrave is plain, and its face is situated nearly vertically over the circumference of the foot of the column, though some examples exist in which this is not the case; in the Portico of Philip, the face of the architrave, if produced downward, would cut the front of the shaft of the column about the middle of its height; and, in the Temple at Pæstum, it stands over the circumference of the top of the shaft. Above the facia of the architrave is a plain rectangular fillet which serves to mark the separation of this member from the frize.

It seems to have been the intention of the Greek artists to consider the exterior faces of the triglyphs as coinciding with the general face of the frize, and to consider the metopes as sunk within it; for in the best examples of the Order, such as the Temples of Theseus and of Minerva, at Athens, the faces of the triglyphs are in a vertical plane coinciding with that of the architrave nearly, and the metopes are in a plane parallel to that of the architrave, and distant from it, towards the axis, about one-twentieth of the diameter of the column. There are some exceptions, however, to this disposition; for in the Temples at Selinus and at Ægesta, in Sicily, and of Apollo at Delos, the faces of the metopes are in the same vertical plane as that of the architrave, and those of the triglyphs project before it. The breadth of the triglyph is nearly an arithmetical mean between half the upper and half the lower diameter of the column, and is divided into three vertical parts, each of which, called by the Greeks *meros*, is formed into three sides, of which one is parallel to the front, and the others make angles with it equal to those between the sides of a regular octagon, so that there are left two channels between the three parts; the middle of a triglyph is made to correspond with the axis of each column, but the exterior edges of the two extreme triglyphs are placed close to the extremity of the frize. This may be considered as universal in the Grecian Doric Order; the only exception, perhaps, being in the hexastyle Temple at Pæstum, where the centres of the extreme triglyphs correspond with the axis of the columns at the angles.

The metopes are nearly equal in breadth to the height of the frize; consequently they are nearly of a square form, though the practice is not universal; and this equality of breadth, together with the disposition just mentioned, of the extreme triglyphs, is the cause why the interval of the two columns nearest to each angle of the building is always less than that between any two of the other columns. On the flanks of the building, as well as on the front, a triglyph is placed close to the angle, so that, at each angle, two triglyphs come together; a circumstance which is at variance with the idea that the triglyphs represent the ends of beams placed across the building, since two such beams could not have their extremities visible on both faces, as has been before observed.

Distribution of the triglyphs, &c.

An opinion has been entertained that the Greek artists aimed at perfect regularity in the dimensions and disposition of the triglyphs and metopes, and, consequently, in the magnitude of the intercolumniations, which were limited by the necessity of having a triglyph to correspond with each column, and either one or two over each interval between the columns. It has been supposed that those persons considered it indispensable that the breadth of the triglyphs should be invariably equal to half a diameter of the column, and that the metopes should be perfect squares. In consequence of this opinion, no small embarrassment has been felt in distributing the several parts of an edifice which was to be constructed according to this Order; and the formation of a Doric design, in which all the conditions shall be fulfilled, has been considered as a Mathematical problem of great intricacy. But the works of the Greek Architects do not indicate that any such perfect regularity was attained in practice. The triglyph at the angle is frequently made wider than the others; and, in the most superb building of antiquity, the Parthenon itself, all the metopes are not complete squares; the three of them nearest to each extremity of the front having greater breadth than height, in order, no doubt, to gain a small increase in the corresponding intercolumniations, for the convenience of persons passing between the columns. In some of the ancient Grecian Temples, it appears that the spaces between the triglyphs remained unclosed; in proof of this it has been observed that in the *Iphigenia in Tauris* of Euripides, Pylades proposes to Orestes to enter the Temple through those spaces. These apertures, which must have been in the entablature over the walls of the cella, were, probably, as is observed by Lord Aberdeen, for the purpose of giving light or air to the interior; or it might be that the Temple was left in an unfinished state.

It has been shown that the Doric frize is sometimes ornamented with sculptured figures; and of these the best specimens are, perhaps, found in the Temples of Theseus and of Minerva at Athens. One peculiarity in the design of the Greek sculptured frizes deserves to be noticed, *viz.* that where sitting figures are introduced, the height of them is equal to that of the standing figures, so that, if the former were to rise from their seats, they could not be contained in the frize; this was probably done to avoid leaving unoccupied that part of the frize which would be above the head of the sitting figure. A proof that in sculpture, as well as in Architecture, the Greeks sometimes sacrificed Truth and Nature to the production of a rich effect.

The corona or cornice.

Above the frize is a course of masonry which seems to support the corona, and, on that account, is called the bed-moulding of that member; it is generally divided horizontally into two faciæ, both of which project beyond the faces of the metopes and triglyphs, being broken vertically, at intervals, so as to form such projections; and those parts which are immediately above the triglyphs are called the capitals of those ornaments. The corona, properly so called, which forms the principal member of the cornice, is a course of masonry placed above the bed-moulding; and, from a mean of several examples of this Order, we find that its projection from the axis of the column is equal to 0.882 of a diameter of the column, or 0.426 of a diameter from the face of the frize or of the architrave. The soffit, or under surface of the corona, is generally formed in an inclined plane both on the faces and flanks of the building, the outer extremity being the lowest. The mutules are thin plates applied to the soffit of the corona, both over the triglyphs and over the middle of the metopes; they are of a rectangular form; their length, in the direction of the face of the building, is equal to that of the capital of the triglyph, and their breadth equal to the projection of the corona beyond that capital. From their under surfaces are suspended three rows of conical or cylindrical or sometimes trochoidal guttæ, or drops, each row being parallel to the face of the building and containing six drops. One row of similar drops is attached to the under surface of a block, to which the name of *regula* is given, and which is placed under each triglyph against the face of the architrave.

Over the front and rear faces of the building, a fillet or some small moulding, above the plain face of the horizontal corona, forms the termination of the Order: the inclining sides of the pediment consist each of a plain member similar to the corona with a fillet above, and over this is a large moulding, generally in the form of a cymatium, but sometimes of an echinus, which being the crowning member of the building, has the name of epitithedas. This moulding in some cases, perhaps, returned along both flanks in horizontal directions, and, consequently, formed the summit of the Order on those parts; but, in the Parthenon it only extends a little way on each flank and terminates in a lion's head. Over the cornice of the flank is, in this case, a row of fleurons, at intervals from each other, extending from front to rear of the building.

The fillet, or the curvilinear moulding, at the upper part of the corona, has its under-surface generally excavated so as to form a bird's-beak; this practice was, probably, in some measure intended to prevent the rain from the upper part of the building flowing down upon the part below; but it is, besides, supposed to have been dictated by the wish to produce a great contrast between the light and shade, in preventing any reflected light from falling upon the part in shadow, which, afterward, arriving at the eye, would diminish the obscurity.

Doric pilasters.

With respect to the antæ pilasters, in the Doric Order, we find, from the Greek examples, that, except where the pilasters are placed on the pavement of the Temple, which is higher than that of the peristyle, the pilasters are of the same height as the columns of the peristyle; they are rather less in breadth than the diameters of those columns, and the breadths at top and bottom are equal. Instead of an echinus, similar to those of the capitals of the columns, there are, in some examples, three plain faciæ formed at the top of the pilaster, of which the upper one projects over the shaft about half as much as the abacus of a column projects over the top of its shaft, and its under-surface is, usually, excavated upward so as to form a groove along the face and flanks of the pilaster. In other examples, as in the Athenian Temples, the upper facia is formed in mouldings the sections of which are curvilinear, and the under-surfaces of some of these are also excavated upward so as to give to the mouldings the bird's-beak form. The thickness of the antæ pilasters in flank is about equal to half the diameter of the columns in the same building: greater thickness than this would have made them appear too heavy.

The pilasters being of equal breadth at top and bottom, while the columns diminish in diameter upward, it is evident that if the former were equal in breadth to the lower part of the column, they would appear larger than the columns; and this effect would be increased when the pilasters were viewed obliquely on account of the diagonal breadth being larger than that of the face. These circumstances justify the rule given by Vitruvius, and which the Greek artists have uniformly adhered to; *viz.* to make the breadth of the pilaster rather less than the diameter of the column adjacent to it, for, by so doing, they both appear to the eye of equal magnitude.

Uncerta estimat the anti quity of amples their pr portion

In contemplating the examples that remain of this Order, in Greece and Sicily, we find that its proportions were various in respect, first to the ratio between the height of the column and its diameter; secondly, to the degree of diminution of the shaft; thirdly, to the ratio between the height of the capital and the diameter of the column, and, lastly, to the height of the entablature. Various efforts have been made to determine the degree of antiquity of any example by the proportions of the columns in some or all of these respects; but the only thing certain is, that, in general, the oldest columns are those the heights of which are the least multiples of the diameters of their shafts; the other conditions are too variable to serve for the establishment of a general law.

The practice of embellishing the Grecian Doric Temples by painted ornaments, may be inferred from the description we have given of those on the Parthenon; and we have only to add that this practice seems to have been very general. The traces of the paintings are, now, nearly obliterated, but, from what has been discovered, it is evident that the greatest pains have been taken in executing the outlines of the ornaments, which have been drawn by masterly hands. We cannot, however, avoid contrasting this species of embellishment with that executed in the marble itself; the former has long since vanished, while the latter remains an eternal monument to the talent of the artist.

Genera proport of the cian Io Order.

From the examples that have been given of Temples constructed by the Greeks according to the Ionic Order, we perceive that the essential forms remain nearly the same as those of the Doric Order, but that the difference in the proportions of the column and entablature is considerable. In order to make the comparison with more facility we subjoin a Table similar to that which has been given for the Doric examples. The dimensions are in English feet, and the height of the epitithedas is not included in that of the cornice.

Names of Edifices.	Height of shaft.	Height of capital.	Height of base.	Lower diam.	Upper diam.	Height of architr.	Height of frize.	Height of cornice.	Height of entablat.
Minerva Polias at Athens.....	22.76	1.954	1.108	2.786	2.291	2.354	2.217	0.942	5.513
Erectheus at Athens..........	19.8	1.833	0.921	2.317	1.933	2.084	1.98	0.871	4.935
Temple on the Ilyssus near Athens	12.789	1.014	0.889	1.783	1.517	1.644	1.472	0.484	3.600

By taking a mean of these examples, we find that the height of the columns is 8.95 times the diameter of the lower part of the shaft, which is a much higher ratio than was found to subsist in the Doric Order. A new member is introduced; *viz.* the base of the column, the height of which is about equal to half a diameter; the capital is altered in form from that of the Doric Order, though not in proportion. The mean height of the entablature, not including the epitithedas, is $\frac{1}{44}$ of the height of the column, or $\frac{1}{5}$ of the height of the whole Order. The heights of the architrave and frize are nearly equal to each other, as in the former Order, but that of the cornice is about one-third of either of these, or one-seventh of the whole height of the entablature. From all which it follows that the general effect of this Order is considerably lighter than that of the Doric.

In the Temple of Erectheus, and in that on the Ilyssus, the bases of the columns consist of two tori, of a semicircular form, separated from each other by a scotia, with plain fillets above and below; the lower torus rests immediately upon the pavement, or upon a step which serves as a general plinth for all the columns of the building, and the upper fillet is joined to the shaft by a curve, concave outwards, called the *apophyge.* In the bases of the columns of the Erectheum, the fillet above and below the upper torus projects only as far from the axis of the column as the centre of the curvature of the torus; but, in the Temple on the Ilyssus, the fillet below the upper torus projected as much as the extremity of the curvature of the torus itself. The fillet below the scotia falls vertically over the centre of the lower torus, but its projection is greater in the Temple of Minerva Polias than in that on the Ilyssus, and, on that account, the base of the former possesses greater elegance. In the Temple of Minerva Polias, the thicknesses of the upper torus, the scotia, and the lower torus are, nearly, in the ratios of the numbers 6, 7, and 8 respectively, and the lower torus projects, from the axis of the column, as much more than the upper torus as is about equal to its thickness; while, in the Temple on the Ilyssus, the projection was not above half as much, and, on this account also, perhaps, we may be allowed to prefer the former. Bases, consisting of such members as we have described, are all called Attic, though they seem to have been used, indifferently, both at Athens and in Asia. The bases of the Ionic columns, belonging to the Asiatic Temples, are, in general, far from possessing the elegance of form which characterises those belonging to the Temples of Athens: in the Temples of Minerva Polias, at Priene, and of Apollo Didymæus, at Miletus, the lower part of the base of the column consists of three double astragals, separated from each other by two small scotiæ, and, above these, is a large torus, nearly equal, in height, to all the rest of the base, and seeming to crush the small mouldings below.

In the Greek bases the mouldings sometimes are, and sometimes are not, ornamented with sculpture. In the Temple of Minerva Polias, at Athens, the upper torus is enriched with what is called a guilloche; in the Temple of Erectheus and that on the Ilyssus, it is fluted horizontally: but this latter method, by cutting the profile of the principal moulding into a great number of minute parts, destroys the character of the whole, and is, perhaps, not to be considered as the most happy refinement adopted by that ingenious people.

The shaft.

The diminution of the shaft, or the difference between its upper and lower diameters, is equal to about one-sixth of the latter, or the difference between the upper and lower semidiameters is $\frac{1}{90}$ of the whole length of the shaft, (taking the mean dimensions of the principal columns of this Order in existence.) Consequently, the diminution in the Ionic Order is much less than in the Doric. A section of the shaft, through the axis, has its sides gently curved, and the surface of the shaft is channelled, longitudinally, in twenty-four or thirty flutes, of a semicircular or semielliptical form, and a plain fillet, equal in breadth to about a sixth part of the breadth of a channel, is left between every two channels.

The capital.

In this Order, the capitals are distinguished by volutes, the planes of which are parallel to that face of the building before which they stand, except in the capital on the column at each angle of the building, which has volutes on both the exterior faces of the capital; and, in order to give symmetry to the two sides of each face, the volutes which meet at the exterior angle are formed obliquely to the faces; for this purpose a projection is made diagonally at that angle, of such extent that the horizontal distance of its extremity from the centre of the column, in a plane parallel to the face of the building, is equal to that of the volute at the next angles of the capital. The volutes being formed on each side of this diagonal projection, the two exterior faces of the capitals on the columns at the angles are similar to each other, and to the front of the capitals of the other columns: by this ingenious contrivance, the Greek artists avoided the defect of presenting the profiles of the volutes of the angular columns on the side faces of their buildings. The spiral curves, or balthei, composing the volute, are double or triple; the principal one springs from under each extremity of the face of the abacus, and bends downward, while the others hang in festoons on the face of the capital, between the volutes.

The top of the shaft of the column is, sometimes, surrounded by an echinus, passing behind the volutes, and having its surface sculptured with figures representing oves and darts; below this is an astragal, and the hypotrachelion, between the echinus and astragal, is ornamented with delicate sculpture. Each side face of the volutes presents the appearance of two frusta of irregular cones, joined together in the middle, and surrounded by rings; and the abacus, instead of being prismatic, as in the Doric columns, has each of its four faces moulded in the form of a cymatium.

The entablature.

The architrave is either plain in front, or it is divided into two or more faciæ, of which each projects over the one below it. The frize and corona are either plain or sculptured; and the bands which separate the architrave from the frize, and the latter from the cornice, are formed in mouldings, which, also, are generally adorned with sculpture. In some examples, as in the Temple of Minerva Polias at Priene, there is a row of dentels immediately above the frize, and over these comes the moulding which forms the bed of the corona. In this situation, we must consider the dentels as representing the extremities of the smaller joists, placed above the timbers of the frize, to support the covering of the roof. The soffit of the corona is excavated so as to form an inverted channel, in a direction parallel to the face of the building, and occupying nearly the whole breadth of the soffit; this was, probably, intended to prevent the rain which fell on the roof from running down the entablature. The lower extremity of the face of the corona is in a horizontal plane passing through the foot of the bed-moulding of the cornice; consequently, the latter member is concealed from the view by the projecting corona, except when the spectator is almost close to the building. By a mean of several examples, the projection of the corona is 0.9 of a diameter from the axis of the column, and 0.41 of a diameter from the exterior of the frize. An epitithedas, generally, in the form of a cymatium, finishes the entablature on the inclining sides of the pediment, and, sometimes, it is continued on the horizontal cornices of the flanks of the building.

Ionic pilasters.

The antæ pilasters employed in this Order have capitals which are sometimes similar to those of the columns, but without volutes; in other cases they consist of several mouldings either plain or richly sculptured. Their bases are, also, generally, similar to those of the columns, but a remarkable difference occurs in the bases of the pilasters at the Erectheum; the lower torus, instead of being smooth or cut in concave flutes, is formed into a number of astragal mouldings, like a cluster of reeds placed in a horizontal position. The breadths of the shafts of the Ionic pilasters, like those of the Doric Order, are less than the diameters of the columns, and they have no diminution.

It is said that the earliest specimens of the Ionic Order of columns were not in possession of that which, afterward, became one of its most distinguishing characters; *viz.* the volutes in the capital; and this strengthens the opinion that the Order was, originally, nothing more than an improvement on the Doric, by making its columns more slender than those of the more ancient Order, and by giving them bases. The volutes might, subsequently, have been added, in imitation of the small branches of trees, placed about the capital to decorate the Temple; for these, curling under the angles of the abacus, would easily lead to the idea of a permanent ornament like that in question.

Our knowledge of the Greek Corinthian Order imperfect.

The opinion most generally received among the antiquaries of the present day is, that the capital of the columns of the Corinthian Order is an improvement on some of those which crowned the massive columns of Egypt, and the foliage employed on the latter, certainly, in some cases, resembles that which adorns the former. But, without going so far as Egypt for the origin of this capital, we think we may, with equal propriety, consider it as an extension of the principle exhibited on some of the columns at Pæstum, the capitals of which very much resemble vases placed on the stems, and surrounded by the leaves of plants, and it required but the taste of a sculptor of the best days of Greece, by giving height and delicacy to a Doric member, thus ornamented, to produce the elegant capital which adorns the Corinthian column. However this may be, on account of the small number of examples of this Order remaining in Greece, and the uncertainty we are in, whether these are to be considered as correct specimens of the style adopted in that Country, we think it advisable to postpone the general description of the Order till we can introduce it into our account of the Roman Architecture, of which it forms a distinguished part. The few Greek Corinthian examples which can be referred to, are those of the Tower of the Winds, the Choragic Monument of Lysicrates, and the capital of a pilaster at Eleusis. See plates vi. and vii.

Upper; lower t of colu

The hypæthral Temples of the Greeks generally contained in their interior two tiers or Orders of columns placed one above another; but, of such a disposition the only remaining example, which is sufficiently perfect to allow us to form an opinion of the principles on which it was regulated, is the great Temple at Pæstum. In that edifice the columns of both tiers are of the Doric Order, and similarly proportioned; a plain architrave rests on the abaci of the lower columns, and the upper columns are placed vertically over those below, but the height of the former is equal only to about four-sevenths of the others. We learn from Pausanias that the Temple of Minerva at Tegea, which was built in the XCIVth Olympiad, (about 400 years before Christ,) was adorned interiorly with two rows of Doric columns, surmounted by others of the Corinthian Order; or, as Lord Aberdeen supposes, with Ionic columns below, and Corinthian columns above. Those of the exterior peristyle he supposes to have been of the Doric Order.

Opinio conce the or of Car tides.

Besides the three kinds of columns which have been just described, we find, in that division of the triple Temple at Athens, which was dedicated to Pandrosus, female figures employed for the support of the entablature. These figures are called Caryatides, and it has been a subject of much inquiry how the human figure was first employed for such a purpose. If, as Vitruvius intimates, some Grecian artist had conceived the notion of making the proportions of the Doric and Ionic columns the same as those of the human figure; it is not unreasonable to suppose that it might, also, occur to an artist, either Grecian or Egyptian, to cut the column in the form of a man or woman; the idea of making such figures serve for the support of an entablature would easily originate in what must have been the subject of daily observation, *viz.* the application of human strength to the bearing of burthens. The sculpture might, at first, be rude, and, perhaps, some of the earliest examples were those statues which Pausanias saw in Laconia, consisting of shafts of columns, on which a face was carved for the capital, and feet for the base; but, in the progress of Art, such figures would, at length, be brought to the perfect form exhibited in the female statues first mentioned. But so simple an account of the origin of the practice of placing human figures to serve as capitals was, probably, not agreeable to the taste of Vitruvius, and he has heightened the interest of the subject by relating the following circumstances concerning it.

The inhabitants of Carya, in the Peloponnesus, having joined with the Persians, at the time of the invasion of Greece, the city, after the invaders were driven out of the Country, was taken by a combination of the other Greek States, and the people were either put to the sword or made slaves; to perpetuate their disgrace, these statues were employed in the buildings of Greece, and represented their women in the condition of bearers of burthens. Again, Vitruvius asserts that male figures in the Persian costume were employed, in a similar way, in a Portico erected at Sparta, after the battle of Platea, to solemnize the victory gained by Pausanias, the son of Cleombrotus, over a large army of Persians. Now there is nothing to disprove this latter story, but we must not suppose that male figures were then first employed for the support of an entablature; since we find that in Egypt the same practice existed from a period which, there is every reason to believe, is much more ancient than that of the Persian war in Greece.

With respect to the female figures, the account given by Vitruvius of their origin falls to the ground, as, in an inscription brought from Athens by Dr. Chandler, and containing a description of this Temple, the figures are called *κόραι*, or virgins; whence Lord Aberdeen concludes that they were intended to represent the young ladies employed in the celebration of the Panathenaic Festival, who were selected from the best families of Athens. Mr. Gwilt, in his Paper on the origin of the Caryatides, and in his edition of Sir William Chambers's *Architecture*, shows that they, originally, represented the virgins who celebrated the worship of Diana; this Goddess was, sometimes, called Caryatis, either from *καρύα*, the nut-tree, into which Bacchus transformed Carya, one of the daughters of Dion, King of Laconia, or from the fact mentioned by an old commentator on Statius; *viz.* that some virgins who were celebrating the rites of Diana, being threatened with danger, took refuge under the branches of a nut-tree: the same commentator adds, that a Temple in honour of Diana Caryatis was, afterward, erected on the spot, to commemorate the event.

CHAPTER VIII.

Construction of the Grecian Buildings.

of
a-
by
eks.

We know but little of the mechanical disposition of the materials in the Greek buildings; all that we can say on this head being derived from the short account given by Vitruvius in the VIIIth Chapter of the IId Book, and from the information of those travellers who have had opportunities of examining the remains of the edifices we have described.

Different kinds of walls appear to have been constructed by the Greeks; one of these is called by Vitruvius *incertum*, and he says it is the most ancient, but, from the obscurity of his description, there is great doubt concerning its nature; some thinking that the bricks or stones were placed irregularly, without regard to either vertical or horizontal courses; others, and their opinion seems the most probable, that the materials were disposed in horizontal courses, but that care was not taken to make the vertical junction of every two bricks, in each horizontal course, fall between the masses of two bricks in the courses immediately above and below them.

He describes the stone walls of the Greeks as of three different kinds: the first, called *isodomum*, has its horizontal courses of equal thickness; the second, called *pseudisodomum*, has the courses of unequal thickness; and he considers both these kinds of wall as possessing great durability. It does not, however, appear whether the Greeks always used smooth, squared stones in masonry of these denominations, or whether the same names were applied to it when the materials were roughly hewn. The third sort is called *emplectum*, and consists of two thin walls of squared stone at a certain distance from each other, the interval between them being filled with flints or rubble stones: these were disposed carefully, perhaps in horizontal courses, at least so that the vertical joints in any two courses were not coincident; and by this means the whole was united firmly together. The Greeks also placed bond-stones, which they called *diatones*, at intervals, stretching quite through the wall, from one face to the other, and serving to increase the stability of the work. The commentators on Vitruvius are, however, divided in opinion concerning these walls, and some think that the Greek isodomum and pseudisodomum, were, at least in some cases, of the kind just now called emplectum.

The walls built by Epaminondas about the city of Messene still remain in part, and these are particularly worthy of remark, because they afford an ancient example of that mode of building described by Vitruvius under the name of emplectum. The entrance leads to a circular court 63 feet in diameter, in the interior surface of which are two niches of rectangular forms both on the plan and elevation, with projecting sills and cornices. On the side of the court opposite this entrance is an interior one which is divided into three parts by two piers of masonry. The exterior entrance was probably flanked by two square towers, of which the foundations remain; from these proceeded the walls of the city, which were strengthened at intervals by square and semicircular towers; the former about 20 feet in length on each side, and the latter about the same in diameter. The walls are 9 feet 3 inches thick; they consist of two faces of wrought stone connected together at certain distances by transverse courses of the same material, and the interval is filled with rubble. The towers and certain parts of the walls are crowned by battlements, and the former are pierced with loop-holes whose sides diverge towards the interior.

Masonry of the Greek buildings.

The labours of Messrs. Stuart and Revely have shown that the wall enclosing the cella of the Parthenon was formed of horizontal rows of marble blocks, each of which was equal in thickness to the wall itself, and that the junctions in each alternate horizontal course were vertically over each other. And this was, no doubt, the method employed by the Greeks where great durability was aimed at. The same gentlemen describe the construction of the other parts of the Temple as follows, and their account will give a good idea of the practice of that people in executing their finest works. The pavement is composed of square stones, of equal size, and the joints are so neatly fitted as to be scarcely discerned. The columns consist of several single blocks placed one on another, and the height of each block is equal to about two-thirds of a diameter of the column. The architrave rests merely on the capitals of the columns, without any fastening, and consists of three blocks in thickness and one course in height, each block reaching, in length, from the axis of one column to that of the next. The frize is formed of one course in height; the metopes are thin plates of stone fixed against the face of the frize, and the block of stone on which the triglyphs are cut are inserted partly in the frize. The cornice is formed of blocks, each of which is equal, in extent of front, to one mutule and a triglyph.

In executing the steps to their buildings, the Greeks left the exterior surface in the rough, about the upper edge, both on the vertical and on the horizontal faces; this was, no doubt, intended to protect the edge of the step from accident during the progress of the building, and was smoothed off after the work was completed. A similar practice was adopted in other parts of their edifices. On the middle of the vertical face of each stone forming a step, a rectangular projection was also left, in order, perhaps, to serve as a handle for the convenience of bringing it to its position; this was afterwards cut off and the face of the step brought to a smooth surface. The inclining faces of walls were also frequently built in the form of steps, by each course of stone projecting beyond the one above it; this was, no doubt, intended to enable the workmen easily to give to the face of the wall the required slope, by cutting off the angles of the courses. In many unfinished works of the Greeks, we find the steps and walls left in the states we have just described.

The close union of the marble blocks, particularly at the vertical joints, in Greek buildings has been frequently the subject of admiration, and is justly considered as a proof of the care taken by the ancient artificers to ensure the stability of the edifices they raised. In order to accomplish this accurate junction of the blocks with the least labour, each of the faces which were to be placed in contact vertically, had its middle part hollowed out in a square or rectangular form to a small depth, so as to leave a raised margin a few inches broad all round the exterior; the surface of this was highly polished, and consequently the two corresponding margins of the adjoining blocks came closely together, so that often the line of junction on the face of the building is imperceptible. By this practice it is evident that the trouble is saved of polishing the whole of the two contiguous surfaces.

In general the Grecian buildings were erected before the ornaments in sculpture were executed; and it seems that these were always cut out of the solid stone, the surface of which had been previously smoothed; the flutings of the columns were evidently executed in that manner, from the appearance of some of the unfinished buildings; though, in some cases, the flutings may have been formed, roughly, on each block before it was brought to its place; and some persons have thought that the plug in the axis of the column, at the junction of every two blocks, served as a pivot for the adjustment of the flutes during the erection of the column.

It is probable enough that, in the earlier periods of Grecian Architecture, the ornaments on the mouldings were painted, and that it was not till a succeeding time, when considerable progress had been made in the Art, that the ornaments were sculptured in the marble. In proof of this it may be observed that, in the capitals of the Doric columns, oves and palmettes are sometimes represented by painting, but never by sculpture, whereas in the Ionic capitals, which are later works, such ornaments are cut in the mouldings, with different degrees of delicacy in different examples. Oves, indeed, are sculptured on the Doric pilasters, but the execution of these is bad, and seems to indicate that they were among the first examples of the application of sculpture to the mouldings in the Orders.

The Greek mouldings are, in general, elegantly turned even in situations where such delicacy may be supposed scarcely perceptible except to a critical eye; the lower part of the echinus for example, always preserves a gentle curvature though it differs almost insensibly from a portion of a cone. But the greatest care seems to have been taken in forming the bird's-beak moulding, where both the anterior and posterior faces of the projecting part are made beautifully convex, and the latter joins the swelling surface of the lower moulding by a concave turn; thus causing the whole to assume the appearance of a beautifully undulating curvature.

The Ancients have sometimes formed the profiles of their mouldings so that, to an eye situated below them, in some given position, they might appear similar to the regular mouldings which they were intended to represent. And, to obtain a good effect, the projections of even the rectilinear mouldings were, by the rules of Optics, adapted to their elevation above the eye. It was for this reason the faces of the architrave and frize of an Order, were sometimes made to incline forward at the top, that, to an eye below, they might appear vertical. This practice, however, is not general, and in the Parthenon the members incline back pyramidally.

Forms
the ro

The upper part of the Temples, except those of the hypæthral kind, was covered by one general roof consisting of two inclined planes, meeting in a horizontal ridge at top, and projecting over the flank walls of the Temple. The lower extremities of the roof were either left so that the rain-water might run off at every point, or else the corona was terminated above by a cymatium which formed one side of a gutter to receive the water from the roof; this water was discharged through apertures terminated by lions' heads. The inclination of the sloping sides of the roof to the horizon, in the Greek examples, varies from eleven to fifteen degrees; a mean of several gives, for the angle of inclination, 12° 40′, and the height of the apex of the pediment above the horizontal cornice is about one-ninth of the whole length of the corona in front.

The centre of an hypæthral Temple not being covered by a roof, it may seem that the building must have presented an unfinished appearance to a spectator viewing it in flank, since a chasm must appear to have existed between the pediment roofs at the extremities of the edifice. To fill up this chasm it has been supposed that the four walls of the cella were carried up vertically, like those of a tower, at least to the height of the ridges of the roof, which might then terminate against the upper parts of the end walls of the cella. The whole building would thus appear complete; but it must be owned that no traces of such a tower has ever been observed.

In the small circular, or polygonal buildings, the roof consisted of one solid stone resting on the walls, as may be seen in the Temple of the Winds, and in the Choragic Monument of Lysicrates, at Athens. The inclining roofs of large buildings were covered with rectangular plates or slabs of marble placed in rows, the lower part of the slabs in one row overlapping the upper part of those in the next lower row; and to prevent the rain from entering at the side joints, which, by the arrangement of the slabs, formed continuous lines parallel to each other, from the ridge to the foot of the sloping side, those joints were covered by pieces of marble, called ἁρμὸι, whose superior surfaces were cut so as to form two inclined planes meeting in a ridge over the joint, and whose inferior sides were grooved to receive the two contiguous edges of the plates, which were made to project a little above their general surface.

An accurate idea of the form and proportions of the doors and windows in Grecian edifices may be obtained from those of the Temple of Minerva Polias at Athens, which afford, perhaps, the only specimens remaining of the style of ornament employed about such apertures in the most finished buildings. The doorway under the tetrastyle portico is of a rectangular form, 16.86 feet high, and 7.5 feet broad, and surrounded, both on the horizontal and vertical architraves, by plain faciæ and curvilinear mouldings, separated from each other by lines of beads. The whole breadth of the architrave is 1.625 feet, and on the exterior faciæ are sculptured elegant pateræ. Above the horizontal architrave is a carved moulding ornamented with oves, and over this, but separated from it by a cavetto, is an elegantly sculptured cymatium, which is supported at the extremities by ornamented consoles, contiguous to the vertical architraves and extending downward to the level of the top of the doorway. Between the half columns which are attached to the wall at the Western extremity of the Temple, and elevated considerably above the pavement, are three windows, each 6.375 feet high, 3.1 feet wide at bottom, and 2.862 feet wide at top. The architraves, at the sides, stand on a plain projecting sill, and each extremity of the horizontal architrave is vertically over the exterior of the foot of the jamb. The whole is surrounded by a moulding, whose exterior fillet projects from the face of the wall, and is broken at right angles about the extremities of the horizontal architrave. See pl. vii. figs. 3 and 4.

This subject may, not improperly, be concluded by a description of the methods of tracing the several mouldings employed in the Grecian Orders; their situations on the column and entablature have been already pointed out.

The outline of a section of a Greek moulding is, in almost every case, a portion of some conic section, and to describe such curves it will be only necessary to fix upon the positions and lengths of their axis, and then to apply the usual geometrical or mechanical rules.

The echinus forming the principal feature of the Doric capital, we begin by considering its profile, which may be either elliptical, parabolical, or hyperbolical. A very elegant elliptical echinus will be traced if we assume the lowest point A, (pl. vii. fig. 8.) to be the extremity of the conjugate axis, and the upper point B, both of which may be supposed to be given, to be one extremity of the transverse; we may then draw B C in any direction at pleasure, or parallel to an assumed line A D, (representing a tangent to the curve,) for the direction of the transverse, and A C, perpendicular to it, for that of the conjugate; the intersection of these lines, at C, will be the centre of the ellipse. From the known equation of the ellipse the curve may then be described, *viz.* by determining the length of as many ordinates as we please, and tracing a curve line through their extremities. Or it may be done by any of the means taught in elementary books. The parabolic or hyperbolic echinus may be determined in a similar manner, by assuming the point B for the vertex, and B C for the direction of the axis; a line from A, perpendicular to B C, and meeting it in C, will be a semiordinate to the curve; which, therefore, from the equation, or, by various other means, can be described.

The large torus moulding in the bases of some of the Ionic or Corinthian columns is sometimes made of a semicircular, sometimes of a semielliptical form, the methods of describing which are known; but, in a few cases, we find it in the form of an inverted echinus; which, therefore, may be traced as above.

The scotia, or excavation between two tori in the base of a column, if we consider it as elliptical, may be traced in the following manner. Join A, B, (pl. vii. fig. 9.) for a diameter, bisect it in C, and through C draw C D perpendicular to the axis of the column and equal to the given depth of the excavation; C D will then be a semiconjugate diameter, and the equation of the curve will give the values of the ordinates, by which it may be drawn.

For a cymatium; the given points A and B may be joined, (pl. vii. fig. 10.) and the line A B bisected in C; the vertical line D C E may then be drawn through C, and quadrants of ellipses formed as in the figure, C D and C E being each equal to the semitransverse axis, and A D, E B, each, equal to the semiconjugate.

It has been observed by Mr. Nicholson that the volutes in the capitals of the Grecian Ionic columns resemble that curve which is called a logarithmic spiral; and, in fact, from the best admeasurements that have been obtained, of some of those volutes, particularly those of the Temple on the Ilyssus, and of the Erectheum, they appear to differ so little from that species of curve, that we may safely consider them as such; and, in describing them, we may employ the rules usually given by Geometricians for that purpose; that is, we may determine a number of points through which the curve is to pass, and then trace it, by hand, through them.

A property of the logarithmic spiral is, that if lines be drawn from its centre, making equal angles with each other, the lengths of the several successive lines, terminated by the centre and curve, are in geometric progression. Hence, if we would trace an Ionic volute according to this principle, it will be only necessary to know the whole height, and the position of the centre of the spiral; but, as there may be an infinite number of such spirals formed with the same data, and all are not equally elegant, it becomes necessary to make a choice among them before the rule is applied. In the two examples above-mentioned, there are three complete revolutions of the spiral, besides the circle which forms what is called the eye of the volute; and to produce a figure resembling one of these, it will be necessary to fix the position of the centre of the volute so that its whole height, which we may suppose to be given, shall be divided by the centre in the ratio of about 1.6 to 1, or of 8 to 5. In the Erectheum that ratio is 1.588 to 1, and in the Temple on the Ilyssus, it was 1.621 to 1; the ratio which we have chosen is nearly a mean between both, and the larger space is to be above the centre.

In describing such a volute, then, it will be necessary to divide the given height in that proportion; by this the centre is determined; then, from this point, draw any number of lines at pleasure, making equal angles with each other, and find a mean proportional between any two of them which are known or have been determined, it will be the length of that line which is equidistant from both. Thus A B (pl. vii. fig. 7.) being the given height, and C the centre of the volute, and the several lines C A, C E, C D, &c., making equal angles with each other, a mean proportional between

C A and C B will give the length of C D; a mean proportional between C A and C D will give the length of C E, &c. A third proportional to C D and C B will give the length of C H; whence other mean proportionals may be found, and so on. These lengths may be all determined arithmetically and taken from a scale of equal parts; or they may be determined by any geometrical method, and a curve being drawn through the extremities of these lines, will form the required spiral. The interior spiral in the volute of the Erectheum may be described in the same manner, having assumed any one point through which it is to pass; and the same thing may be said of the spiral curves which form the fillets.

When we consider the high state of the inventive faculty among the Greeks, we are tempted to believe that they may have been acquainted with some of the scientific properties of this curve which was, so many Ages after they first used it, invented, or reinvented in the Northern parts of Europe; for we can hardly suppose that they traced the curve at random, though they may have adopted it as an Architectural feature from a perception of its beauty alone.

Several methods have been proposed for describing these volutes by compasses, on the supposition that a quarter of each revolution of the curve line is a quadrant of a circle; it is evident, however, that this was not the method of the Greeks, since no part of their volute is circular except the eye at the centre; and it may be doubtful whether the finding the centres for describing the quadrants is not more troublesome than the strict geometrical method above shown. If, however, the method of circles should be preferred, that invented by Mr. Goldman, which will be explained when we come to the description of the Roman Ionic Order, seems the most perfect, and may be employed.

With respect to the capitals of the Corinthian columns, it is, obviously, needless to assign any measures to the parts that compose them, on account of their variety and the minuteness of their divisions; the tracing of them must, therefore, be left to the judgment and taste of the artist.

CHAPTER IX.

Description and Character of the Egyptian Edifices.

Extent of the remains of Egyptian Architecture.

The reasons have been given why we began with an account of the Grecian Architecture, though we were willing to admit that, in the simplest state of the Art, this might not be the most ancient. We proceed, in the next place, to exhibit a sketch of what is known of the Architecture of Egypt and Asia previous to the time of Alexander, when that manner of building, which before seems to have been general in the East, was partly superseded by the more scientific and elegant styles of Europe.

The ruins of the Egyptian buildings extend, at intervals, along the banks of the Nile, in a valley fertilized by its overflowings from the Island of Philæ near Syene, in about the twenty-fourth degree of North latitude, to the shores of the Mediterranean, comprehending a line of about five hundred miles in length; and of these ruins, if we may form a judgment from the comparative rudeness of the sculpture, those about Thebes, or, as it is now called Medinet Abou, situated in about 25° 40′ North latitude, are more ancient than any of the others.

Monuments of Architecture, similar to those of Egypt, have been traced through Nubia and into Ethiopia, as far as two hundred leagues to the South of Philæ. Those in Nubia are inscribed with the characters of the Princes who appear to have constructed the edifices of Thebes: but the dominion of these Princes, perhaps, did not extend more than one hundred leagues to the South of Philæ, as, beyond that distance, the inscriptions indicate the names of Sovereigns unknown to Egyptian History.

Ancient splendou Thebes i Egypt.

At what time Thebes became the seat of the Egyptian Empire is not known. Osymandias is the first Sovereign whose History bears any marks of probability, but, of the time in which he reigned, we know nothing more than that it must have been long anterior to that of Homer; though the generally received opinion is that he lived 2270 years before Christ. According to Strabo, this Prince had a Palace at Thebes of great extent; the entrance was by an immense court, and, adjoining to this, was a long portico with a roof supported by animal figures; this led to another court more enriched than the first, and containing three enormous statues. He had also a Tomb, at the same place, ornamented with figures relating to Astronomical subjects, which were enclosed in a circle of gold. It is evident, therefore, that the public buildings of Thebes must, even in that remote Age, have possessed great splendour, and that the Arts must have arrived at considerable perfection.

Homer describes Thebes as a place of great magnitude and importance in his day. But, as the Egyptian cities seem to have been without walls, the hundred gates, by which the ancient Poet designates it, must have been merely such as formed the portals of the Temples or other public buildings. It was the successor of Cetes or Proteus, the reigning Monarch in the time of Homer, who, according to Herodotus, constructed a strong edifice to secure his treasures, which were secretly removed from thence by the Architect or his brother.

Few re- mains Greek Roma buildin Egypt.

About five hundred and twenty-five years before the commencement of the Christian Era, Egypt was conquered by Cambyses, and, from that time, the splendour of the nation declined; two hundred years after this it was again conquered by Alexander the Great. The style, however, of the Temples erected during the reign of the Ptolemies, nearly resembles that of the more ancient ones, and, probably on account of the great durability of all the public edifices, it would not often be found necessary to erect new ones subsequently to that time; consequently, though the old manner of building ceased to be practised, little opportunity would be afforded for the introduction of the Greek or Roman Architecture in the Country, and this may account for the few remains of buildings erected in either of those styles in Egypt.

The expedition of the French army into Egypt gave the scientific persons who accompanied it, an opportunity of examining the structures which remain in that Country after a lapse of, probably, three thousand years; and this good, at least, resulted from the expedition, *viz.* that we are become acquainted with those remains many years before we should have obtained that knowledge from the researches of solitary travellers, who would not have had the means of accomplishing what was done under the protection of a powerful army. It is chiefly from the great Work of Denon that we are able to state what is known of the Architectural works of the Egyptians; though, since that Work was published, much important information has been obtained from the researches of several enterprising individuals who have visited that Country.

Of all the great Pyramids the bases are square; the length of each side of the largest is about 700 feet, and its height about 450 feet. On the sloping surface are steps which lead to the top, where there is a square platform about 30 feet in extent each way. The lengths of each side of the bases of the second and third Pyramids are 650 feet and 280 feet, respectively. The height of the former is about 400 feet, and of the latter 160 feet.

In order to form the pile, the sides of the natural rock upon which it was founded were cut in steps, and the stones were disposed about and upon these, to the required extent, being raised to their places by a very simple contrivance, which is described by Herodotus. (*Euterpe*, sect. 125.) He says, they placed on the ground, under the block of stone, two levers, by which the stone was elevated to the lower step; then two other levers were placed under it to raise it to the next step, and so on, by which means the Pyramid served for its own scaffold. This contrivance shows that, in those days, the builders must have had some knowledge of one of the mechanical powers; though, most probably, they depended less upon machinery than upon the united labour of many persons. The whole exterior seems to have been intended to be faced with stone, in such a way that each side might form a smooth inclined plane: the revetment was begun from the top and completed by working downward; and the passages and chambers were probably formed as the work advanced. According to Herodotus, the lower part of the second Pyramid was covered with Ethiopian marble of various colours.

The faces of all the Pyramids are invariably turned towards the four cardinal points of the horizon; the entrances are on the Northern sides, and passages, inclining downward, lead to the chambers where the dead are deposited. The roofs of these chambers are formed by simply laying long stones across from one wall to the opposite, or where the breadth of the chamber was too great, the roof stones rested upon columns in the interior. The roofs of the passages are, in some cases, formed by laying stones horizontally above the side walls in two or more courses, the interior extremity of each stone projecting beyond that below till the courses on each side meet together at the top, as in the gallery of Tirynthus before mentioned. In other cases, the roofs consist of blocks of granite resting on the side walls at one end, inclining towards each other, and meeting in an angle at the top.

The disposition of their galleries and chambers may be understood from the following description of the interior of the Pyramid raised by Cephrenes, which is taken from the account given by Mr. Belzoni, who lately reopened it.

The entrance is on the Northern side, and the first passage is built of granite, but the rest are cut in the natural sandstone rock, which rises above the level of the basis of the Pyramid; this passage is 104 feet long, 4 feet high, and 3.5 feet wide; it descends in an angle of 26°, and at the bottom is a portcullis; beyond this is a horizontal passage of the same height as the first, and at the end of 22 feet it descends in a different direction, and leads to some passages below. Hence it reascends towards the centre of the pyramid by a gallery 84 feet long, 6 feet high, and 3.5 feet wide, and leads to a chamber, which is also cut out of the solid rock. This apartment is 46 feet long, 16 feet wide, and 23.5 feet high, and contained a sarcophagus of granite 8 feet long, 3.5 feet wide, and 2.25 feet deep in the inside. Returning out of this chamber to the bottom of the gallery, there is a passage which descends at an angle of 26° to the extent of 48.5 feet; at this place it takes a horizontal direction, and continues so for 55 feet, when it ascends again at the same angle, and proceeds to the base of the Pyramid, where another entrance is formed from the outside. About the middle of the horizontal passage, there is a descent into another chamber, which is 32 feet long, 10 feet wide, and 8.5 feet high.

Temple at Apollinopolis Magna.

At Apollinopolis Magna, near Edfou, about 20 miles South of Thebes, is a Temple, one of the largest in Egypt, which, at the same time, possesses considerable simplicity of character and remains to this day in excellent preservation. It is of a rectangular form, 450 feet long and 140 feet wide. The entrance is in the centre of one of the short sides, which is constituted by two masses of building, each 100 feet long and 32 feet wide; both are of a pyramidal form, and lie in the same direction, with an interval between them 20 feet wide, forming a passage which has a doorway at each extremity. This passage leads to a quadrangle, 140 feet long and 120 feet wide, with twelve columns on each side toward the right and left, and eight on the side adjacent to the entrance, all placed at a few feet from the walls toward the interior. The space surrounded by the columns is open above, but the passages between the columns and the walls are covered by a flat roof. On that side of the quadrangle which is opposite the entrance is a covered portico, extending the whole breadth of the quadrangle, and 45 feet in depth. This is enclosed by a wall in the rear and on each side, but is open in front; it contains three parallel rows of massive columns, six in each, and is covered by a flat and ponderous roof. A doorway through the rear wall leads to the body of the Temple, which is also a rectangle, 200 feet long and 98 feet broad, enclosed by walls and covered by a roof. No light seems to have been admitted to this part of the Temple, except from the door; and an exterior wall has been built on three sides, at a little distance, leaving an uncovered corridor between it and the walls of the Temple.

The exterior surface of the walls of the building is covered with figures, and in the interior of the masses at the front of the Temple are chambers and staircases; the latter leading to the roof. All the walls of the building incline inward like the sides of a Pyramid, and the upper extremities, as well as the edges formed by the meetings of every two faces, are ornamented with reed-shaped mouldings. The columns are of a cylindrical form, surrounded by horizontal mouldings at intervals, like rows of cordage, and crowned by bell-shaped capitals adorned with leaves of various forms; and above them is a plain architrave. The walls of the Temple and the architrave of the peristyle are crowned by an inverted cavetto, whose upper extremity projects over the lower: the face of this moulding is ornamented with triple reeds, in vertical planes, at certain distances from each other, and the intervals are filled with sculpture. See pl. ix. figs. 1, 2, and 3.

The Temple at Karnac.

The site of ancient Thebes is covered with ruins on both sides of the Nile; on the Eastern side are two villages, called Karnac and Luxor, situated about two miles from each other, where those ruins are most numerous; and the greatest edifice in Egypt is a Palace, or Temple, whose remains exist at the former of those places. Its general plan is one simple rectangle, and it consists of several apartments and courts, separated by walls extending quite across the Temple. The entrance is at the extremity of one of the short sides, and in front are two masses or towers of masonry, 140 paces long and 25 paces wide, exactly similar to those in front of the Temple at Apollinopolis. A passage between the adjacent extremities of these masses leads to the first court, which is rectangular, and 110 paces deep. This court is crossed by two rows of columns, at the extremity of which are two other masses disposed similarly to those in front of the Temple; and a passage between them leads to the next court, which is 78 paces deep, and entirely filled with 126 columns, disposed in nine parallel rows across the Temple. Beyond this is another court, containing several apartments besides obelisks, and colossal figures; and lastly, from this is an entrance to a vast quadrangle, nearly square, the central part of which is surrounded by a double colonnade; and between this and the exterior walls are the apartments for the Priests attached to the Temple, if it was one; or for the Monarch and his attendants, if the building has been a Palace. Adjacent to this are many other buildings of great extent, connected with it by avenues of sphinxes, lions, and rams, some of which extend as far as 1200 yards, towards Luxor.

In front of the mass, through which is the entrance to the Temple, or Palace, are colossal statues, and the exterior of the mass is decorated with paintings, representing battles, sieges, and triumphs. Among the ruins of this Palace is said to be a portion of a building still more ancient than that which now exists, and bearing inscriptions indicating the name and title of a King, whom M. Champollion supposes to be Osymandias himself.

Temple at Luxor.

Near Luxor are the remains of another building of a nature similar to that at Karnac, but of a less simple plan. At one extremity are, as usual, two great pyramidal masses of masonry, each 98 feet long and 90 feet high, placed both in the same direction, with an interval of 20 feet between them. In front of these towers, and on each side of the interval between them, is an obelisk of a pyramidal form, 12 feet square and nearly 100 feet high, and covered with hieroglyphics; and the interval forms a passage leading to a rectangular peristyle which has been enclosed by walls. In front of the entrance is a doorway, crowned by a cavetto, with a winged globe over the centre, and on each side is a colossal bust standing on the ground. Beyond this is an avenue 18 feet wide, between two rows of columns, 56 feet in height and 9 feet in diameter, which leads to an avenue 120 feet broad, in the same direction as the former, and consisting of two double rows of columns, 30 feet high and 4 feet diameter. At the extremity of this is a covered portico enclosed by two side walls, and forming a sort of pronaos to the building beyond; the portico is filled with thirty-two columns disposed in four parallel rows. This leads to the body of the Temple, which consists of several small square enclosures, or chambers, communicating with each other, and whose roofs are supported by columns in the interior.

Ruins a
Medinet
Abou.

On the Western bank of the Nile, opposite Luxor, is an immense statue of red granite, which is said to have been thrown down by Cambyses; between this and Medinet Abou, which is about 1¼ mile from it, the ground is covered by colossal statues, two of which are seated on pedestals, and are said to be the largest in Egypt. At Medinet Abou are the remains of a Palace, or Temple, in front of which is a rectangular peristyle, 55 paces long and 65 broad. The columns are 45 feet high and 7 feet diameter, and of better execution than most of the works in this place; on the exterior of the walls is a bas-relief, representing a chase of lions, and an invasion of enemies, who by their dress seem to be Indians. Near this place are situated the Tombs of Osymandias, and of the other Kings of Egypt, which are mentioned by Strabo.

Temple
Tentyris

The Temple of Isis, at Tentyris, or Dendra, on the Western side of the Nile, about 30 miles to the South of Thebes, is also one of the most complete yet remaining in Egypt. The plan of the exterior walls is a double rectangle, of which the first forms the vestibule; this is 160 feet wide and 90 feet deep, enclosed by a rear and two side walls, and covered by a roof. In front are six cylindrical columns, 55 feet high and 7 feet diameter, the capitals of which consist each of four female heads supporting a cubical block under the architrave; and in the interior are eighteen similar columns disposed in three parallel rows. The spaces between the exterior columns are each filled by a wall 26 feet high, except that in the centre, where there is a doorway; and the ceiling is painted with zodiacs. The second rectangle, which joins the rear of the vestibule, is 115 feet wide and 180 feet deep, and serves as a peribolus, or enclosure, to the apartments of the Temple itself. In the rear wall of the vestibule before mentioned, is an entrance to a square hall, 55 feet long in each direction, and covered by a roof which is supported by six columns in two parallel rows; the capitals of the columns are formed by heads similar to those of the vestibule. Beyond this hall there are two others in succession, of the same breadth, but each is only 18 feet deep, and from the last there is an entrance to the sanctuary, whose breadth is 24 feet and depth 40 feet. In the second hall are two staircases leading to the roof, or terrace, upon which is an apartment 9 feet square, having a zodiac painted on the ceiling.

About this Temple are three others, one of which appears to be unfinished; a circumstance from which we may perhaps conclude that the Temples of Tentyris are among the latest specimens of the ancient Egyptian Architecture. And from the Greek inscriptions found among the ruins, it is probable that the Architecture has suffered some modification from the intercourse subsisting between the two people. Elevations of a doorway and of one of the columns belonging to this Temple are given in pl. ix. figs. 4 and 5.

Templ
Latop
Philæ
Eleph

Near the same place, and at the village of Esne, on or near the spot where the city of Latopolis is supposed to have stood, are the remains of a Temple of Jupiter Ammon, consisting of a portico enclosed by three walls, and containing twenty-four columns disposed in four parallel rows. The capitals are bell-shaped, and ornamented with leaves, and above each is a plain cubical abacus supporting the architrave: the shafts are fluted in part of their length, and the lower part is rounded so that the foot is less in diameter than the part above. The columns stand upon plinths, and between every two is a wall 18 feet high. The whole column, including the plinth and abacus, is 42 feet high, and its diameter 6 feet.

At the Southern extremity of Egypt, near Syene, are the two Islands Philæ and Elephanta, in which are the remains of several Temples. The famous Nilometer, or chamber, containing a column for ascertaining the elevation of the waters of the Nile, was in a Temple dedicated to Horus, or Apollo, in the latter of these Islands. The Temple of Isis and Osiris, at Philæ, resembles the rest of the Egyptian Temples, but in front of it is a rectangular space, without roof, enclosed by three walls. Its length is 492 feet and breadth 157 feet, and there is an interior colonnade at a little distance from each of the side walls.

At Ypsambul, in Nubia, near the second cataract of the Nile, is a great Temple, buried about two-thirds of its height in the sand, which has been for many Ages accumulating about it. With incredible labour Mr. Belzoni made an excavation, by which he obtained access to the interior, and from his description we have the following account. The Temple is 117 feet wide and 86 feet high, and the entrance is by a large pronaos, 57 feet long and 52 feet wide, whose roof is supported by two rows of square pillars about 5½ feet broad; each pillar has a figure on it, finely executed, and very little injured by time, and the top of its head-dress reaches to the ceiling, which is above 30 feet high. Both pillars and walls are covered with beautiful hieroglyphics, exhibiting battles, storming of castles, triumphs over the Ethiopians, sacrifices, and the like. The second hall is about 22 feet high, 37 feet wide, and 25½ long; it contains four pillars, about 4 feet square, and the walls are covered with hieroglyphics. Beyond this is a shorter chamber, 37 feet wide, in which is the entrance to the sanctuary. At each end of this chamber is a doorway leading into smaller chambers, each 8 feet long and 7 wide, in the same direction as the sanctuary. The latter is 23½ feet long and 12 feet wide: it contains a pedestal in the centre, and at the end four colossal sitting figures, the heads of which are in good preservation.

Before the entrance are also four sitting figures, whose heights are about 51 feet, not including the caps, which are 14 feet high. On the top of the door is a figure of Osiris, 20 feet high, with two colossal hieroglyphic figures, one on each side, looking towards it. The Temple is crowned by a cornice 6 feet high, ornamented with hieroglyphics, and under it is a torus and architrave, the latter of which is 4 feet high. Above the cornice is a row of sitting monkeys, 8 feet high and 6 feet broad across the shoulders. The Temple seems to have had a fine landing-place from the river, but this is now buried under the sand.

The era of the greatest splendour of the Egyptian Monarchy seems to have been that which extended from the expulsion of the Palli, or Shepherd Kings, to the reign of Sesostris, and the greater part of the more ancient edifices are thought to have been the works of that Age. The hieroglyphics in rings, discovered by Mr. W. Bankes, among the subterranean ruins of Abydus, near Thebes, have been shown to express the names of Kings who reigned within the same period.

The more ancient buildings of Egypt seem to have met with the fate of many of those in Greece and Rome; that is, their materials have been employed in the construction of works subsequently erected; this has been the case, at least, with those about Thebes, as may be inferred from the paintings, sculptures, and hieroglyphics, on some of the masonry, which belong to a period more ancient than that of the present existing structures.

Strabo's description of the Egyptian Temples.

The description which is given by Strabo, in his XVIIth Book, of the Egyptian Temples, is nearly verified by the accounts we have of the remains existing at the present time. He says that, at the entrance was a paved court the length of which was three or four times its breadth. Within this were plantations, and it was ornamented with sphinxes. At the extremity of the alley of sphinxes was a vestibule, or propyleum, which led to another court, and at the extremity of this was a second portico, which led to a third court: all these courts were surrounded by galleries. The body of the Temple was divided into the pronaos and the *secos;* the latter of which corresponded with the naos of the Greek Temples. On the two sides of the pronaos were pteromata, or walls like wings, of the same height as the Temple, and ornamented with figures. The secos was small, and contained the image of the God, or the sacred animal which was the object of worship. It was surrounded by chambers for the lodgings of the Priests, or of those who had the care of the Temple.

General characters of the Egyptian Temples.

Of the Egyptian Temples it may be said that they are characterised by uniformity of plan, elevation, and decoration. That at Karnac is a simple rectangle, but in that at Tentyris, the walls of the portico project laterally beyond the side walls of the Temple. The one at Luxor consists of several squares or rectangles clustered together, nearly in the form of a double cross, and the sides are situated obliquely with respect to the directions of the avenues of columns by which the Temple is approached, as if to avoid some defects of ground. They are distinguished from the Greek Temples by having flat roofs; which being formed of solid stone-work, the blocks could not always be obtained of sufficient length to rest on the walls of the larger apartments; consequently it was necessary to place columns in the interior, for the support of the roofs; and these, in some cases, are so numerous as to look like a forest.

In the Egyptian Architecture almost every consideration yielded to that of strength, though beauty was not neglected, and the edifices of that Country possess a species of magnificence from their bulk, independently of the delicacies of Art with which many of them were adorned. The quarries of Egypt afforded blocks of the greatest size; and the labour of a multitude of slaves, aided perhaps by the simplest of the mechanical powers, accomplished the removal of the heaviest masses to their place of destination. According to Herodotus, the stone which served for the roof of the Temple of Latona, at Butos, was forty cubits long in each direction; and if we suppose the cubit to be equal to 20½ inches, that block must have contained above 300,000 cubic feet of stone. This enormous mass was transported on rafts, from the Island of Philæ to Butos; a space of 150 leagues.

Manner of constructing the Egyptian Temples.

Calcareous stone was generally employed in the walls of buildings, and granite in the obelisks and statues. The skill of the workmen was exhibited in squaring the blocks with precision, and fitting them accurately with each other. Plugs of wood seem to have been occasionally employed to connect them together, but there is no appearance that metallic cramps were used for that purpose: nor was the Art of constructing vaults at all known to this people. The hieroglyphics and figures were sometimes executed in relief, but generally they were sunken and embellished with colours.

None of the Works hitherto published give any notion of the rich and elegant decorations of some of the Temples, the ornaments of which are nearly as various as those of the Grecian edifices; but we have been favoured with a sight of the drawings executed by Mr. Charles Barry, when in Egypt, which, it is to be hoped, that gentleman will one day communicate to the public: from these it appears, that not only the exterior and interior surfaces of the walls of the buildings, but the soffits of the porticos, the beams and intervals between them, were richly ornamented with sculpture, painting, and gilding.

The walls of the Temples invariably have their exterior faces considerably inclined at top towards the centre, so that the figure of the whole edifice resembles a frustum of a Pyramid. This seems to have been intended chiefly for stability, but perhaps partly, as is observed by M. Quatremer de Quincy, to diminish the breadth of the building at top, in order to suit the lengths of the stones which were to cover it. Still further, for the same object, the workmen sometimes placed courses of stone along the tops of the walls, the upper projecting over the lower towards the interior, like inverted steps.

At all the angles formed by the faces of the walls, instead of leaving a sharp edge, the artists executed a reed moulding, equal to about three-quarters of a cylinder, with lines cut obliquely upon it, very much resembling a pole having a string wound about it; and the same kind of moulding was continued, horizontally, along the tops of the walls. This seems to have been an imitation of the system of poles which might have been originally constructed to form an outline of the edifice, and guide the workmen in building the walls; though, possibly, it might have originated in the desire to ornament the angles, as the Greeks, for the same purpose, employed pilasters, and the Italian artists rustic quoins. The tops of all the walls were crowned by a sort of cornice, of a concave form on the exterior, and having its summit projecting forward; the front of this member was covered with sculpture, generally resembling a series of reeds parallel to each other, and directed from top to bottom; and both the exterior and interior faces of the walls were covered with hieroglyphics.

The pronaos was roofed and enclosed by walls on all sides except the front, where the first row of columns stood between the extremities of the two flank walls; the exterior angles of the front were inclined, as has been said, but those terminations of the front which were next to the two outer columns of the row were vertical. Between the columns, and up to about half their height, a wall was constructed from which the lower parts of the columns appeared to project as much as half their diameter; the wall was adorned with sculpture, and was terminated by the usual cavetto or curved cornice, but it was interrupted between the two middle columns to form a doorway.

The towers and portals.

Generally, in front of the Temple, were one or two of those towers, or masses of masonry, mentioned in speaking of the Temples at Karnac and Luxor; these also were tapered toward the top, the reed moulding was cut at the angles, and the whole was crowned by a cavetto and covered with hieroglyphics. A pair of obelisks, or statues, was frequently placed in front of the passage cut through these masses; and within the latter were staircases which led to the platforms on their tops; these staircases were always directed straight forward, or the parts were made to turn at right angles to each other. No reason can be given for the formation of such immense masses of masonry, except it be that the artists of the Country intended to produce a grand and striking effect by a vast accumulation of materials as well as by the forms of their edifices. Two of these towers were generally placed in the same direction at a little distance from each other; and, in front of the interval, was a portal constituted by two jambs and a lintel; the exterior and interior edges of the jambs were generally made to incline inward like the walls of the building itself, though sometimes the interior edges were vertical. The faces of these members were adorned with a great profusion of hieroglyphics; a reed moulding surrounded them on the exterior, and the lintel, like the building itself, was crowned by a cavetto ornamented with sculpture. On the centre of the lintel was, usually, carved a scarabeus or beetle, or, sometimes, a globe having a wing on each side.

Windo

Where windows occur, they are, generally, in the shape of a long square without any ornament, but splayed on the interior side. The windows of Egyptian Temples are, almost in every case, extremely small; and the only example, perhaps, in which they approach the magnitude and proportions of those found in Grecian or Roman buildings, is the Temple at Dendour in Nubia; and, probably, this is the work of a late period of Egyptian Architecture. Its outline is pyramidal, as usual, and in the façade is a doorway crowned by a cavetto; but, above this, are three rectangular windows occupying nearly the whole breadth of the façade. Over the middle one is the winged globe, and the whole pier between the two windows has the form of a pilaster with a capital resembling those of the Corinthian Order. The capitals do not reach to the level of the tops of the windows, and appear as if placed there, in bad taste, for no purpose but that of ornament.

Ceilin

The ceilings of the Egyptian buildings are generally smooth; but, in some cases, they seem formed in hollow panels by the architraves of stone, which cross each other at right angles over the tops of the columns. Frequently there are traced upon the ceilings what are called zodiacs; that is, representations, *in plano*, of the zodiacal constellations, disposed in a circular order about the centre of the compartment. From the positions of these constellations, an effort has been made to ascertain the dates of the construction of the edifices in which they are found; but nothing satisfactory on this head has yet been elicited.

The simplicity of the forms of Egyptian buildings has led some persons to suppose that the workmen might have dispensed with any previous design like that, which, in the edifices of other Countries, is necessary to guide them in the execution; and it is the opinion of M. Denon that the Temples were entirely constructed by the eye, and according to a routine established among the builders, who, he observes, were unembarrassed by any adjustment of the members of the frize or cornice, or by any care of providing against a lateral thrust in their roofs.

Form the Eg colum

That the Egyptian columns were copied from the form of certain trees is probable, not only from their appearance, but from the testimony of Herodotus, who says, (*Euterpe*, sect. 171.) that King Amasis actually caused columns to be made resembling palm-trees. They are without bases, or have only a plinth, and that is frequently circular. The capital is generally of the bell-shape, and is either quite plain, or is ornamented in several different manners; frequently it is surrounded by rows of lotus leaves, either simply marked by lines, or sculptured in relief; in the latter case, the capitals resemble some of those of the Corinthian Order. On the columns of the Temple at Philæ, the capital is sculptured to represent three rows of plants, the tops of which are like palm-leaves; and in some examples, as in the Temple at Tentyris, it has the form of a female head. But, what is very different from the practice of the Greeks, is that in the same building, and even in the same row, the capitals of the columns do not resemble each other. In the Egyptian Temples the intercolumniations are generally small, not exceeding 1.5 diameters.

The height of the column, from the bottom of the plinth to the top of the capital, is equal to from three to eight diameters, and the tallest column is above fifty feet high; in some cases the shaft diminishes gradually from bottom to top, and is sculptured as if it were a bundle of reeds bound together, at intervals, by three or more turns of cordage; these intervals are either plain, channelled, or reeded, and sometimes all the three kinds exist upon one column. Two circumstances are peculiar to the Egyptian columns; the first is, that there are often cubical blocks of stone between the capitals and the entablature; and the second, that the lower part of the shaft is sometimes cut away, so that the part which rests upon the plinth is smaller than the part above; such is the case with the columns of the Temple at Latopolis. It is difficult to assign any reason for the latter practice, since it can only tend to weaken a column in a part where it ought to be the strongest; the lower parts of these columns are rounded and ornamented with sculptured foliage, which makes them appear as if they stood upon the roots of plants. In other instances the upper part of the column swells out from the shaft suddenly, and then tapers again to the top, making it resemble a post crushed by a weight above; and, that the form has been adopted from observing some such effect seems evident, because under this swell there are mouldings, resembling cordage, about the column, as if to prevent its splitting further by the weight. The most remarkable example of this kind of column is that observed by Mr. Barry in the interior of the Tombs at Benihassan, about forty-eight leagues South of Cairo; he compares each column to a bundle formed by four large reeds of the Nile placed upon a plinth and tied together by cords near the top; small sticks are introduced between the reeds at the place of ligature, to render the column more circular, and afford the means of firmly tying the whole together. See pl. ix. fig. 6.

The porches of the Tombs at Silsilis, about seventy miles South of Thebes, are formed by columns of a similar nature; but the same gentleman also observes, that the fronts of two of the Tombs at Benihassan consist each of two fluted columns resembling those of the Doric Order, one on each side of the entrance; the columns are about 5½ diameters in height; the flutes are shallow and twenty in number; the capital consists of an abacus only, and there are no indications of a base or plinth. Above the architrave, which is plain, is a projecting ledge of the rock, in the form of a cornice, the soffit of which is sculptured, apparently in imitation of a series of reeds, laid horizontally, for its support.

Mr. Barry gives another instance of fluted Egyptian columns in an excavated Temple at Kalaptchic, about twenty-five leagues above the first cataracts. The Temple consists of two chambers, and the roof of one of them is supported by two such columns; their shafts are each 7.667 feet high, and 3.167 feet diameter, with a slight diminution upward: they have a square abacus and a circular plinth. In a Temple at Eleuthias, a few miles South of Esne, is a large vestibule whose roof is supported upon polygonal columns of sixteen sides. (Gwilt's edition of Chambers's *Architecture*, p. 37. note.) In the Egyptian buildings there are no pilasters, properly so called, except the small ones in the sepulchral chamber of the great Pyramid; but, sometimes, human figures are placed as columns, either alone, or, as it were, attached to the fronts of square piers, of which the Temple at Ypsambul, described by Belzoni, affords examples. It is observed by Mr. Forsyth that, in general, the Egyptian statues are well adapted for the support of an entablature, their backs are flattened as if for the purpose of adhering to a wall; their arms are placed close by their sides, and the head is secured to the body by broad tresses which fall down on the shoulders and breast.

The entablature.

In general, the entablature of the Egyptian buildings consists of an architrave, either plain or ornamented, with a cornice over it; but in some examples, as in the Tombs of Silsilis, the entablature consists of an architrave, frize, and cornice, each projecting over the one below it, like an inverted step; the upper part of the cornice projects still further, and the projection is supported by a sort of modillon. The height of the entablature is about one-third of that of the columns. Over the architrave of the interior range of columns in the great Temple at Karnac is a wall with rectangular perforations, like windows, immediately over the intervals of the columns below.

Above the capitals of the Egyptian columns is an abacus, sometimes resembling that of the Greek Orders; but, at other times, it consists of a cubical block, either plain or sculptured. Over these blocks is placed the horizontal beam parallel to the line of columns, and corresponding to the architrave of the Greeks: and above all, is what may be called the cornice, the section of which is concave outward, and which has its top projecting beyond the face of the architrave. The concave front of this member is adorned with sculpture, in some cases consisting of a series of reeds parallel to each other from top to bottom of the cornice, in other cases the reeds are in groups of three or six in each group; the intervals, or metopes, if they may be so called, are sculptured with winged globes, as on the portico of the Temple at Tentyris. These reeds are disposed with regularity, but not over the middle of the front of the columns as in the Greek Temples; for, in the portico of the Temple at Latopolis, each group is equally distant from the next, and one is placed over the middle of the intercolumniation, but the middles of the other groups fall over the sides of the columns. The interval between every two groups is occupied by a channel cut in a vertical plane down the face of the cornice. The Egyptian reeds differ also from the Greek triglyphs in an essential circumstance, *viz.* that the latter are so situated as evidently to indicate the supports of the roof; whereas the others are ornaments in the front of the roof itself, above which there is generally nothing to be supported.

The entablatures are frequently sculptured with figures of animals, and it is possible that the zophorus or frize, in the Greek Architecture, received its name from this circumstance; winged globes and the scarabeus are, almost invariably, the ornaments of the Egyptian architraves.

The Architecture of Egypt scarcely applicable to modern edifices.

It was an observation of a French author, that there is nothing in the Egyptian Architecture conformable to the circumstances of the moderns; for, says he, we do not possess those immense blocks of stone which, in Egypt, are the motives, or excuse, for a style of building distinguished by being enormously massive; and he supposes that an imitation of their works on a small scale, or with materials of small dimensions, would inspire ridicule rather than afford pleasure. This observation, to a certain extent, may be just, but it would be improper to exclude the Egyptian Architecture entirely from the modern practice, as it is possible that there may be some cases in which it may be employed to advantage. That style has lately been adopted, with success, in the construction of an iron-foundry in Wales; and, if it were only applicable to such buildings as Manufactories, Prisons, or Tombs, it would contribute to the production of an agreeable variety in our Architecture.

CHAPTER X.

Ancient Edifices of Syria and Persia.

Temple at Aradus.

While the Egyptian Empire flourished, the style of its Architecture extended itself into Syria and, perhaps, still further towards the East. To this period may, perhaps, be referred the execution of a work which was observed by Pocock on the Island of Aradus, or, as it is now called, Tortosa. According to the description of that traveller, it is a court formed by cutting down the solid rock from top to bottom. In the centre of the court is a throne composed of four stones besides the pedestal on which it stands; one serves for the back, another for the canopy, and two others for the sides. Between these was, probably, placed the Idol worshipped in the court, which, no doubt, was a kind of Temple. In two of the corners of the court there appear to have been small apartments cut also in the rock.

The Temple at Jerusalem

In the sacred Scriptures is given an account of the construction of the Temple at Jerusalem by Solomon; from which we perceive that the plan of the building very much resembled that of the Temples of Greece or Egypt. According to the description in the Book of *Kings*, the plan of the Temple was a parallelogram; its length was 60 cubits, and its breadth 20 cubits, and it was divided into three principal parts by walls parallel to its breadth. There is some doubt about the precise value of the cubit here supposed to be employed, but assuming it to be equal to 1.824 feet, which is that generally assigned to it, it will follow that the length of the Temple was 109.44 feet, and its breadth 36.48 feet. In front was a pronaos or portico; then followed the cella, or main body of the Temple; and, thirdly, at the other extremity, was the sanctuary. The breadth of the portico was equal to that of the Temple, and its depth was 10 cubits, or 18.24 feet; the body of the Temple was 30 cubits, or 54.72 feet deep, and the sanctuary 20 cubits, or 36.48 feet. The height of the Temple, probably the middle part, was 30 cubits, or 54.72 feet; that of the sanctuary was 20 cubits, or 36.48 feet, and that of the portico, if we may judge from the height of its columns, was about the same. The latter was covered by a roof, and the body of the Temple was, probably, similar to that of the Greek hypæthral Temples; it was surrounded, in the interior, by three tiers of chambers, one above another, there was an ascent by stairs from the ground to the middle and upper stories, and the central space was a court open to the sky. The bells which were suspended about the Temple were, probably, intended, by the sound they produced, on being agitated by the wind, to keep off birds from the consecrated edifice. The like means are known to have been adopted, for the same purpose, on the roofs of the Grecian Temples.

The floors of the upper chambers were laid on beams of cedar, the ends of which were not inserted in the walls of the Temple, but rested on corbels of masonry attached to their faces. The interior of the walls was boarded with cedar, on which were figures of cherubim and palm trees sculptured and covered with gilding. Within the sanctuary were two figures of cherubs, made of wood and covered with gold; these were 10 cubits high, and their expanded wings extended across the breadth of the Temple.

In front of the portico and between the extremities of the side-walls, were two brass pillars, each 18 cubits high and nearly 4 cubits in diameter; the chapiters, which may mean either the capitals of the columns or the whole entablature, were also of brass, and 5 cubits high, ornamented with wreaths and leaves of pomegranates or lilies, and covered with network. Pillars are also mentioned whose capitals were only 4 cubits high; probably these were within the portico, and formed part of the support of its roof.

The house of the forest of Lebanon seems to have been similar to the Temple, but more extensive, being 100 cubits long and 50 broad. It had a portico in front, the breadth of which was equal to that of the house, and the depth 30 cubits; its roof was supported on four rows of pillars of cedar wood, fifteen in each row.

The height of the columns of the Temple being equal to about five diameters, the proportions are nearly the same as those of the Egyptian and earliest Greek examples, and the capitals bear a considerable resemblance to those of the former Country.

Persia was the seat of a powerful Empire, from the time at which Nimrod built the city of Babylon till the invasion of the Country by Alexander the Great; and during that period the Art of building must have been practised there to a great extent. The frequent changes, however, which the Government experienced, and perhaps other circumstances with which we are unacquainted, have caused the destruction of nearly all the monuments of the Architecture of this highly civilised people; indeed, if we except the ruins at present existing in one place, not a vestige of them remains. These ruins are found in the Province of Farsistan, a few miles to the North of Chyras, or Shiras, and are probably on the spot where the city of Persepolis anciently stood. This city, one of the Capitals of the Persian Kings, is supposed to have been built or embellished by Cambyses, or rather by his successors Darius and Xerxes; but its prosperity must have been of short duration; for with the other cities of the Empire, it declined after the death of Alexander and the division of the territories he had conquered.

Le Brun, to whom we are indebted for the description and measurement of the ruins, supposes them to be the remains of the Palace of Darius destroyed by the Macedonian Monarch in one of his revels: and the inequality of the ground, together with the appearance of distinct apartments for men and women, are more favourable to the opinion that the ruins have formed part of a Palace than of a Temple. This traveller observes that the whole of the edifice has been founded upon a marble rock, which has been levelled, and constitutes a platform about 400 yards long from North to South, and about half as much from East to West; and on the margin of the rock, there has been erected a wall surrounding the whole building, and following all the sinuosities of the ground. The Western side of the platform is elevated 22 feet above the plain in front, and there is an ascent to it by steps in two ramps, which first diverge from one another, and then come together at the top. The steps, which are about 4 inches high and 14 inches broad, lead, at about 42 feet from the edge, to two great masses of masonry, resembling those which are placed before the Temples of Egypt: like them, they diminish upward, and are crowned by a cavetto, the upper part of which projects over the lower. In them are formed doorways which, no doubt, led to the front courts of the Palace, the magnificence of which is attested by the number of broken columns which lie scattered about.

These masses are 22 feet long and 13 feet thick, but the height of one is 39 feet, and of the other 29 feet. On the sides are sculptured winged horses with human heads, wearing Persian dresses. The bodies of the horses are in bas relief, but the legs are detached from the wall, and the style of the figures indicates a taste for whatever was capricious and extravagant in sculpture.

Beyond this first assemblage of ruins, and to the right of the above-mentioned masses, is another assemblage upon more elevated ground, and seeming to form the principal part of the Palace. This terrace is supported by walls, on which are numerous sculptures representing processions and sacrifices of horses and oxen; several of the figures have the particular kind of head-dress and umbrella which were worn by the Persian Nobles, but others have long robes resembling those worn by the Medes. The proportions of the figures are good, but the execution is without taste, and appears to have been hasty. Near these are the remains of some subterranean vaults, which M. Le Brun supposes were intended to convey water to the Palace.

The columns are of grey marble, from 70 to 72 feet high and 5¾ feet in diameter; consequently, their height is equal to about 13 diameters; which appearing too slender to support a great weight, has led that traveller to believe that this must have been a summer Palace, roofed with timber, or having some temporary covering. Each column has a base, which is 4¼ feet high, with sculptured mouldings. Some of the columns are decorated with zig-zag ornaments, resembling those on the fragment found near the Treasury of Atreus, at Mycenæ; the upper parts of others are ornamented with several small scrolls which are not much unlike the spirals in the capitals of the Ionic Order. The shafts consist of four or five different pieces besides the capital, and some of them are fluted with as many as forty longitudinal channels, each about three inches wide, with fillets between them. A representation of one of these columns is given in pl. ix. fig. 7; and if we include in the capital all the scrolls, that member will occupy about one-fifth of the height of the column. On some columns are represented camels stooping; on others figures resembling horses. One of these is given in fig. 8, and the sculpture on one of the piers at this place is represented in fig. 9.

Persian or Parthian Tombs.

In some rocks, about two leagues from Persepolis, are formed excavations, which have been taken for the Tombs of the Persian or Parthian Kings; and from the view and description given by Le Brun, the following account of the ornaments about the façade of one of them has been taken. One side of the rock being cut away, a vertical front is formed, about 70 feet broad and as much in height; in the lower part of which is the entrance to a gallery. The sides and top of the entrance are cut in the rock, so as to form three faciæ parallel to the front, each deeper than the one on its exterior; and over the top is the Egyptian cavetto. Parallel to the front wall, and a little in advance, are four columns at intervals from each other, about equal to the breadth of the doorway, with capitals formed of the heads of oxen projecting beyond the columns. Over these, comes an architrave extending along the whole breadth of the front, and divided into three faciæ projecting beyond each other, upwards; above this is a kind of cornice, projecting about 2¾ feet, and supported by modillons. Upon the top of this is a wall, like a parapet, of the same length as the architrave, and sculptured with lions.

On the upper part of the rock, and attached to its front, are sculptured two rows of human figures about six feet high, one row above the other, and fourteen in each row. The rows are separated from each other by a sort of entablature, and another entablature is placed on the heads of the figures in the upper row. On the right and left of these rows is sculptured an upright figure about twenty feet high, having the head and feet of some animal, and the body forming an inverted frustum of a cone; and in the sides of the excavation of the mountain are three recesses, one above another, over the extremities of the portico, each containing statues. Above the two rows of figures before mentioned, is the figure of a man about fourteen feet high, standing on steps and holding a bow; an altar, with a fire on it, is before him.

The sculpture on some of these rocks represents, in bas relief, combats, in which the warriors are mounted on horses; this is not the case in the bas reliefs of Persepolis, and it is therefore probable that these Tombs are works of the Parthians, to whom Persia was at one time subject. A façade of one of these Tombs is represented in pl. ix. fig. 10.

From the resemblance of some of the features in the ruins of Persepolis to those of the Egyptian buildings, it seems probable that the Persian Architecture is derived from that of Egypt; and the Palace we have noticed has been supposed to be executed by artists of the latter nation, who were brought into Persia at the time of the invasion of Egypt by Cambyses. All the sculptured Tombs above mentioned bear the name of Naxi Rustan, or rather Neksha-e-Roostem; that is, the sculptures of the hero Rustan, or Roostem, the Hercules of the East.

PART II.

ANCIENT ARCHITECTURE OF THE ROMANS AND SARACENS.

CHAPTER I.

The Origin of Latin Architecture, and the oldest Temples of Italy.

Architecture cultivated by the Etruscans.

The people of Italy seem to have begun, at an early period, the cultivation of Architecture; and the ancient inhabitants of Etruria or Tuscany are said to have invented a particular Order, before any communication was established between Italy and Greece. But, though it is not meant to deny this fact, yet it is also possible that, as a colony of Arcadians are said to have, very anciently, established themselves, under Evander, in that Country, this colony may have introduced a mode of building which had been previously practised in Greece; and, in this case, the Order alluded to, which is commonly called the Tuscan, might be only a copy or modification of the very ancient Grecian Doric; which it, in some respects, resembles, if we may judge from the description given of it by Vitruvius. That the ancient Etruscans possessed a certain degree of taste and elegance in Art cannot be doubted, when we consider the remains of antiquity which have been discovered in their Country; and there is sufficient reason to believe that the Romans employed artists of that nation to execute their great works before they became acquainted with the more splendid performances of the Greeks.

Early buildings of the Romans.

Architecture was probably unknown in Rome till the time of the Tarquins; but that, from that period, the Romans had some acquaintance with the Art, and that their edifices were, even then, not entirely destitute of ornament, is rendered probable by the circumstances we are about to mention. The ancient Temple of Jupiter in the Capitol was begun during the reign of the elder of those Princes, by Etruscan workmen, though it was not finished till long afterwards. According to Cicero, it had two rows of columns in the interior, by which it was divided into three parts, longitudinally, and its front was crowned by a pediment. It might, therefore, resemble the Temples at Pæstum which have been already described, and, perhaps, was not inferior to them in magnificence. We learn from the same authority, that it was twice destroyed, and as often rebuilt upon the same foundations. According to Palladio, the ancient Temple of Vesta at Rome, which is supposed to have been built by Numa Pompilius, was of a circular form, and surrounded by columns whose capitals resembled those of the Corinthian Order which was, subsequently, so much employed in Roman buildings. Again, what Palladio calls the double Temple of the Sun and Moon, but which, it is now supposed, was dedicated to Venus and Rome, and which is said to have been built by King Tatius, or rebuilt at a subsequent period according to the original design, must, even in its primitive state, have possessed great magnificence of character. To these we may add the *Cloacæ*, or sewers at Rome, which bear marks of very high antiquity, if they were not executed by the elder Tarquin, as is commonly supposed. No doubt many structures for Religious and Civil purposes existed in Rome and Italy, during the times of the Monarchy and Commonwealth, which have since gone entirely to ruin; and it is probable enough that they possessed neither the stability nor the splendour of the Grecian buildings.

Invention the Comp site Orde in Italy.

From the time that a constant intercourse subsisted between Italy and Greece, the artists of the former Country laboured to copy the works of their more refined neighbours; and, not having sufficient correctness of taste to relish the simple beauties of the Grecian Architecture, or perhaps, being unwilling to confine themselves to the repetition of forms which already existed, they applied themselves to make variations in the style, and increase the embellishments of the different Orders. From this propensity to change has, no doubt, arisen the fifth, or that which is called the Roman or Composite Order, which consists in a union of the volutes of the Ionic with the foliage of the Corinthian capital.

It is supposed that this Order is alluded to by Vitruvius, in the Ist Chapter of the IVth Book, but he does not give any particular description of it; and, consequently, it has been doubted whether that which we describe under this name existed in his time; it is very likely, however, to be the production of some Roman artist who, in search of novelty, has found nothing better than a combination of the ornamental parts of two Orders already existing.

Roman A chitectu directed objects utility.

It was an observation of Strabo that the Romans excelled the Greeks in their attention to objects of the highest national utility. The latter people confined their Architectural labours to the embellishment of their Temples, the entrances of their cities, and their places of public exercise; while their private dwellings were mean, and, except the Palæstræ, every work which, in another Country, would be considered essential to the comfort of the people was, in Greece, disregarded, or, by the nature of the Country, rendered unnecessary. The former people not only gratified their piety or vanity by erecting splendid edifices for the Gods, but formed bridges and high roads for facilitating the communication with every part of the Empire; immense sewers to drain and purify their cities, and magnificent aqueducts to supply them with an abundance of that indispensable element, water.

Probabl that the was un- known t the Anci out of Italy.

One thing in particular there is reason to believe that Italy may value itself on, *viz.* the invention of the arched vault and dome, of which not a trace exists in any other Country of an earlier date than the time of its intercourse with Rome. And, though it is barely possible that the invention may have taken place in some part of Asia where, large masses of stone being scarce, it is to be expected that such a contrivance would be thought of, to form a cover to a building, or a bridge across a river; yet the total absence of examples the antiquity of which is authenticated, proves that the arch could not have been in general use, and even renders it probable that it was entirely unknown; since, if known, its obvious utility would necessarily have led to its frequent application.

In mountainous Countries natural appearances are not wanting which might suggest the idea of a curvilinear arrangement of materials constituting an arch; the entrances of caverns and the perforations of rocks frequently bear this form, and these have been imitated on some occasions at a very early period. Mr. Hamilton describes an artificial perforation like an arch, made in a solid wall, and serving as a doorway in an ancient Fort at Ephesus; but we do not mean to class under the name of arches such apertures as this, nor the covered passages described in speaking of the works at Mycenæ and the Egyptian Pyramids. These methods are nearly as old as the Art of building itself, and have been practised not only in Greece and Egypt, but also in Britain, in India, and in America. By an arch we mean a number of wedge-like stones disposed in a vertical plane, and sustaining themselves in the air by their mutual pressures. Of this kind of arch no vestige appears among any of the remains of the early Architecture of Greece; even the river Cephissus, which crosses the road to Athens, had no bridge over it till one was erected by the Romans when they had possession of the Country. The *tholos* mentioned by Homer and other Greek authors, and which is usually translated a dome, signified, as Lord Aberdeen observes, merely a building on a circular plan without regard to the roof, which, in works of that kind, is supposed to have been frequently of timber and of a conical form; and the roof of the monument of Lysicrates, at Athens, is merely a mass of stone resting vertically on the side walls of the building. The roof of the Temple of the Winds is that which approaches nearest to the character of a dome, being composed of twenty-four separate blocks which abut on a key-stone at the vertex; but the editor of Stuart's *Athens* does not consider them as exhibiting any feeling of the principle of the arch.

In Italy we find the earliest traces of arches, and, whoever was the inventor, the Romans have certainly the merit of bringing them into general use, and of employing them for the most important purposes. A work which is with reason considered as one of the earliest specimens of arches, is the conduit at Tusculum near Rome. This is a subterranean channel proceeding from a reservoir under a mountain; it has vertical sides and is covered by stones, in the form of frusta of wedges, abutting against each other at their oblique sides, in which construction the principle of the arch is distinctly exhibited. The reservoir is 10 feet broad, and 10½ feet high, and is formed similarly to the Treasury of Atreus, its sides being composed of circular courses of stones, horizontally disposed, and gradually contracting towards the vertex; which gives an antique character to the reservoir confirmatory of the opinion that the conduit is an original example of vaulting, and not a rude imitation of a more perfect form. (See Kinnaird's *Supplement* to Stuart's *Athens*.) Next to this may be mentioned the arches found in part of the ancient walls of Rome, built by Tullius, and the *Cloaca maxima;* the latter of which is formed of immense blocks of stone joined together without cement, and constituting a semicircular vault, as perfect as any subsequently constructed. These are generally supposed to have been built by Tarquin the Elder; and though Mr. Mitford thinks the present arches were executed in the time of Augustus, yet the Etruscan character of the workmanship renders the former opinion more probable. They are now nearly choked up with earth, but, during the prosperity of the city, they were large enough to admit a carriage laden with hay, and boats could pass through them.

We have no further knowledge of the employment of arches at Rome till we come to the time of Julius Cæsar, who erected the Theatre of Marcellus, on the exterior of which are rows of arches in good preservation. From the way in which Dion Cassius speaks of the erection of this Theatre, it has been supposed that it was an exact imitation of the Theatre which had been before built by Pompey; and it is also supposed that Pompey's Theatre was an imitation of one at Mitylene, erected in, or about, the time of Alexander. Now both Pompey's Theatre and that at Mitylene have disappeared; but as there are arches in the Theatre of Marcellus, it has been inferred that there must have been also arches in both the others; it must be owned, however, that this fact is far from being certain. It is true that there are some remains of Theatres in Asia Minor, in which arches are to be found, but it is believed that they were erected subsequently to the reign of Alexander; and, therefore, do not militate against the prior claim of Italy to the honour of the invention of both the arch and dome.

In speaking of the windows of buildings, Vitruvius, who probably lived about the time of Augustus, describes the construction of arches in an unequivocal manner, and it is evident, therefore, that they must have been in use before his time. In the XIth Chapter of the VIth Book, he says that the upper parts of the openings between the piers may be formed horizontally, or in an arc of some curve; and, he continues to observe, that if the materials are small with respect to the breadth of the aperture, they will neither stand in their places nor support an incumbent weight if they are made rectangular. He prescribes, therefore, that the arches should be made of wedges whose joints, or faces, tend towards the centre; by which form they discharge the weight above; and that the angular piers, or the piers forming the extremities of the wall, should be of greater breadth than those between the arches, that, by confining the wedges, they may give firmness to the work.

Rome embellished by Augustus.

In the time of Augustus we find a degree of magnificence in the Italian buildings beyond that which they had before attained. The conquest of nearly the whole of the then known World, and a general Peace, allowed the Sovereign to turn his thoughts to the improvement of his Country; a constellation of illustrious Poets and Philosophers at that time shone in the metropolis of the Empire, and gave the minds of the people a tendency towards subjects more useful and honourable than the conquest of remote and unoffending nations. With the other Arts, that of building was cultivated at Rome; Augustus himself caused to be erected several Temples besides other superb edifices, and so far changed the face of the city, that, in speaking of him, it could be said, "*marmoream se relinquere quam lateritiam accepisset.*"

The Architecture of Vitruvius written in the time of Augustus or Titus.

It is a generally received opinion that the celebrated Vitruvius wrote his Treatise on Architecture during the reign of this Prince, and, therefore, we may avail ourselves of his authority for an account of the style of building in use at that period. We know, however, that the precise time at which Vitruvius lived is uncertain, and the arguments in favour of that Work being written in the reign of Titus have considerable weight; yet this will be of little consequence, since Vitruvius describes buildings which had been executed, and delivers precepts which had been acted on, before his time, and therefore, in admitting the latter opinion to be correct, we shall still, by following him, be carried back to a period, perhaps even earlier than that of Augustus.

In the Proem to his VIIth Book, after mentioning about twenty Greek authors, who had written on Architecture and Mechanics, Vitruvius observes that very few books had been written on the Art by Romans; he names Fussitius as the first, afterward Terentius Varro and Publius Septimus, and he says that these were the only writers previous to his time; yet he allows that there must have been some great Architects among the ancient citizens of Rome, and he instances Cossutius, who was employed to complete the Temple of Jupiter Olympius, at Athens, in the reign of Antiochus, and Caius Mutius, who built, at Rome, the double Temple of Honour and Virtue, in the time of Marcellus. Of the Works of the above-mentioned authors, that of Vitruvius is the only one in existence; the others must have perished before the time of the revival of Learning in Italy.

In describing the Architectural works of the Greeks, we began with their Temples, because the construction of those edifices is more simple than that of any other species of building; and because a certain system had been adopted in the distribution of their parts before any rule was established for the Palaces of Princes, or the dwellings of private individuals. In an account of the Roman Architecture, it will be also proper to begin with the Temples of that people for the same reasons.

Forms of the Italian Temples.

The Italians occasionally erected Temples of a circular form, having the naos, or cella surrounded by columns, in a manner similar to that of the monopteral Temples of the Greeks; but the rectangular Temples are, in Italy, as in Greece, much more general than the others. They had the same denominations in both Countries with respect to the disposition of the columns, the number of columns in front, and the magnitude of the intercolumniations; but there are some differences in the proportion of the lengths to the breadths, and the Roman buildings have not always the same simplicity of plan as those of the Greeks.

No Tuscan Temples remain.

There is no Temple remaining to afford an idea of the style in which such edifices were constructed by the Etruscans; and from the brief description given by Vitruvius, we only learn that they were of a rectangular form, like those of the Greeks, with a portico in front, the columns of which were placed at a considerable distance asunder; that the shafts of the columns were plain and were supported on simple bases; that the walls and columns were of stone, and the entablature of timber.

A Temple at Cora, and another which is supposed to have formerly existed at Albano, both of which places are in the vicinity of Rome, have been considered as Etruscan works, but this is certainly a mistake; the Architecture of the former is evidently a modification or corruption of the Grecian Doric, and was no doubt executed by Greek colonists; and the fragments of a column and entablature which have been found at Albano no less evidently belonged to a Doric building executed in the time, and probably at a late period of the Empire. A Temple dedicated to Jupiter Latialis, is said to have been built at this place in the time of Tarquin the Proud, and both here, and at Tusculum, in the neighbourhood, are many substructions, which probably belonged to Tuscan or Latin buildings; but the Temple has entirely disappeared, and all those substructions seem to have been subsequently built upon, so that it is quite uncertain to what works the remains which have been discovered at these places are to be ascribed.

Temples Vesta a of the Si

Of the Roman circular Temples, there exist the remains of two, of ancient date, which deserve to be particularly mentioned. One of these is in Rome, and was dedicated to Vesta; the other is a Temple of Vesta, or of the Sibyl, and is situated at Tivoli. Their cells are cylindrical, and were supposed to have been covered at top by domes which rested on the walls, though they do not possess any feature which may render this fact certain. The Temple at Rome stands on three steps surrounding the building, and that at Tivoli on a circular basement, about five feet high, and bounded by a vertical wall. The exterior of each cella is surrounded by a colonnade of the Corinthian Order, and of a circular form; and Palladio says, that the lengths of the columns are equal to the diameter of the cella, agreeably to a rule given by Vitruvius in his IVth Book. The same Architect observes, that the columns are not planted vertically, but are inclined a little at top towards the wall of the cella; and this he supposes to have been intended to resist the horizontal thrust of the vault. But it has been since determined by measurement that the contrary is the case in the Temple at Rome; the axes of the columns being inclined outward at the top; and this inclination, which might be supposed to have arisen from the pressure of the vault towards the exterior, a pressure which the other construction was intended to prevent, is now believed to have been designedly given to counteract the effect of the general diminution of the upper part of the building, caused by the particular diminutions of the surrounding columns. In the Temple at Tivoli, the leaves of the capitals are cut into the substance of the vases, whereas they are generally executed in relief. Mr. Gwilt observes that this Temple, though not highly finished, is of a beautiful form.

The P theon.

But the circular Temples of Italy, which by some are supposed to have been adopted from the form of the Tower of the Winds, or the Monument of Lysicrates, are exhibited in the greatest perfection in the Pantheon at Rome. This remarkable building is generally supposed to have been built by Agrippa, about A. D. 14; though there seems reason to believe that the body of the Temple was erected during the Republic, and that only the portico was added or renewed by Agrippa. Its plan is a complete circle, whose interior diameter is 137½ feet; the wall is about 23 feet thick, with eight hemicylindrical cavities formed vertically in the thickness, at equal distances from each other, about the building, in order to save materials; and there are three semicircular, and four rectangular recesses, formed in the interior face of the wall, with two columns about 83 feet high in front of each, and a pilaster at each angle.

It is probable that, originally, all these seven recesses constituted as many semicircular-headed alcoves, open towards the interior of the building from top to bottom; though now the upper parts of some are concealed by the ornaments above the entablature of the columns and pilasters before-mentioned. The alcoves perhaps then contained altars, and, at present, they serve as chapels. All the lower part of the interior is of marble, and probably is as ancient as the time of Agrippa.

The cylindrical wall of the Temple, which is chiefly of brickwork, is 102 feet high, on the exterior, terminated above by a horizontal cornice, and divided into three parts, horizontally, by two other cornices, at the heights of 45 feet and 74 feet respectively; and within the thickness of the wall, in each of the two upper divisions, is formed a row of arches the interiors of which are filled up with horizontal courses of brickwork.

The curvature of the wall is interrupted in front by a rectangular projection 103 feet broad and advancing 20 feet from the circumference of the cylinder. This projection has a plane surface on the exterior, in which is the doorway, with a cylindrical recess on each side; it has four pilasters in front, and is terminated above by a pediment the horizontal cornice of which is on a level with the second of those on the cylindrical wall; the apex of the pediment is 20 feet above the base, so that the height of this member is about one-fifth of the whole length of the horizontal cornice. In front of this projection, and of equal breadth with it, is an octastyle portico, projecting 62 feet from the circumference of the circular part of the edifice; the columns have plain shafts, and are about 47 feet high, and there is a double row, each containing four columns, between those in front and the pilasters beforementioned. The portico is covered by a pediment similar to that on the wall of the building, and the horizontal cornice of the latter is cut by the sloping sides of the roof of the portico.

Above the columns and pilasters, in the interior of the building, is a horizontal entablature, over which is a podium surrounding the Temple; this formerly supported a row of small pilasters with rectangular recesses between them, and the whole was crowned by a second entablature, the top of which is on a level with the second exterior cornice. The pilasters, which seem to have been of later date than the columns below, are now removed, and a different arrangement of the ornaments has taken place. From the second entablature, as a circular base, 75 feet from the ground, springs the dome, which is of a hemispherical form, 137½ feet diameter, ornamented interiorly with five horizontal rows of sunk panels, whose sides have the appearance of inverted steps, and ending at top with a circular opening the diameter of which is 26 feet. Several horizontal courses of brickwork surround the dome at the top of the wall on the exterior, and seem as if intended to resist its lateral thrust. The whole Temple, inside and out, is of the Corinthian Order, and the foliage of the capitals resembles clusters of olive leaves. Formerly the pavement of the Temple was ascended by steps, but the ground has now risen so much on the exterior that it is necessary to descend in order to get within the building. A plan, elevation, and section of this Temple is given in pl. xii.

The height of the columns of the portico is 47.029 feet, and the lower diameter of the shaft is 4.797 feet; the architrave is divided into three faciæ, which are not exactly in vertical planes, but their upper extremities incline towards the building, and the height of the whole entablature is 10.217 feet, or $\frac{1}{4.6}$ of that of the column. The cornice has no dentels, and their place is occupied by a plain facia, but below the modillons is an echinus moulding sculptured with oves; the distances of the modillons from each other are equal to half a diameter of the column, and their breadths are equal to 0.2 diameter. See pl. xi. fig. 1.

In the interior of the Pantheon, the height of the columns is 34.674 feet, and the lower diameter is 3.642 feet. The shafts are fluted and the channels are filled with cablings, or reeds, as far as one-third of their height. The extremities of the modillons, and those sides of the lacunaria, or coffers, in the soffit of the corona, which, in a building formed by plane walls, would be parallel to the face of the wall, are here portions of circles the centres of which are in the axis of the building; and those sides of the modillons and coffers which would be perpendicular to the face, all tend to the same axis.

Temples of Bacchus

We may conclude our account of the circular Temples at Rome with a short description of those supposed to have been dedicated to Bacchus and Minerva Medica in the same city, though the changes they have undergone render it difficult to ascertain what was their primitive state. The former consists of a cylindrical wall, 89.36 feet diameter, raised upon twelve semicircular arches, springing from a double circular peristyle, the columns of which are coupled in the direction of the radii of the plan of the Temple, and the whole is crowned by a hemispherical brick dome, 65.6 feet high from the pavement. On the exterior of this circular peristyle is another cylindrical wall, enclosing a corridor 14.75 feet wide, which surrounds the colonnade; this corridor is crowned by a semicircular vault 32 feet high from the pavement, and between its roof and the base of the dome is a row of semicircular-headed windows in the cylindrical wall of the central part of the building. In front there has formerly been a portico, which is now destroyed.

and Minerva Medica.

The body of the Temple of Minerva Medica is of a cylindrical form on the exterior and 110 feet in diameter; but the interior of the wall is formed in ten plane vertical faces, in each of which is a semicircular recess open towards the centre of the building. The whole is covered by a hemispherical dome of brickwork, the vertex of which is 113 feet from the pavement. On each side of the body of the building there was formerly a semicircular wing covered by a vault in the form of a portion of a sphere, but these are now gone to ruin. At the entrance of the building is a rectangular vestibule, with four Corinthian columns, and two pilasters of the same Order in front. The whole vestibule is covered with a pediment roof.

It is observed by Mr. Forsyth that a custom has prevailed of considering every circular edifice containing alcoves, as part of a Roman Bath, and the three Temples last mentioned are among those to which that destination has been ascribed; the opinion may not be often well founded, but there is some probability that with respect to the Pantheon it may be correct. The Baths which, according to Dion, were executed by Agrippa, are supposed to have constituted an immense edifice of a rectangular form; and from the traces of walls which have been discovered at the back of the Pantheon, as well as from the great alcoves in the interior, this building is thought to have been a sort of vestibule connected with them on the side opposite the portico. Cameron's *Description of the Roman Baths.*

CHAPTER II.

The Religious Edifices of the Romans between the Times of Augustus and Constantine.

The generality of the Temples erected during and subsequently to the time of Augustus, in every part of the Roman Empire, were of rectangular forms; and though the plans of most of them have the simplicity of the Grecian models, yet there are some among them of a more complex character, and seeming to have been the prototypes of a style of building which, at a later day, became universal in the Religious Architecture of Europe.

Temple of Jupiter Tonans

At the foot of the Campidoglio, (the ancient Capitol of Rome,) formerly existed one of the Temples said to have been built by Augustus, and supposed to have been dedicated to Jupiter the Thunderer. The whole of it is now destroyed, except three columns, but by tracing the ruins, it is found to have been of a rectangular form, 115 feet long and 92 feet wide, measuring on a line circumscribing the columns. At that extremity of the cella which is opposite the pronaos was a hemispherical recess, open to the interior, and occupying nearly the whole breadth of the face. The Temple has been octastyle and dipteral, but the columns were not continued on the rear face, because that part was next to the rock, and nearly joined it. It seems that on this face was a very thick wall, and at a little distance behind it was an arcade, forming a facing to the rock of the Capitol, with half columns attached to the piers. The columns of the Temple are fluted, and of the Corinthian Order. It was about this building that, according to Suetonius, Augustus caused small bells to be hung, either for ornament, or that, by the sounds they emitted when agitated by the wind, birds might be deterred from settling upon the consecrated edifice.

The height of the columns is 47.082 feet, and the lower diameter is 4.598 feet, consequently the height is equal to 10.24 diameters. The base consists, besides the plinth, of two tori, between which are two scotiæ, with the fillets, and the scotiæ are separated from each other by a double astragal. The capital consists of two rows of leaves, the exterior surfaces of which have considerable obliquity to the axis of the column, and above these are the stems which curl under the abacus. The architrave is divided into three faciæ, all of which incline backward, and the mouldings which separate them are ornamented. A great rectangular panel, with ornamented borders, occupies nearly the whole of the architrave and frize over the front of the columns, for the purpose of containing an inscription, the faciæ of the architrave being interrupted abruptly to make room for it. The cornice contains a row of dentels between two quarter-circle mouldings, and over the upper of these is a row of modillons, which support the corona. The height of the entablature, not including the cymatium, is 9.514 feet, or $\frac{1}{49}$ of the height of the column.

Temple of Jupiter Stator.

Between the Campidoglio and the Palatine Hill are yet standing three beautiful Corinthian columns, which have usually been named the remains of a Temple dedicated to Jupiter Stator; but so little certainty is there of the truth of this denomination that the ruins are now supposed to have been part of the comitium in front of the Senate-house. Very little has been ascertained of the form of this Temple, if it has been one, but Palladio thinks it was peripteral and octastyle. The columns are 47.646 feet high, and the lower diameter is equal to 4.841 feet; consequently the height is equal to about 9.8 diameters. The architrave is divided into three faciæ, nearly equal to each other in breadth, and the exterior surface of the frize, as well as that of the lower facia of the architrave, is vertically over the circumference of the upper part of the shaft of the column: there are both dentels and modillons in the cornice. The height of the entablature, not including the epitithedas, is equal to 11.93 feet, or about one-quarter of the height of the column, and the under part, or soffit, of the corona has, formed in it, square coffers, or panels, ornamented with sculpture. (See figs. 2, 3, 4, pl. xi.)

Temple of Peace.

We are brought next to the remains of a Temple dedicated to Peace, which is remarkable for exhibiting a great deviation from the general simplicity of the Roman and Greek Temples. Its plan is rectangular, and a vestibule or porch was formed along the whole breadth of the building in front. The vestibule was covered by a vault, the height of which from the pavement was about 35 feet; in front were six semicircular-headed apertures serving as entrances, and, corresponding to these, were as many semicircular apertures in the front wall of the building. The length of the Temple on the exterior, not including the depth of the porch, is 294 feet; the depth of the porch is 30 feet, and the breadth of the Temple is 197 feet. The pavement was 10 feet above the ground, and there has been an ascent to it by steps in front of the vestibule.

The building may be considered as divided longitudinally into three parts nearly equal to each other. The central division, or as it would be now called, the nave, was a grand hall of a rectangular form, extending the whole length of the Temple, and equal in breadth to one-third of that of the Temple. This was covered by a vault, consisting of three groins, formed each by the intersection of two hemicylindrical vaults at right angles to each other. The height of the crown of the vaulting from the pavement must have been about 116 feet, and the interior surfaces of the groins show traces of having been ornamented with sunk panels. A hemicylindrical recess, 13½ feet deep, is formed in the wall at that end of the Temple which is opposite the entrance, and is covered by a half-dome, or quadrant of a sphere, the height of the vertex of which from the pavement is 71 feet. The front of the recess is open to the interior of the Temple, and the interior surface of its dome is ornamented with octagonal and square panels sunk in the masonry, with sides in the form of inverted steps.

The two lateral divisions of the Temple were each subdivided into three rectangular parts, nearly equal to each other, by two walls parallel to the breadth of the Temple; these parts were open towards the central division, and were covered above by hemicylindrical vaults springing from the walls just mentioned, and from the parallel extremities of the building. The height of the crown of these vaults from the pavement was 71 feet, and in each of the walls is an aperture of communication. The central part in each of the grand lateral divisions is terminated by a hemicylindrical recess, covered and ornamented like that at the extremity of the building; only one of these two recesses is now standing, and in its vertical wall are two tiers of small niches. Those parts of the side walls of the Temple which form the extremities of the other four parts into which the two lateral divisions are subdivided, are pierced with two tiers of apertures, like windows, with semicircular heads. Each of the four cross-walls terminated towards the central division of the Temple by a Corinthian column, from the entablature of which sprang the ribs of the groins which covered this part of the building. The columns are now destroyed, but parts of the entablatures and bases remain, which are sufficient to give indications of their character. The etchings of Rossini give an accurate idea of the present state of this Temple, and to them we refer the reader.

The roof being entirely destroyed, it is impossible to say how the building was covered on the exterior, but if the restoration given by Palladio were correct, it would appear that two sides of a sloping roof rose from the side walls of the building till they met the walls above the piers on each side of the central division; these were carried up higher than the walls of the two lateral divisions, and, according to that Architect, were terminated by a pediment roof.

The Temple was begun by the Emperor Claudius, and, after the conquest of Judea, it was finished by Vespasian, who deposited in it the spoils of the Temple at Jerusalem. It is said to have been destroyed by fire, or an earthquake, during the reign of Commodus, and, subsequently, to have been restored.

Of the sacred edifices, constructed according to the Ionic Order, which still exist at Rome, the Temple of Fortuna Virilis is the principal. This, which is nearly entire, is of the kind called prostyle, with four columns in front, and one on each side between these and the cella; the sides and angles of the latter are also ornamented with half-columns. The length of the columns is 27.348 feet; the lower diameter of the shaft is 3.109 feet; and this member is fluted with twenty-four semicircular channels having fillets between them. The base is of the Attic kind; and between the volutes in the capital, is a double echinus, of which the larger one is above the other, and immediately below the last is a small astragal and fillet. The architrave is divided into three faciæ, each of which inclines backward, in order, perhaps, to give a greater appearance of stability; the frize is ornamented with sculpture, and there are dentels in the cornice. The height of the entablature, including the cymatium, is 6.784 feet, or one-fourth of the column. (See figs. 5, 6, pl. x.)

This example is remarkable for having the middle of a dentel nearly corresponding with the axis of each of its columns, and all its similar ornaments placed with regularity vertically over each other in the different members of the entablature; circumstances which have not been attended to, perhaps, in any other edifice constructed by the Ancients.

The Temple of Concord is supposed, by some, to have been originally built in memory of the union between the Patricians and Plebeians, when the latter took refuge on the *Mons Sacer*; others think it was dedicated by Tiberius to consecrate the harmony between Augustus and Livia. Be this as it may, the inscription states that it had been destroyed by fire, and subsequently restored; and the bad taste of the restoration sufficiently indicates that it took place about the time of Constantine.

It appears to have been peripteral, with a hexastyle portico in front. The eight columns which remain are of red and white granite of different diameters; the bases are Attic, and all are without plinths, except those of the two angular columns. The capitals are deficient in elegance and badly cut; the architrave has been smoothed to unite it with the frize, and form a plain surface to contain the inscription; there are both modillons and dentels in the cornice, and the interior frize is sculptured.

The columns are 42.861 feet high, and the diameter of the shaft at bottom is 4.486 feet; consequently, the height of the columns is equal to about 9.5 diameters. The shafts of the columns are plain, and the inequality in their lengths is some proof that they have been taken from other edifices. Each capital contains eight volutes, formed diagonally with respect to the abacus; between the volutes is an echinus, with an astragal below it; under this comes a cima recta and fillet; and below these, that is, at the top of the shaft, is another astragal; the first three mouldings are sculptured, and the other plain. The architrave and frize are each equal to half a diameter in height, and the former has been divided into three faciæ. The height of the whole entablature is equal to 7.2 feet, or about one-sixth of that of the column; and above the cornice, over the intervals of the columns in front of the Temple, is a row of flat segmental arches, seemingly intended to relieve the weight of an incumbent structure from that part of the entablature.

Notices of sundry other Temples at Rome.

Of the remaining Temples at Rome, the following are the principal; we notice them only to show their general form, where this can be ascertained; for the proportions existing between the parts of the Orders employed do not differ materially from those in the examples which have been already exhibited.

Among the Temples built by Augustus at Rome there remain the ruins of one dedicated to Mars the Avenger. Its plan is rectangular; the whole length of the cella and pronaos together, including the thickness of the walls, was about 116 feet and the breadth about 73 feet. The Temple was peripteral and octastyle, with four columns between the antæ pilasters. The columns of the peristyle are of the Corinthian Order, and the intervals between them are equal to about a diameter and a half.

The Temple of Nerva Trajanus has a cella which is nearly square, but a portico without side walls projects in front. It is hexastyle, and there were two columns on each side, between the front wall of the cella and the front columns of the portico; all the columns are of Parian marble, and of the Corinthian Order, with fluted shafts. The pavement is raised from the ground and supported on arches; a method which, Vitruvius says, was practised in his time. The ascent to the pavement is by a flight of steps in front.

The Temple of Antoninus and Faustina was similar to the one last mentioned. Before this building, was a grand rectangular peristyle, consisting of coupled columns, which were surrounded by walls on three sides, the Temple occupying the fourth.

The building which has been supposed to be the Basilica of Antoninus, is now, with more reason, thought to have been a peripteral Temple. Its plan was rectangular, it had eight columns in front, and seven half-columns were attached to the interior face of the wall on each side of the edifice.

No traces now exist of the great pseudodipteral Temple of Jupiter on the Quirinal Hill, which was supposed by Palladio to have been of the kind called hypæthral; nor of an octastyle Temple of Mars, which he places between the Pantheon and column of Antoninus.

By the late excavations in the Forum of Rome, the following particulars have been ascertained respecting the grand double Temple, dedicated to Venus and

Rome, which formerly existed within the circuit of that magnificent place. It appears to have been a peripteral edifice, of a rectangular form, 351.5 feet long, and 166 feet wide between the centres of the extreme columns; and consisting of two square Temples joined together at their rear faces; in each of which was a hemicylindrical recess covered by a half dome. The building was decastyle, with twenty columns in flank and four columns between the antæ, both of the pronaos and posticus. To the pavement of the peristyle was an ascent by steps, and the whole was surrounded by a peribolus 525 feet long, and 318 feet wide, consisting of a double row of columns, twenty-six in front. The columns on the flanks of the peribolus were interrupted by a portico in the centre of each side, that is, opposite the place of junction of the two Temples; and there was an ascent to the platform of the peribolus by a magnificent flight of steps extending along the whole front. See the Work on the restoration of the Forum, by Caristie, and a Plate recently published from a design of Mr. C. H. Cockerell.

The Roman people must have beheld with pride the splendour of this Temple when in a perfect state; the perspective of the long files of columns forming the peribolus, blended with that of the more lofty columns about the richly ornamented building in the centre, must have produced an effect perhaps unrivalled in sublimity by any work in the ancient World.

We may conclude this account of the Temples in the city of Rome, by observing that in the Colonna Gardens have been found some fragments of an entablature which is believed to have belonged to the portico of a magnificent Temple, of the Corinthian Order, built by Nero. The Temple is supposed to have been dodecastyle, or to have had twelve columns in front; and from the measurements which have been made of the fragments we are enabled to determine the dimensions of the several members of the Order.

The height of the columns was 65.5 feet, and equal to about ten times the lower diameter. The architrave is divided into two faciæ, of which the separation and the crowning moulding are both sculptured, and the frize is filled with immense scrolls of the richest sculptured foliage, remarkable for its elegance, and for its approach to the purity of the Grecian style. The cornice is without dentels, and contains a row of modillons which are bounded every way by plane surfaces; these, as well as the modillon band, are divided into two faciæ of which the upper exceeds the lower in height and breadth; the corona is bold and plain, and the epitithedas is delicately sculptured. See fig. 5, pl. xi. The height of the entablature, not including the cymatium, is 14.184 feet, or $\frac{1}{4.6}$ of the height of the column; and the whole height of this gigantic Order must have been above 81 feet; the length of the portico was, probably, about 220, and the height of the vertex of the pediment from the pavement about 106 feet.

Within the limits of the Roman Empire innumerable Temples must have been erected previous to the time of Constantine, many of which were splendid edifices; but, of these, a few only have escaped the destroying hand of time: and, besides those in Rome, and the very ancient Temple at Tivoli, before-mentioned, the following are, perhaps, the most considerable.

Temple on the Clitumnus

On the Clitumnus, below Trevi, is a small prostyle Temple raised on a basement eight feet high, to which there is an ascent by steps in front, on each side of the centre, and leading to the entrances on the flanks of the porch. In front of the porch are four columns between two antæ pilasters which are detached from the walls; the pilasters are fluted vertically, as usual, but the columns are remarkable on account of two of them being fluted obliquely round the shaft, and the shafts of the other two being sculptured all over with leaves· sure proofs of a decline of good taste. Both columns and pilasters are of the Corinthian Order.

Temple Assisi,

At Assisi in Umbria is a Corinthian Temple with six columns in front, and two columns on each side of the portico between the wall of the cella and the front columns. The Temple is rectangular, and its length is nearly equal to twice its breadth; it is remarkable on account of the columns being placed on pedestals, a circumstance which has not been observed in any other ancient example. The ascent from the ground to the pavement of the Temple is by steps along the front of the building; upon the middle step are placed blocks which rise as high as the level of the pavement, and the bases of the pedestals stand on these blocks. The height of the pedestals is about equal to the breadth of an intercolumniation; that is, to about twice as much as a diameter of a column.

Templ Fortu Præne

But every building of Italy must, in grandeur of effect, when seen from a distance, have yielded to the Temple of Fortune at Præneste, about twenty-one miles from Rome. We have already given some account of this Temple in our *Miscellaneous Division*, (FORTUNE,) and we shall here add a few more peculiarly technical particulars. It was built on the upper part of a rock, one side of which was cut into four broad terraces supported by walls or arcades; and, from the little which is now visible, the following particulars have been ascertained. On approaching the rock, the spectator arrived at a flight of steps, 7 feet high from the ground, extending in length about 570 feet, and only broken by a rectangular projection from the centre; this led to a narrow landing-place from which, by a flight of steps at right angles to the former and commencing at the distance of 180 feet from the centre on each side, there was an ascent to another landing-place, 18 feet above the former, and supported, in front, by a row of semicircular arches on piers, of which many traces remain. In the centre of the second landing-place were steps leading to a third, which was 600 feet long, 22 feet above the first landing, and supported in front by a plain wall. Again, in the centre of this landing-place, were steps leading to the first grand terrace, which was, also, 600 feet long, and 80 feet broad. A few steps, extending the whole length of this terrace, led to the next, which is 570 feet long, and about the same breadth as the other. Near the centre of this were two quadrangular buildings, each 50 feet long, 33 feet broad, and 65 feet distant from each other. At the back of each of these Temples was a flight of steps at right angles to the former, leading to a third terrace, 270 feet long, 26 feet wide, and 36 feet above the first landing. On the right and left of the centre of this terrace was a high flight of steps parallel to the last and leading to the fourth, or upper terrace; this is 160 feet long, 70 feet wide, and 90 feet above the first landing; along its whole front and on each side was a colonnade. At the centre of the opposite face of the platform, appears to have been a semicircular colonnade, 43 feet diameter, which might have been part of a Theatre; and on this, which was the principal terrace, was probably the great Temple.

Similar systems of buildings exist in places once occupied by the Greek colonists in Asia Minor.

These extensive terraces, rising gradually above each other in a pyramidal form, to the height of above 100 feet from the plain, and adorned with splendid colonnades, must have presented an imposing spectacle; which, aided by the veneration inspired by the Oracle, whose seat was at this place, must, also, while the superstitions of heathen Rome prevailed, have rendered Præneste one of the most interesting spots in a land where almost every object, natural or artificial, could excite in the mind of the observer admiration or devotion.

The five Temples last mentioned are within the limits of Italy; and there now only remain to be described a few of the principal Roman Temples the ruins of which still exist in the Provinces of the Empire.

es at
s.

At Nismes, in Provence, are the remains of two buildings which are generally believed to have been Temples, though one of them has been supposed to be a Basilica, or Court of Justice. The latter, which goes by the name of the *Maison Quarrée*, is of the Corinthian Order, and stands on a stereobata, 10 feet 5 inches high, with steps along the whole front; it is hexastyle, with two columns on each side between the cella and the front columns, and there are half-columns placed at intervals against the walls on the sides and rear of the building. Above the basement are two courses like steps along the side-walls, and the plinths of the columns rest upon the upper of these courses.

The other is a rectangular Temple, on the exterior of which are no columns but, instead of them, a wall surrounds the cella at the distance of about seven feet from it, and encloses a passage. There is a doorway leading into the passage on each side of the building, but the door of the Temple was in the interior wall in front, so that the cella of the Temple must have been completely dark; and, hence, Palladio infers that it must have been dedicated to the Infernal Gods; others suppose it to have been a Temple of Diana. There are recesses all round the interior of the cella, in which, perhaps, were statues, and there are columns on pedestals between the recesses. From the entablature, above the tops of these columns, sprang the principal arches which, like semicircular ribs, extended across the Temple, and from one of these arches to another were placed slabs of stone, longitudinally, which formed the vaulted roof, but this is now fallen down. At the extremity of the cella opposite the doorway, the breadth of the floor is divided into three equal parts, forming divisions which are nearly square; the middle space had pilasters at the angles, and is on a level with the floor of the Temple; the two side-spaces are raised as high as the pedestals of the columns and pilasters; and the ascents to the two platforms are by steps formed in the thickness of the adjoining wall of the cella, through which the entrances are made from the passages round the building. The capitals of the columns in this Temple have two rows of leaves, above which is a sort of fluting, and, over all, a circumference of oves; but they are remarkable for having no volutes. The edifice is thought to have been a Roman work executed at a late period of the Empire.

The conquerors of mankind have, almost always, caused the style of Architecture practised in their own Nation to be adopted, and even to supersede that which originally prevailed in the Countries they subdued. Thus we find the rude majesty of the Egyptian edifices was exchanged, in the Northern part of that Country, for the lighter Grecian and Roman styles, after the invasions of Alexander and Cæsar; the Doric and Ionic Orders, which were almost exclusively employed by the ancient Greeks, were supplanted by the Corinthian, after the Roman conquest. Thus, also, whatever style prevailed in Syria in the earliest times, whether the Egyptian or some modification of it, nothing now exists of such a style in that Country; and the Architectural monuments which Time and the Barbarians have partly spared, were, evidently, erected during the existence of the Roman power in that part of the World.

Temple at Balbec.

This is the case with the Temple of the Sun at Heliopolis or Balbec, in Syria, a city once of great importance and situated in the neighbourhood of Tyre. According to the testimony of the Historian, John of Antioch, this Temple was built by Antoninus Pius, probably to replace a more ancient one erected by the Greeks or Syrians; and from the descriptions given by Messrs. Dawkins and Wood, who visited Balbec in 1751, we are enabled to obtain a just idea of these interesting remains, which had been so long unknown to the people of Europe. The Temple itself was of a rectangular form, and occupied the Western extremity of a great quadrangular enclosure, the sides of which were parallel to those of the Temple. On the opposite side of the rectangle was a hexagonal court serving as a sort of vestibule, and a grand portico formed the Eastern extremity of the whole.

The Temple was surrounded by two rows of Corinthian columns; its length, from West to East, was 268 feet, and its breadth, from North to South, was 146 feet, measured on a line circumscribing the exterior columns, and the entrance was on the Eastern side. The portico had ten columns in front, and there were nineteen in the exterior row along each flank. No more than six of these columns were standing when the gentlemen above-mentioned were on the spot; their height is 58 feet, their diameter 6.917 feet, and the height of the entablature about 13 feet. The intercolumniations are equal to 14 feet, and the distance of the columns from the walls is the same. The shafts are plain; each consists of three cylindrical blocks connected together by iron-plugs about one foot diameter, and the bases are of the Attic kind. The entablature is extremely enriched; in its cornice are both dentels and modillons, and a pediment roof probably crowned the whole. The colonnade of the Temple was surrounded by a terrace 30 feet high, above the level of the neighbouring ground, and supported on the exterior by a sloping revetment wall.

The pavement of the portico of this Temple is ascended by thirty steps, and the front wall within the portico is enriched with sculpture; the jambs of the portal are of marble richly sculptured, and the soffit of its architrave is ornamented with a great eagle, in bas relief, with extended wings and holding a caduceus. The interior of the Temple is divided into three parts longitudinally, by two rows of fluted Corinthian columns standing on pedestals, and supporting an entablature. The walls are ornamented with pilasters corresponding to the columns, and the intervals are occupied by niches with semicircular heads; the bottoms of the niches are on a level with the bases of the columns, and above these niches are others crowned by pediments. Towards the Western extremity of the central division is an ascent by thirteen steps to a hemicylindrical recess forming a sort of sanctuary, the entrance to which is between two great pilasters, and the interior is ornamented with festoons, flowers, birds, Neptunes and Tritons. The pavement of the Temple is supported by great vaults which, perhaps, covered a subterranean Temple.

The great quadrangle is in length about 360 feet, and breadth about 350 feet, and the Temple is situated on the middle of the Western side; on the three other sides are quadrangular recesses, or apartments, 60 feet long and 22 feet broad; these are open towards the centre of the area, and, in front of each, were four columns supporting the roof. Between these, on the Northern and Southern sides of the quadrangle, there are semicircular recesses, each 32 feet in diameter, with two large columns in the open sides next to the court.

The hexagonal court, before-mentioned, on the Eastern side of this peribolus, is itself enclosed within a quadrangular area 146 feet broad, and having its length equal to the breadth of the great quadrangle, of which this appears to be a continuation. The hexagonal court is also surrounded by recesses, or apartments, contiguous to the interior faces of the walls, and similar to those in the great quadrangle; they had columns in front, and their walls were adorned with niches or tabernacles.

On the Eastern side of the hexagonal court is the grand portico, which is 180 feet long, 40 feet deep, and elevated 24 feet above the ground in front, from which there is an ascent to the pavement by steps of the same length as the portico itself. The latter is flanked at each end by a tower 38 feet long, and 31 feet wide, ornamented by pilasters attached to the exterior faces of the walls; the towers are open towards the interior of the portico, and in the aperture of each were two Corinthian pilasters. The front of the portico was formed by twelve columns of the Corinthian Order, with plain shafts and Attic bases. The diameters of the columns at bottom are 4 feet 3 inches, and their height, including the entablature, was 52 feet. The architrave is divided into faciæ, of which the upper one is enriched with sculpture; the frize is plain, and there are both dentels and modillons in the cornice. Over the portico was an Attic Order, 10 feet high, with pilasters above each column. The bases of the columns rest upon pedestals, 3 feet 6 inches high, the faces of which project from that of a podium, of the same height, and extending the whole length of the Eastern face of the wall enclosing the quadrangle. Under the portico are recesses or tabernacles, in two rows, with circular and triangular pediments, of which some are complete, and others interrupted at the vertex. In the wall under the portico are three doorways, of which the middle one is 34 feet high, and 17 feet wide; these lead into the hexagonal court, on the opposite side of which are three similar doorways forming the entrances to the great quadrangle.

On the Southern side of the great Temple is a smaller one, of later construction, with a vaulted roof; this Temple is of a rectangular form, peripteral and octastyle, with a double row of columns in front, and thirteen columns on each flank; all are of the Corinthian Order, with shafts 44 feet high, and 4 feet 11 inches diameter. The roof under the colonnade has been sculptured in tablets of hexagonal, rhomboidal, and triangular forms, within which are represented Jupiter, Leda, and Diana; also some busts, probably of Emperors and Empresses. On each side of the doorway in the middle of the wall is a staircase, and at the interior angles of the cella there are portions of two columns the shafts of which are joined together. Along the wall in the interior of the cella there is a row of half-columns, 4 feet diameter, attached to the faces of a number of square piers projecting from the wall, and distant from each other 6 feet 7 inches. The columns stand on pedestals 11 feet high, and their height, including the entablature, is 49 feet; the latter is broken over the columns, and, above it, springs the vaulted roof. Between the columns are two tiers of recesses, of which those in the lower tier are terminated by semicircular, and those in the upper tier by pediment heads. At the Western extremity of the cella is a rectangular space, like a sanctuary, on a higher level than the pavement, from which there is an ascent to it by steps; in front are two piers with a half-column attached to the face of each.

Near this edifice are the remains of a third Temple with a circular cella, 32 feet diameter, standing upon a high stereobata, and appearing to have been crowned by a hemispherical cupola. The cella is ornamented with Corinthian pilasters attached to the walls, between every two of which are semicircular-headed niches. One face of the stereobata is rectilinear, and the remainder is cut in five faces in the form of rentrant arcs of circles. On the rectilinear front are four columns, each 39 feet high and 3 feet diameter, which constitute a façade 50 feet long on that side; and over each of the salient points of the basement is placed one column, so that the cella of the Temple appears to be surrounded by columns, all of which are of the Corinthian Order. The columns support a horizontal entablature, which forms rentrant arcs of circles between the columns, like the basement. The interior of the cella is octangular, and surrounded by insulated columns, between every two of which are niches; and a general entablature crowns the whole.

Temple, Palmyra

In the middle of the Desert, between Balbec and the Euphrates, lie the remains of the ancient City of Palmyra, which, by some, has been thought to be the Tadmor in the Wilderness, built by Solomon. Innumerable ruins now cover the ground on which the city stood; but nothing has been observed among them which can justify our assigning them an antiquity higher than the time of the Roman Empire; and it is probable that the edifices to which they belonged, were raised about the same time as those of Balbec.

The principal object is a Temple of the Sun, which stood in the centre of a rectangular peribolus, nearly square, and about 740 feet long in each direction. The walls forming the peribolus were 59 feet high, and were raised upon a continued podium, the height of which from the ground was 16 feet; both on the exterior and interior faces of the walls was a row of attached Corinthian pilasters, and an entablature crowned the whole. On the Western side of the enclosure was a portico, 138 feet long; its pavement was on a level with the top of the podium, and the ascent was by steps extending the whole length of the portico. The front of the latter consisted of ten Corinthian columns with Attic bases; of these, the three extreme on each side are single, and the others are coupled together in two pairs, one on each side of the centre. The line of columns projected 49 feet from the face of the wall, and was crowned by a pediment. The architrave was divided into several faciæ; the front of the frize swelled in an elliptical curve; and there were both dentels and modillons in the cornice. The portico was continued through the wall, and formed another on the interior. Within the enclosure, and parallel to each wall, were two rows of columns, except on the Western side, where the portico stood, and here there was but one row. The columns on this side were 48 feet 7 inches from the interior face of the wall, and 8 feet 3 inches from each other; but, on the other sides, one row was 19 feet from the face of the wall, and the other at the same distance from the first. Altogether, there were two hundred and eighty-eight pillars surrounding the court, with a highly enriched entablature above them. The shafts of the interior columns were all plain, and on each was fixed a bracket to support a vase or a statue.

The Temple within the enclosure was quadrangular, the length of its cella, from North to South, was 133 feet 4 inches, and its breadth, from East to West, 47 feet. The walls of the cella were terminated by antæ pilasters; between which, at each extremity of the building, were two Ionic half-columns at equal distances from each other and from the ends. The Temple was raised upon a platform, which was ascended by steps surrounding it; it was peripteral, with eight columns in front and fifteen on each flank, and the distances between the faces of the pilasters on the wall and the nearest sides of the columns are about 22½ feet. The columns stand on plinths 1 foot 8 inches high, and the height of the column and entablature, including the plinth, is 64 feet. The shafts are fluted, and the capitals seem to have been ornamented with metallic leaves and volutes, fixed to the vases; the entablature is filled with sculpture, and there are both dentels and modillons in the cornice. The principal entrance faces the West, in one of the long sides of the Temple; where there is a doorway, 33 feet high and 15 feet wide, between two clustered columns which form part of the peristyle of the Temple; and there are four windows on each side of the cella, rather narrower at top than at bottom. In the interior, at each extremity of the ceiling, are panels of square, octagonal, and rhomboidal figures, each having a flower in the centre; and, about the circumference of a circle, in one division, are the signs of the Zodiac.

About 1200 feet to the North-West of this Temple commences a quadruple row of columns, about 82 feet broad, and supposed to extend to the distance of 4000 feet. At the entrance of this colonnade is a gateway, resembling a triumphal arch, having three passages, and crowned by a pediment; it stands obliquely to the lines of columns, and is adorned with Corinthian pilasters, whose faces are panelled and enriched with sculpture. Near this is a Temple, the cella of which is square with a portico consisting of four Corinthian columns in front, and one on each side between the front row and the antæ; and there are half-columns attached to the exterior on each face. On the shafts of the columns in front of the portico are brackets for the support of statues, and the frize is enriched with festoons.

in the
polis.

In various parts of Syria are remains of Roman Architecture, similar, in style, to that of Balbec and Palmyra. One of the cities of the Decapolis, now called Djerash, situated on the Eastern side of the Jordan, in about 32° 20′ North latitude, and which is thought by Mr. Burckhardt to have been the ancient Gerasa, contains many interesting objects which have been attentively examined by Mr. Barry, who lately visited this place in the course of his extensive travels in the East. We are informed, by this gentleman, that the city consisted of two long streets crossing each other at right angles, and, at the extremity of one, is a great elliptical area, which, as well as the sides of the streets, is adorned with magnificent columns; but, as accurate delineations of these ruins have not yet been published, we content ourselves with quoting the general description given by Mr. Burckhardt, which will convey some idea of their character.

This enterprising traveller states that the first object which strikes the attention, on coming from Souf, after passing the wall surrounding Djerash, is a Temple in the form of an oblong square, 25 paces long and 18 broad, executed in a style of Architecture which belongs to the best period of the Corinthian Order, and superior to every building of the kind, except the Temple of the Sun at Palmyra. The ruin stands on an artificial terrace, five or six feet above the ground, and two rows of columns, containing six in each, adorn the front; it occupies the interior of a peribolus formed by a double colonnade, which is remarkable in having the corner columns composed of two shafts joined together in such a manner that, on the plan, the double column resembles a heart.

Proceeding Westward from this Temple, through the ruins of private habitations, at two hundred yards distant from it, are the remains of a small Temple, of which three Corinthian columns alone exist. The streets are, partly, paved, and on each side are colonnades, which present some peculiarities. In certain places a tall column stands near a short one, the entablature of the latter resting on a bracket placed against the shaft of the former, which must have given to the façade the appearance of patchwork. Behind the columns are several low apartments covered with vaulted roofs. Near the extremity of the long street are the remains of an Aqueduct; hence the ground rises, and on the top of the hill is a beautiful Temple with a Corinthian peristyle. Near this is a large Theatre. Similar ruins are observed at Omkeiss, or Gamala, and at Amman, or Philadelphia.

The Provinces of Asia Minor have been lately traversed in different directions by English Missionaries, and from their notices we learn that there are to be seen in them many interesting remains of Roman, or of the later Grecian Architecture, capable of rewarding the difficulties and dangers to which artists would be exposed in exploring them.

We have now described the principal Religious edifices that were erected within the limits of the Roman Empire, previously to the Age of Constantine; and we may conclude this Chapter by stating some general rules, which have been given by Vitruvius, concerning the proportions employed in, or recommended for this species of building.

Proportions
of circular
Temples.

We have seen that circular Temples were frequently constructed by the Romans, and that they possess an important feature which is not to be found in any Grecian work; *viz.* the vaulted roof, of a hemispherical form. This mode of building seems to indicate a considerable acquaintance with the laws of mechanical action; but by whom it was invented it will be for ever impossible to ascertain. Vitruvius prescribes that, in monopteral Temples, the pavement should be raised on a stereobata, at a height, above the ground, equal to one-third of their diameter. But when the circular range of columns encloses a cella, the basement should be surrounded by steps; the space between the columns and the wall should be equal to one-fifth of the whole diameter of the Temple, and the height of the columns above the basement should be equal to the interior diameter of the cella. (Book iv. ch. vii.)

Proportions of rectangular Temples.

For the plan of those which he calls Tuscan Temples, Vitruvius gives the following proportions. The breadth is equal to five-sixths of the whole length; half this length is occupied by the cella, which is divided into three parts by walls parallel to the length; the other half is taken up by the pronaos, which has four columns in front, with, perhaps, another row of columns between these and the front of the cella. Such Temples, constructed of timber, probably existed, in Italy, in his time, but not a single example of this kind remains at present.

With respect to rectangular Temples in general, he states that their breadth should be equal to half their length; five-eighths of the whole length should be occupied by the length of the cella, and the side walls of the latter should extend, beyond the front wall, as much as the remaining three-eighths, to form a pronaos; these walls should be terminated by antæ pilasters. If the cella is more than 20 feet wide, two columns might be placed between the antæ, to separate the pronaos from the pteromata, or walks about the Temple. Between the antæ and the two columns just mentioned, he supposes there is raised a *pluteus*, or fence, of marble; he does not say of what height, but probably it was a low wall or species of balustrade. If the breadth is more than 40 feet, he directs that another row of columns should be placed between the front of the cella, and the row between the antæ; and these, though they have the same height as the others, are to be made less thick, it being supposed that, in a space enclosed by three walls, they will appear thicker than the outside columns; or, rather, that the latter will appear more slender than the others, for reasons which have been before stated.

By making the length of a Temple equal to double its breadth, as above prescribed, it will be found that, in peripteral Temples, (supposing the length and breadth to be limited by the centres of the extreme columns in front and flank,) the number of columns in the flank of the Temple should be one less than double the number in front, the extent of the intercolumniations being all equal, and including the extreme columns in reckoning the number both in front and flank. This disposition of the columns is different from that which is supposed to have been affected by the Greeks, as has been shown, and has the advantage of greater simplicity. Among the Romans, it seems to have been generally attended to, when a peripteral Temple was constructed of considerable magnitude, like those of the Sun, at Palmyra and Balbec; but the proportions of the cellæ were very various; far from being conformable to those prescribed by Vitruvius, they are frequently square, or nearly so, as in the Temple of Fortuna Virilis at Rome; and, often, the extremities of the Temples were without pteromata or wing-walls, instead of which, there were merely columns on each side of the pronaos, as in the Temples of Fortuna Virilis and of Concord at Rome.

Doorways of the Roman Temples.

Vitruvius, in the VIth Chapter of the IVth Book, states the forms of the doorways of Temples to be of three different kinds; the Doric, the Ionic, and the Attic. In all three, the members about the aperture have a correspondence with the parts of an entire Temple; thus the jambs, or, as he calls them, the *antepagmenta*, correspond with the columns; the lintel, or *supercilium*, corresponds with the architrave; above the supercilium is a kind of frize, which he calls *hyperthyrum*, and, over this, a *corona*, or cornice.

According to the text of Vitruvius, the height of the aperture of the Doric doorway is to be four-sevenths of the height of the soffit, or ceiling of the pronaos, from the pavement of the Temple; but, as he had before directed the top of the cornice of the doorway to be on a level with the tops of the capitals of the columns in front, this makes the space above the aperture too high, and Newton, his translator, proposes to make the height of the aperture equal to five-sevenths of that of the soffit, as is practised in the Temples at Cora and Tivoli. The breadth of the aperture at bottom is made equal to eleven-twenty-fourths of its height, and the breadth at top is less than that at bottom by one-third, one-fourth, or one-eighth of the breadth of the antepagmentum, at bottom, according as the height of the doorway does not exceed 16 feet, 25 feet, or 30 feet, respectively. Above this last height, Vitruvius proposes the doorway to be of equal breadth at top and bottom; and, in these circumstances, there is some analogy with the diminutions of columns.

He makes the breadths of the antepagmenta, at bottom, equal to one-twelfth of the height of the aperture, and to be diminished, at top, as much as one-fourteenth of the breadth at bottom. The heights of the supercilium, the hyperthyrum, and, perhaps, the cornice, are each to be equal to the breadth of the antepagmentum, at top, not including the cymatium, or moulding on its exterior; the projection of the corona is equal to the same. The supercilium extends, right and left, beyond the exterior of the antepagmenta, at top, so much as to make the extremities stand vertically over the foot of those members, and the cymatium, or exterior moulding, bends round this projection. From this description it will appear that the form of the doorway, with its vertical and horizontal architraves, very much resembles that of the window in the Temple of Minerva Polias at Athens.

The Attic doorway is like the Doric, except that the antepagmenta and supercilium are each divided into two faciæ, of which the exterior projects a little more forward than the interior; and the breadth of the latter is, everywhere, equal to five-sevenths of the breadth of the whole antepagmentum within the cymatium.

In the Ionic doorway, the height of the aperture is found as in the Doric; its breadth at bottom is equal to three-fifths of its height, and the contraction at the top is the same as before. The breadth of the antepagmentum is one-fourteenth of the height of the aperture, and that of the cymatium is one-sixth of the former: the antepagmentum is divided into three faciæ, whose breadths are respectively one-fourth, one-third, and five-twelfths of that of the entire member. The corona over the door is supported, at each extremity, by a console, which Vitruvius calls *ancon* or *prothyris*.

The members about the windows of the Roman Temples were formed in a similar way.

CHAPTER III.

The Dwelling-houses of the Romans.

We turn our attention next to the domestic structures of the Romans, which we purpose to describe from itec- re.

such remains of them as are yet in existence, and from the short, and, generally, obscure accounts given by Vitruvius.

iption ny's

The Consul Pliny, in epistles to two of his friends, Apollonius and Gallus, describes, at some length, the interior arrangement of two Villas, the one in Tuscany, the other, which was the place of his winter residence, at Laurentinum; and the description of the latter, which is in greater detail than that of the other, may serve to convey some notion of the style of the houses occupied by the wealthy Senators of Rome, in the most brilliant period of the city. No remains of this Villa are now to be seen, and there is not sufficient precision in the account to allow a plan of it to be given; it may, however, be worth while to exhibit an outline of that account, which, with a faint idea of the disposition of the apartments, will afford an opportunity to introduce the names by which they were designated.

The entrance, he says, was by a plain *atrium*, or court, which led to a circular portico, or colonnade, surrounding a pleasant area; the colonnade was roofed and had windows of lapis specularis, which excluded the rain and rendered it a convenient retreat in bad weather. After passing this colonnade there was a *cavedium*, or open square, and, beyond this, a handsome *triclinium*, or state dining-room, which looked towards the sea on three sides, through folding-doors or windows. On the left of the passage leading to this *triclinium* were two *cubiculi*, either bed-chambers or saloons, of which one was smaller than the other, and had windows looking East and West. The angle, on the exterior of the building, between the *triclinium* and these *cubiculi*, formed a space screened from the cold winds, and serving as a *gymnasium*, or place of exercise, for the family in winter. Near this was a circular building, the windows of which, he says, admitted the sun during the whole day; it was, therefore, probably elevated above the ground floor; this served as a small *bibliotheca*, or library, and close to it was a dormitory, which was heated by a stove under, or near it. The remainder of this wing of the building was appropriated to slaves and freedmen. On the right of the passage leading to the great *triclinium* was an elegant apartment, and, beyond that, a larger one, serving as a *cœnatio*, or common supper-room; after this came a bed-chamber and *procoiton*, or anteroom, and separated from these by a wall, were two other rooms of the same kind. From these, there was an entrance to a cold-bath, in which were two *baptisteria*, or bathing-places, large enough to swim in; and, joining it, were the *unctuarium*, or anointing-room; the *hypocaustum*, or vapour-bath, and the *propigneon*, or furnace, with two small sitting-rooms. Adjoining these, was the *calida piscina*, or warm bath, from which the bathers had a view of the sea. Near this, there were two turrets, or summer-houses, one of which contained two *diætæ*, or suites of apartments, one on the ground, and another on the upper floor; from the latter there was a beautiful prospect of the sea and the neighbouring villas; the other turret contained a *triclinium*, below, and an apartment above, and, near this, were sundry *apothecæ*, or store-rooms, and a gallery of curiosities.

In the garden was a *cœnatio*, or banqueting-room, with two other apartments behind, and a gallery or colonnade, with windows on each side, looking, on one hand, towards the sea, and, on the other, towards the garden; before this was a *xystus*, or terrace for walking. At one end of this terrace stood a detached building, in which was a *heliocaminus*, or an apartment warmed by the sun, on one side of which was a recess containing a couch, and adjoining this, a bed-room heated by a small stove. An *andron*, or open space, between the walls of the bed-room and that of the garden, prevented the inmates of these chambers from being disturbed by any noise made by the servants.

Houses of Pompeii.

The ruins of the town of Pompeii, which were discovered in the middle of the XVIIIth century, after remaining buried in the ashes from Vesuvius about 1700 years, afford considerable knowledge of the interior disposition of the dwelling-houses of ancient Italy. In this town they are generally small, as may be expected in a city of the third degree in the Empire; they appear to consist but of one floor, though there may have been rooms above those which are now visible; and, next to the street, they have shops which often do not communicate with the houses to which they belong; the shops are open from wall to wall, except a low parapet in front; the doorway is narrow, and a stone-slab in the interior served as a counter. Many of the houses have peristyles, surrounding open courts; one of these is described as having five chambers on each of the sides, on the right and left of the entrance, and three on the side opposite the entrance; these are paved with mosaic, and the walls are painted: one of the chambers seems to have been a sleeping-room, as there is a recess formed in the wall, which might have contained a bed; this room is 8¾ feet long, and 7 feet wide, with a vaulted ceiling; the walls are covered with stucco, and painted red; but it is remarkable that, neither at this place, nor at Herculaneum, have any chimneys been discovered, though it is evident from passages in ancient authors, that the Romans had such. In these towns, instead of chimneys, there seem to have been *hypocausta*, or stoves, with pipes for conveying the heat to the different apartments. The *triclinia*, or dining-rooms, have but little light from the windows; whence we may conclude that these apartments were only occupied at the time of the principal meal, which took place in the evening by the light of lamps.

At a little distance from the town is a sort of villa, consisting of two divisions, in one of which the apartments are adorned with paintings; in the other is a court, 94 feet square, with a covered gallery on two sides, supported on square piers; the other two sides were occupied by trees, of which some of the trunks and branches lately remained. Beyond this is an open portico supported by six columns. The galleries and apartments are remarkable for their tesselated pavements, arabesque walls, and Doric columns, the flutings of which have been filled with a painted coat of plaster. On some of the walls have been scratched ill-shaped horses, ill-spelled names, and coarse jests; circumstances which have led to an opinion that these buildings have been originally barracks; but Mr. Forsyth considers them to have constituted the Governor's *prætorium*.

From what has been published of the buildings at Herculaneum, it appears that the rooms are small in dimensions, and contain some specimens of rich painting. But Mr. Forsyth states of the latter, "that every extravagance condemned by Vitruvius enters into it; the human and brute forms are fantastically represented, the landscapes are but the caperings of a sportive genius, and the Architecture is as bad as that of the Chinese."

The Villa of Hadrian.

The Villa of Hadrian, at Tivoli, seems to have contained specimens of all the different buildings which were ever constructed by the Romans for use or pleasure; it is now in ruins, but among them can be traced a Temple, two semicircular Theatres, a Palæstra surrounded by arcades, a Bath, a Circus, and a Naumachia, which may have been filled from the waters of the Anio, or Teverone; a long wall pierced by arches, and at its extremity a small tower, the circumference of which is formed of three concave and three convex arcs, placed alternately. This immense edifice had but a short existence; for eighty years after it was finished, Caracalla took away some of the statues which adorned it, and soon afterward it was totally abandoned.

Palace of Dioclesian.

We may conclude this account of the Roman dwellings by a short notice of the Palace of Dioclesian, at Spalatro, which was erected by that Prince in the beginning of the IVth century, and the plan or disposition of which is probably similar to that of the Palatial buildings of former Emperors. It is described by Mr. Adam as an assemblage of buildings within an enclosure nearly rectangular, and the sides of which nearly faced the four cardinal points of the horizon; its length, from North to South, is 698 feet, and from East to West, 592 feet; six octangular and ten square towers flank the wall; but they seem to have been intended rather for ornament than defence. The interior is divided into three principal parts by two streets, each of which is about 36 feet wide; one is directed from East to West, through the centre of the building, and is terminated by a gate formed in the exterior walls on each side; the other is at right angles to this, and leads from a gate in the middle of the Northern wall to the centre of the Palace. Both streets are bounded on each side by an arcade, 13 feet wide. The Northern gateway is crowned by a horizontal lintel, consisting of small stones with oblique joints which are broken horizontally in the middle; above this is a semicircular-headed arch, and on each side a small hemicylindrical niche, with Corinthian pilasters; over the whole is a row of seven segmental arches, springing from Corinthian columns which rest on consoles projecting from the wall, and are ornamented with zig-zag mouldings. Above the capital of each column is a plain block of stone, between which and the foot of the arches is a horizontal band adorned with sculpture; the upper mouldings of the archivolts do not bear on the supports of the foot of the arch, but come to a point a little above them.

In the middle of the Palace, and on the Southern side of that street which is directed from East to West, is a peristyle of Corinthian columns, from the capitals of which spring semicircular arches; above these is an entablature, with a frize, the exterior of which is formed like a portion of the convex surface of a cylinder, having its axis horizontal, and there are modillons in the cornice. On the Southern side of the peristyle is a flight of steps leading to a *vestibulum*, with a portico in front, consisting of four columns of the Corinthian Order, the tops of whose capitals are on a level with the tops of the arches on each side of the peristyle; above these columns is a pediment, the horizontal entablature of which is broken, and forms an arch over the interval of the two middle columns. The *vestibulum* is of a circular form, and seems to have been lighted from the roof. A doorway on the Southern side of this leads to the atrium, a large rectangular hall divided into three parts, by two rows of columns parallel to its length; on each side of the door into the atrium is a small room, one of which Mr. Adam supposes to have been a porter's lodge, and the other the *tablinum*, or repository for the archives and records of the family. On the Southern side of the atrium is a doorway leading to a *crypto-porticus*, an immense gallery, 22 feet wide, extending quite along the Southern side of the building, and commanding an extensive view of the harbour and of the Adriatic; it was probably adorned with paintings and statues, the beauties of which, as Gibbon observes, added to those of the prospect, must have caused it to afford a delightful promenade. The Southern side of this gallery, and of the whole building, is formed by an arcade, with columns standing on consoles projecting before the exterior face of the wall; the capitals of the columns are plain bell-shaped vases, and over the arches is a horizontal entablature which is broken so as to project over the columns; it consists of an architrave and cornice, of which the latter is supported by modillons.

On each side of the *atrium* is a passage, the mesaula of the Greeks, so called from its situation between the halls. These lead to the great apartments of the Palace, and beyond the latter are the rooms for bathing.

In an area Westward of the *atrium* is a rectangular Temple which was dedicated to Æsculapius; fifteen steps afforded an ascent to its pavement, beneath which are vaults of great strength, and the roof is of a hemicylindrical form, adorned with sunk panels of beautiful workmanship. In the cornice of the doorway are modillons, the soffits of which are sculptured to represent birds, and men whose legs end in tails like those of fish.

On the other side of the *atrium* is an octagonal Temple, dedicated to Jupiter; to this, also, there is an ascent by steps, and it is roofed by a hemispherical dome of bricks. Round the inside of this Temple are two Orders of columns, placed one above another, and standing a little beyond the face of the wall; the lower Order is Corinthian, and the other Composite; the columns have no bases, are only seven diameters high, and behind them are pilasters attached to the wall. The entablature is broken, so as to project over each column, and its frize, which is convex outwards, is sculptured with foliage. Over the pilasters spring slender brick arches in the concave surface of the wall, and their interiors are filled up with horizontal courses of the same material. The dome springs from the foot of these arches, and the bricks composing it are disposed in a sort of fanwork, which assumes the appearance, and may have given the first idea, of pendentives. Below the entablature, the interior of the Temple is surrounded by bas reliefs, and in the ornaments about the doorway are sculptured the heads of men and horses in the centres of the scrolls of foliage.

In the North-Eastern and North-Western quarters of the Palace are two piles of building, each two stories high, but in a ruinous condition: Mr. Adam supposes them to have contained apartments for women, or for the various attendants on the Court. Along the interior face of the Northern, Eastern, and Western sides of the Palace are vaults, which may have been intended as dwellings for the slaves, or, while the Emperor resided in the Palace, they might be lodgings for the Prætorian soldiers.

In the interior of the building are two or three specimens of arches, formed of segments of circles meeting in a point at the vertex, but they have the appearance of being more modern than the rest of the edifice. The style of the whole resembles that of the buildings of Palmyra and Balbec, which were probably erected about the same period, and several circumstances indicate a decline of architectonic taste; such are the columns standing on consoles projecting from the walls, which give them the appearance of hanging in the air; the swollen frizes; the pediments whose horizontal entablatures are broken in the form of arches; and the fantastic forms of the sculpture. In pl. xiv. is given a general plan of this Palace, and an elevation of its Southern front.

From such descriptions as those we have given, and the writings of Vitruvius, Palladio has endeavoured to trace the plan of a Roman dwelling-house; and though it is likely enough that a variety of modes of distribution prevailed among a people possessing such a taste for magnificence as the Romans exhibited in their public buildings, yet the general features may be considered correct. The arrangement which Palladio has adopted, is nearly as follows.

The entrance was by a vestibule on the South side, and a door led from this to the *atrium*, or what would be now called the grand hall; this was generally adorned with the busts, arms, and trophies of the ancestors of the family. To the right and left of the *atrium*, but without any communication with it, were the servants' offices. On the North side was the *tablinum*, an apartment in which the family records seem to have been kept, or it might be a sort of office where the master of the house transacted business relating to his estate. Between the *atrium* and the servants' offices were the passages which led to the *cavædium*, a kind of square court, which, according to Vitruvius, was of five different kinds; *viz.* the Tuscan, which was open at the top, and had a portion of the roof projecting from the walls, so as to throw the rain which fell on the top of the building into the middle of the court; the Corinthian, which was similar to the former, only the extremities of the roof of the house were supported by columns surrounding the open part of the court; the Tetrastyle, so called, from the number of its columns, which were placed one at each angle of the projecting roof; the *Displuviatum*, which was also open at the top, but in which the roof of the house did not project over any part of it, the rain-water being carried off by a gutter behind the tops of the four walls of the court; and lastly, the *Testudinatum*, in which the whole court was covered by a roof; this was done where the span was not great, and dwelling rooms were then made over the court.

The columns of the *cavædium* were sometimes made high enough to include the two stories of which the building was composed; in this respect, the *cavædium* differed from the interior peristyle of a hypæthral Temple; the latter containing two Orders of columns placed one above another

On the right and left of the *cavædium* was a *triclinium* with its *procœton*, or anteroom; beyond these, on one side of the house, were the baths; and on the other, the *cubiculi*, or bed-rooms. Through the Northern colonnade of the *cavædium* was the entrance into the *basilica*, a hall, in which, probably, the master of the house, as a magistrate, or lord of some territory, gave judgment to his clients.

On the right of this hall was the *pinacotheca*, a room containing paintings; on the left were the libraries, and between the *basilica* and the rooms just mentioned, were passages leading into a large *peristylium*, the right and left sides of which were occupied by servants' rooms; and on the Northern side were the different *œci*, or halls where the family seem to have resided, and where they generally dined; probably they were more particularly appropriated to the mistress of the house. The principal of these was the Egyptian *œcus*, which was placed in the centre, and appears to have had two Orders of columns, one above another, all round the interior, with a floor between the two Orders, equal in breadth to the distance from the lower columns to the walls: above this floor was a passage, open towards the exterior of the house, and windows were formed between the upper columns to give light to the interior. On one side of this apartment was the Corinthian *œcus*, which differed from the Egyptian, in having but one Order of columns, and these rested either on the ground, or on a *podium;* this hall was covered by a hemicylindrical ceiling. On the other side was the tetrastyle *œcus*, so called, perhaps, from four columns placed in the interior, one near each angle; and, on the North, was the Cyzicene *œcus*, a name given by the Greeks, apparently, to those rooms which admitted of two dining couches, or tables, placed opposite each other, and which had windows, or doors, opening to the garden.

The disposition above given is supposed to approach nearly to what Vitruvius intended for the houses of persons of the highest rank; he recommends that bed-chambers and libraries should be situated with a view towards the East, that they may have the benefit of the morning sun; that time of day being the most proper for study. The baths and winter *triclinia* should be situated towards the West, for the benefit of the setting sun, because the bathing and dining took place in the evening; and the summer *triclinia* are directed to be placed on the Eastern side of the house, for the sake of coolness; but it is not to be supposed that a strict adherence to these rules was always possible.

Vitruvius describes also the dispositions of houses for traders and agriculturists, but it will be needless to mention them.

The proportions of the apartments in Roman houses.

The propriety of adhering to a system of proportions, in the distribution of the parts of an edifice, seems to have been fully recognised in the time of Vitruvius; since this writer gives, as a reason for making the proportion of the length, breadth, and height of apartments to vary with their absolute length, that, if they were otherwise, the minor parts would either appear too diminutive, or too clumsy.

In the IVth and Vth Chapters of the VIth Book, he states, as follows, what those proportions should be in the principal divisions of a dwelling-house. In the *atria*, or entrance courts, the breadth should be to the length in a ratio which, when simplified, is either that of 1 to $\sqrt{2}$, of 1 to $1\frac{1}{2}$, or of 1 to $1\frac{2}{3}$; but he has omitted to give the absolute lengths to which these breadths are respectively applicable. The width of the uncovered part he makes equal to one-third, or one-fourth of the whole breadth; the height of the ceiling of the covered part, up to the lower side of the beams, is made equal to three-quarters of the length of the court; another fourth is occupied by the depth of the *lacunaria*, or panels, and by the thickness of the roof above them. Of the *alæ*, or passages on the sides of the *atrium*, the breadth varies from one-fifth to one-third of the length when the latter varies from 30 to 100 feet, in order, no doubt, that the apparent forms of the short and long passages may be nearly equalized. The breadth of the *tablinum* is made to depend on that of the *atrium ;* when the latter is from 20 to 60 feet, the former varies from two-thirds to two-fifths of such breadth; what relation the breadth of the *tablinum* should bear to its length, he does not say, and from this silence it may be presumed that the length was equal to the whole breadth of the *atrium;* the height of the *tablinum* to the under side of the beams is equal to 1⅛ of its breadth. Of the peristyles, the width is directed to be equal to three-fourths of the length. The lengths of the *triclinia* are to be equal to twice their breadths, and their heights are to be an arithmetical mean between the length and breadth. But for *exedræ* and *œci*, when square, Vitruvius would have their lengths, or breadths, equal to two-thirds of their heights.

The interior of Grecian buildings seems to have had but few decorations, and to connect the walls with the ceiling, the builder contented himself with an architrave, having mouldings, of small projection, similar to those on the exterior. But, in the Roman edifices, the whole entablature was introduced in the interior, when the building was spacious, and a display of richness required. The cornice, though generally objected to in the interior, because it does not there serve the purpose for which its projection was intended; *viz.* to protect the lower part of the entablature from the rain which fell on the roof; yet, perhaps, is not entirely misplaced, because it may seem to be required for the support of the ceiling.

The ornaments on the ceilings, both of the Roman and Grecian buildings, were generally panels sunk below the surface, as has been shown; and this seems to have been suggested by the crossing of the beams of the roof, which would necessarily leave such coffers between the beams.

Roofs of Roman houses.

The roofs of the ancient rectangular houses of Italy were, perhaps, originally made with two or four inclined planes terminating in a point, or in a ridge at top. The lower extremities of the roof either projected beyond the walls, to throw off the rain, or a parapet was formed at the top of the wall, and a gutter, at the foot of the sloping roof behind it, carried off the water through pipes.

The Ancients considered pediment roofs as objects of the greatest dignity in an edifice; and such were, till the time of Julius Cæsar, only employed to adorn the Temples of the Gods. That Emperor, who had obtained leave from the Senate to wear constantly a crown of laurel about his head, by permission from the same Body caused a pediment to be constructed over his Palace; and from that time they became general.

In some Countries the roof of the building is made horizontal that it may serve as a place of exercise for the inhabitants; but, in general, it is made with a certain inclination, in one or more planes, in order to throw off the rain or snow. The elevation of these planes has always been different in different parts of the World. In those regions wherein rain or snow is most abundant, we find, as is observed by Vitruvius, that the roofs are most elevated, in order to let it flow off most easily; Nature and observation having taught men the form of a roof which is best adapted to their circumstances. The roofs of buildings in Egypt and Syria were generally flat; those of the Grecian Temples, having their heights equal to about one-ninth of their horizontal breadths, make angles of about 12½ degrees with the horizon. In Italy, which is situated more to the North than Greece, the heights of the roofs are about one-fifth of their horizontal breadths, which makes the inclination to the horizon equal to about 23½ degrees. And, subsequently to the Roman times, the roofs of buildings in the North of Europe have been made to form an angle of as much as 60 degrees with the horizon, or the pediments have been made in the form of equilateral triangles; the abundance of snow seeming to require such a slope to secure the edifice from damage.

Stairs.

Vitruvius, in speaking of the steps about a Temple, prescribes that they should be 10 inches high and 18 inches broad, but of those within a building, he makes the proportion between the height and breadth as 3 to 4; both of these rules, but the latter particularly, would now be considered as making the steps much too steep. The Ancients chose to make the ascent from one level to another by an odd number of steps, because, in mounting, they considered it fortunate to begin and end the ascent with the same foot.

Chimney

We have before observed that no chimneys have been discovered in the ruins of Pompeii or Herculaneum, and hence some have inferred that those conveniences were unknown or unused by the Romans; it may, however, be observed, that Palladio mentions the discovery of two ancient chimney-pieces, one at Baia, and the other at Civita Vecchia. He says they stood in the middle of the room, and consisted of columns supporting architraves, on which were placed the pyramids, or funnels, through which the smoke was conveyed. Such chimneys have been noticed by late travellers in some of the inns of the country. See further on this point in our *Miscellaneous Division*, CHIMNEY.

Doors a
window

In the walls of buildings are, necessarily, left apertures to serve as doors and windows; and though little is delivered by Vitruvius concerning those of dwelling-houses, it is probable enough that their proportions and ornaments did not differ materially from those of the doors of Temples, which we have before described. The general proportions between the heights and breadths of these apertures are recommended by Vitruvius to be as 3 to 2, or as 2 to 1; for which no better reason is assigned than that musical strings, which have those ratios to each other, *viz.* the fifths and octaves, produce sounds which harmonize with each other; and he seems to suppose that a proportion which was agreeable to the ear, must also be so to the eye.

Of the manner in which the windows opened, we only know that, in such apartments as the Cyzicene *œcus*, (Vitr. book vi. ch. v.) they opened like doors for the convenience of entering the garden. Some of the windows in the houses of Pompeii were glazed.

CHAPTER IV.

Works of Public Utility and Ornament.

These denominations may be considered as comprehending the *Fora*, the *Portici*, the Triumphal Monuments, the Bridges, Aqueducts, and even the Tombs of the Romans. Some examples of each of these species of buildings are still in existence; and the principal of them we purpose now to describe.

An important feature in a Roman city was the *Forum*, which, within its area, contained the buildings intended for the meetings of the Magistrates, the Courts of justice, the prisons, and the offices for the management of the public revenue. It served, also, as the public market-place, and, occasionally, as a theatre for exhibiting the combats of the gladiators.

e Fora Italy.

The *Fora* were sometimes of a simple, and often of a complex character. We have spoken largely of those in Rome in our *Miscellaneous Division*, (Forum,) and shall here, therefore, be brief. The great and ancient *Forum* at Rome was situated between the Capitoline and Palatine Hills, but its outline is now difficult to be traced; within its limits are the Arch of Septimius Severus, the Temple of Concord, and the Curia or Senate-House, besides the columns supposed to form part of the Temple of Jupiter Stator.

In the same city were several *Fora* bearing the names of different Emperors; of these, the *Forum* of Nerva is supposed to have been 367 feet long, and 164 feet wide, and nearly of a rectangular form. At one extremity were five arched entrances, and at the opposite extremity was the fine Temple of Nerva before described. The interiors of the two side walls of the *Forum* were ornamented with Corinthian pilasters, having columns of the same Order detached in front of them.

If we may trust to the representations given by Piranesi, the *Forum* of Trajan, which stood at the foot of the Quirinal Hill, must have been a magnificent work. The whole length is supposed to be 1150 feet, its general breadth 470 feet, and along the sides were rows of houses and columns. At one extremity stood the Temple of Trajan, and, on the opposite side, the Triumphal Arch; about the centre stood the splendid *Basilica Ulpiana*, and near it the grand Triumphal Column of the Emperor.

A *Forum* discovered at Herculaneum is of a rectangular form, 220 feet long, and 140 feet wide; the interior face of the enclosing wall was ornamented with half-columns attached to it; at one extremity was a rectangular and two semicircular recesses, and at a distance from the walls was an interior peristyle. One extremity of the *Forum* opened into a street, on the opposite side of which are the remains of two Temples. That at Pompeii is in good preservation, and contains several interesting ruins.

The *Forum* at Fano, in the March of Ancona, had, at one extremity, a *Basilica* built by Vitruvius himself; according to his description, the portico of the Temple of Augustus joined that side of the *Basilica* which was furthest from the centre of the *Forum*; and at the opposite end of the latter was a Temple of Jupiter. The Treasury, the Prison, and the *Curia* are stated, by him, to be situated upon the longer sides of the *Forum*, on the exterior of the shops which surrounded the area.

In the 1st Chapter of the Vth Book, Vitruvius gives a few general rules for the design of a *Forum*, which we may suppose to be such as he would have adopted where local or other circumstances did not happen to oppose themselves to the execution of a regular arrangement. He directs that it should contain a large rectangular area, the breadth of which may be about two-thirds of its length, and that the interior should be surrounded by two Orders of columns, one above another, at a small distance from the walls; the lengths of the upper columns are recommended to be about three-quarters of the length of the lower ones; behind the lower columns are to be arranged the shops of the bankers and other traders, and, on the upper floor, the apartments for persons employed in collecting and administering the public revenue.

The Basilica.

At one extremity of the *Forum* was to be placed a *Basilica*, serving as a Court of Justice and as an Exchange for the merchants; this is described as a rectangular building, the breadth of which is supposed to be from one-third to one-half of its length. Within the four walls of the *Basilica*, and at some distance from them, was a row of columns on each of the four sides, leaving two tiers of passages one above another between them and the walls; the upper passage seems to have been covered with a roof of the kind called testudinated; that is, having a flat top with curved sides rising from the entablatures of the columns. Behind, and attached to each column, was what Vitruvius calls a *parastata*, which seems to have been a pilaster, or an upright post to support the beams which bore the floor of the upper tier of passages, which was at a height above the pavement equal to one-half or two-thirds of the height of the columns. Under one of these passages, and at the extremity of a line drawn through the centre of the *Forum*, parallel to one of its sides, was to be the Tribunal of the Judge.

Triumphal Arch of Titus,

The Romans, in order to perpetuate their great achievements, their public acts of beneficence, and sometimes, perhaps, merely to gratify their vanity, erected Triumphal Arches, of which several still remain to attest the bad taste prevalent at the time of their construction. The Arch of Titus is that which possesses the first claim to our attention, having been erected before the period of any considerable decline of architectonic genius; though even this is, perhaps, justly characterised as being too rich to be elegant.

Its plan is rectangular, and it is perforated by a single passage, covered by a hemicylindrical vault. The length is 49 feet, breadth 16½ feet, and the whole height of the building is equal to its length. The width of the aperture is 19 feet, and on each side of it, on both fronts, are two fluted marble columns of the Composite Order, standing on pedestals 9 feet high, and supporting an entablature; this member is adorned with sculpture in bas relief representing the Triumph of Titus after the conquest of Judea. Above the entablature is an Attic Order, 12 feet high, on which is expressed the apotheosis of the Emperor. The Arch is semicircular, and springs from a horizontal moulding, called the *impost*, which crosses the front of the building at about 22 feet from the ground.

The height of the columns is 22.065 feet, and the lower diameter is 2.07 feet, consequently the height of the column is equal to 10.6 diameters. The base is similar to that of the columns belonging to the Temple of Jupiter Stator, and the height of the volutes in the capital is equal to half a diameter. The architrave is divided into three faciæ, the lower of which is vertically over the circumference of the top of the shaft; the frize is highly sculptured, and there are both dentels and modillons in the cornice; the height of the entablature is 5.245 feet, or $\frac{1}{43}$ of that of the column. See fig. 6, pl. xi.

of Severus.

The Triumphal Arch of Severus is, like the others, of a rectangular form; its length is 75.5 feet, width 19.75 feet, and its whole height 68 feet. In its length are three arches, of which that in the centre is 23 feet broad, and each of the others 11.48 feet. These arches spring from imposts on the piers; the crowns of the side arches rise only to the level of the imposts of that in the centre, and all of them communicate by a transverse passage, covered also by a hemicylindrical vault. Each façade is ornamented with four fluted Composite columns standing on pedestals 13 feet high; behind each column is a fluted pilaster, and above is an entablature which is broken over each column; over this is an Attic wall 19 feet high, with one large panel in front, containing an inscription, and having a small pedestal or Attic pilaster at each extremity; the whole is crowned by a small entablature. The *dado* or cubical part of each pedestal under the columns is ornamented with figures, and the whole face of the building above the side arches is covered with sculpture, representing Victories, Rivers, and Seasons. The soffits of the arches are panelled in square forms, and there are modillons in the impost mouldings, which are extended through the whole depth of the building.

The height of the columns is 27.847 feet, and the lower diameter is 2.837 feet. The base and capital very much resemble those of the Arch of Titus, but the shaft is different, being of a cylindrical form up to one-third of its height above the base, from which place it diminishes gradually to the top, whereas the other diminishes from the base to the capital. The architrave is divided into two faciæ; the frize is plain and very low, and there are no modillons in the cornice. The height of the whole entablature is 6.689 feet, or $\frac{1}{4.1}$ of the height of the column; this member is far more meagre than the entablature of the arch last mentioned, and its vertical breaks produce a confused appearance.

of the Goldsmiths,

The Arch of the Goldsmiths, at Rome, which is said to have been erected also in honour of Severus, has but one passage through it, and this, which is 9 feet wide, is remarkable for being covered by a horizontal ceiling. At the extremities of the piers, on each side, are two panelled pilasters standing on a podium, with Composite capitals, and in the entablature is a swelled frize. The whole face of the work is covered with sculpture.

of Janus,

The Arch of Janus, at Rome, is a square building about 70 feet in length and width, and the same in height, and is perforated by two hemicylindrical vaults at right angles with each other. On each of the four faces is a semicircular arch, of which the archivolts spring from imposts. The lower part of the building forms a podium with a cornice; and, between this and the impost of the arch on each face are six niches, *viz.* three on each pier, with heads in the form of quadrants of spheres; these have no imposts, and the archivolt is continued to the foot of the niche. Above the imposts of the arch, on each face of the building, are three other niches similar to those below, and over the niches is a horizontal entablature, which is crowned by a high Attic. There are no columns on any of the faces.

of Constantine,

The Arch of Constantine, at Rome, was raised by the Senate with materials taken from the arches of some of the former Emperors; among which the parts belonging to that of Trajan are very distinguishable by their superior quality. Of all the Triumphal Arches this is the richest and in the best preservation, but it exhibits, at the same time, a melancholy proof of the declining state of the Art at that period. Like the Arch of Severus, it consists of three passages covered by hemicylindrical vaults, the crowns of the two side-arches rising only to the level of the impost of that in the centre. Its length in front is 81 feet, its height 70 feet, and its depth 21.75 feet. The span of the centre arch is 21.4 feet, and the height of its vertex from the ground, 38.2 feet. The imposts of the arches return on the faces of the piers, and are ornamented with dentels and modillons. The building is formed of white statuary marble, and each front is adorned with four columns of jaune antique marble, of the Corinthian Order. These stand on pedestals which are panelled, and have a figure sculptured in front of each, and the bases of the pedestals are continued round the piers. The plinths in the bases of the columns are connected with the cornices of the pedestals by an inverted cavetto. The shafts of the columns, as well as those in the Arch of Severus, are cylindrical up to one-third of their height, and, from thence, they begin to diminish in a curvilinear form; they are fluted with twenty-four channels, which are cabled, or filled up to one-third o their height by a reed. A fluted pilaster is placed behind each column. The entablature is broken over each column, and above it is a high Attic filled with sculpture; over that part of the entablature which is vertically above the columns, are pedestals supporting Dacian captives. The faces of the building in the intervals of the columns, and the soffits and sides of the arches are ornamented with panels, in which figures are sculptured; and there is an ascent to the top by a staircase in the interior. An elevation and plan of this building is given in pl. xiv.

The height of the columns is 28.037 feet, and the lower diameter is 2.902 feet. The base is Attic, but the upper torus is double. The architrave is divided into three faciæ, all of which incline inward at their upper extremities; the frize is plain; there are both dentels and modillons in the cornice, but the latter are thinly distributed over a large and plain facia; the corona is small, and all the parts of the cornice have great projections. The height of the whole entablature is 6.94 feet, or nearly one-fourth of the height of the column.

Out of Rome are many Arches, chiefly remarkable for the indications they afford of a corrupt taste; and it may be, therefore, sufficient merely to describe their features in a general way. The triumphal edifice of Gallienus, at Verona, forms a double gateway, consisting of two arches, with an entablature and pediments, supported by Corinthian columns, placed one on each side of each gate. Above these is a second story containing a row of semicircular arches, with architraves continued to the foot; two of these arches, which stand over the pier between those below, have fluted Corinthian pilasters on each side, supporting a pediment. This story is crowned by a general horizontal entablature, which is broken over the space occupied by the two pediments, and is supported by two twisted Corinthian columns. The third story contains a row of semicircular arches, above those in the second story, but larger. Over these is the upper entablature of the building, which is broken above every alternate arch, and supported by a pilaster at each extremity. Below the ground-floor are elliptical vaults. The breadth of the building is 52 feet, the height from the ground to the soffits of the principal arches is 23 feet, and the whole height is 66 feet. Some of the members of this arch seem to have been the originals of those peculiarities which distinguished the works of the Italian artists in the XVth and XVIth centuries.

of Galli at Ver

The Arch of Trajan, on the pier at Ancona, is also of a rectangular form, and consists of one semicircular arch with a console in the vertex. In its façade are

of Tr at An

four Corinthian half-columns with fluted shafts, and Attic bases, and pedestals beneath. The entablature is continuous over the two middle columns, and broken over the two extreme ones. Above this is a high Attic with small pilasters over the extreme columns, and one general dado over the archway. The profile of the entablature is very coarse; the soffit of the arch is unornamented, and there is a rectangular tablet between the columns on each side of the arch.

ugustus, Rimini.

The Arch of Augustus, at Rimini, appears to have been, when entire, 124 feet long and 88 feet high, to the top of the entablature. It consists of one semicircular arch springing from imposts, and, on each side, a Corinthian half-column, standing on a pedestal which projects from the basement; at each extremity of the façade is a Corinthian pilaster; above these is the entablature, and over the archway a pediment. The entablature is broken over each column, and the pediment, if it formed part of the original design, is a remarkable proof of a declining taste in Art, even in the Augustan Age; since, instead of rising from the extremities of the horizontal cornice, it rises from two points vertically over the interior sides of the columns, so that its span is only equal to the intercolumniation. The sides of the modillons in the oblique entablatures of the pediment are neither vertical nor perpendicular to those entablatures, but are formed between both those directions.

At Orange is a Triumphal Arch of Roman workmanship, remarkable for being of a square form, and for the crown of the side arches rising above the horizontal courses of that in the centre; all the archivolts spring from pilasters, and the soffits are richly panelled. A Corinthian fluted column stands at every angle and on each side of the centre arch. The entablature is continuous over the two middle columns, and above this is a pediment with a double Attic. The whole façade is covered with sculpture. The sides of the building are like the front, but without arches, and are ornamented with figures in alto relievo. The bases of the columns resemble two Attic bases placed one over the other, and the lower one rests on a pedestal.

At Bara, in Spain, is a Triumphal Arch of a semicircular form, with a simple archivolt springing from imposts; on each side are two fluted pilasters, with capitals resembling the Corinthian, on a rusticated podium. The architrave and frize are plain, and there are modillons in the cornice. The whole building may be considered as a specimen of the Roman Architecture in its best state. Near this place are excavations, in the sides of rocks, which have served as sepulchres, probably, in very ancient times.

drian, thens.

Returning towards the East, we come, next, to Athens, where still exists that which is called the Arch of Hadrian; this, when in its perfect state, consisted of a semicircular-headed aperture formed in a wall; the archivolt rises from pilasters which terminate in a capital resembling the Corinthian. On each side of the arch there are two fluted Corinthian columns supporting a horizontal entablature, above which is another tier consisting of four Corinthian columns, supporting, also, an entablature with a pediment over the middle interval. It has been thought that this work, consisting merely of a wall, ornamented as above described, could hardly have been intended for a Triumphal Arch, and that it may rather have formed the entrance to a portico.

Arch at Palmyra.

It would be improper to omit mentioning here, a Triumphal Arch which exists among the ruins of Palmyra. It consists of three semicircular-headed apertures, and the crowns of the side-arches do not rise so high as the imposts of that in the centre. The whole façade is divided vertically into three parts, of which the centre projects before the wings; all the salient and rentrant angles are adorned with pilasters of a Composite Order, having their faces panelled and filled with sculptured foliage. The pilasters support an entablature which is broken to follow the planes of the façade. The frize is enriched with sculpture, and the central part of the entablature is crowned by a pediment. Over one of the lesser arches is a niche which is crowned in like manner.

The Columns of Trajan and Antonine.

Besides Triumphal Arches, the Romans raised lofty Columns to commemorate the remarkable circumstances which tended to exalt the grandeur of their Nation; two of the most superb of these monuments are still to be seen at Rome, *viz.* the Columns of Trajan and of Antonine, on which, as on Historical Tablets, are sculptured the events of the lives of those Princes. And amidst the ruins of Temples, Theatres, and other splendid edifices of the Eternal City, these seem to have been respected by Time, and by Barbarians both ancient and modern. The Column of Trajan is of Parian marble, 125 feet high including the pedestal; the length of the shaft is 90 feet; its lower diameter 12 feet, and its upper 10⅔ feet, so that the difference of the diameters is about one-ninth of the lower. The ascent to the abacus was by steps within, and, on it, was formerly a colossal statue of the Emperor. The Column of Antonine stands on a double pedestal, placed one above the other, of which the lower one has been but lately discovered, and that, by making an excavation at the foot of the column.

The spiral direction of the sculpture on these Historic columns has been ingeniously adopted to give the story a continuity, which horizontal rings would have interrupted. Mr. Forsyth observes, that the columns are of no Order of Architecture; that of Trajan has a Tuscan base and capital, and a Doric shaft and pedestal, with Corinthian mouldings.

The Pillars of Phocas and Pompey.

The Column of Phocas, at Rome, is a Corinthian Pillar, which was erected in the VIIth century in honour of that Emperor. That which is called Pompey's Pillar, near Alexandria, is, probably, a monument of a similar kind, and, therefore, may be mentioned in this place. It is executed in granite, of a mixed Corinthian Order, its diameter is 8 feet, and height 80 feet, exclusive of the pedestal, whose height is 10 feet. Dr. Clarke is of opinion that it was erected by Cæsar in honour of Pompey; on the other hand, Dr. White supposes it was, originally, within the precincts, and an accompaniment to the Temple of Serapis, and, consequently, that it was a work of one of the Ptolemies. Some think it was elevated in honour of Hadrian, or Severus, or Dioclesian, for the inscription on the pedestal is so much obliterated that it is impossible to ascertain which of these Emperors is meant. The shaft is said to be more ancient than either the capital or the pedestal; the latter is supported on a block of stone, which appears to have been part of a more ancient ruin, and this block is surrounded by sepulchral fragments of ancient Egyptian monuments.

Roman Bridges.

No Works of the Romans are more deserving of notice than their Bridges, on account of the great utility of those edifices in facilitating the communication between the different Cities and Provinces of the Empire. If the Romans thought the conquest of any Country was not complete till a military road was made through it, much more must they have thought it of importance to the security of their possessions that the rivers which flowed between them should be subdued by permanent buildings which might, at all times, permit a free passage over them. Some of the Bridges of Rome existed in the time of the Republic, but on account of the changes they subsequently underwent, it is impossible to say in what manner they were at first formed; it is certain that some were of timber, but there seems no reason to doubt that, in others, the roadway was supported by voussoirs of stone, arranged in a circular order.

As the principal Bridges executed by the Romans have been described, *ad v.*, in our *Miscellaneous Division*, it will be unnecessary to mention them here; and we, therefore, proceed to an account of the Aqueducts which supplied the city with water.

Aqueducts.

An Aqueduct in the time of the Romans was a work of no less consequence than a bridge, and the construction of each was in some respects similar. The former conveyed the water from the rivers, or from an original reservoir, to the place required; and being necessarily horizontal, or having but small declivity, whenever hills or rocks intervened, it was necessary to cut through them, and when the course of the water lay across a valley, the canal was supported on arches of masonry, which were, sometimes, of vast height, and placed in two, and even three, tiers, one over another. No reason, except it be that of making a display of wealth and magnificence, can be given for incurring the expense of these extensive canals, since an equal supply might have been obtained in a more economical manner by forming subterranean tunnels, or a system of pipes from the reservoir to the place of delivery; these might have followed all the inequalities of the ground, and it would have been only necessary to take care that, in no part of the course, the tunnel, or pipes, were on a higher level than that of the reservoir. It has been supposed that the Ancients were ignorant that water, flowing in the branches of a bent tube, will rise to the same vertical height as that in the reservoir from whence it proceeds; but this opinion is by no means to be admitted as a reason for their executing these works, since the hydrostatical fact just mentioned is distinctly affirmed by Pliny, and it appears from Vitruvius, (book viii. ch. vii.) that the Romans actually used pipes of lead for the conveyance of water to their houses and baths.

The most ancient Aqueducts which brought water to Rome are those called the Martian, the Appian, and the Claudian. The first, which brings its supply from the Teverone, was erected by Quintus Martius, 312 years before Christ; it consists of two canals, one above the other, supported by an upper and under row of semicircular-headed arches, the apertures of which are each equal to 16 feet; and the height of the whole work is about 70 feet. The second was erected during the same year by the Censor Appius Claudius, and is remarkable for the form of its transverse section, which is narrower at top than at bottom. The last was built by the Emperor Claudius of squared stone, and its whole extent is 46 miles. The canal is borne on a long line of semicircular arches 20 feet wide, supported on lofty piers; and the height of the crowns of the arches above the valley, is, in some places, about 72 feet. Elevations of three of the most celebrated Aqueducts are given in plate xiii. At Vicovaro, near Tivoli, there is a canal more than a mile long, 4 feet broad, and 5 feet deep, which forms part of an aqueduct, and is cut through the solid rock.

It has been remarked, that though, in some cases, water might have been brought in a straight line to the city, yet the Aqueduct has been constructed with several bendings, by which the whole length of the work is considerably increased; some have supposed that this was to avoid the expense of raising the arches to an excessive height over the low grounds, and others, that it was to diminish the velocity of the water, which, if great, might damage the bed, or come less pure to the city. According to Montfaucon, there were formed at intervals along the line of canal, reservoirs called *castella*, in which the water, by expanding, might purify itself; these were a sort of round towers of masonry, raised, of course, to the same height as the canal, and sometimes highly ornamented. The same author observes, also, that, in various places, pits were sunk below the general bed of the canal, in which the water, remaining at rest, might deposit the earthy particles which it conveyed. According to Vitruvius, an Aqueduct should be arched over to prevent, as much as possible, the Sun from shining on the water. Vitruvius also states, in the VIIth Chapter of the VIIIth Book, that, when pipes, for the conveyance of water, pass across the bottom of a valley, it is necessary to form what he calls a *venter;* that is, a subterranean reservoir, in which the water may diffuse itself; and thus, he observes, the force will be diminished, with which the water, by its swelling, meaning its hydrostatical pressure, would act against the pipes, to burst their joints. In such valleys, also, and even in horizontal plains, he proposes that vertical pipes, open at top, should be raised, in order that the air which is conveyed with the water may, thereby, escape. In modern practice such air-pipes, or valves equivalent to them, are placed, not at the bottoms of valleys, but wherever the pipes form a bend the convexity of which is upwards, in order to permit the escape of the air which, in such places, would rest and impede, or entirely stop the movement of the water.

Of Roman Tomb

We may conclude this Chapter with a short notice of the Tombs erected by the Romans to contain the bodies of their dead: some of these were intended for the interment of individuals or families, and some were for the public in general. The latter were merely vaults excavated in the ground, but of such extent that they have been compared to subterranean cities, the others were cylindrical, conical, or pyramidal towers, containing within them ranges of vaults, connected with each other, in which the bodies were deposited.

Of the Horat

On the Appian Way is a great and ancient Tomb, probably constructed by Etruscan artificers; it consists of a squre basement 45 feet each way, on which are raised five masses of earth, in the form of frusta of cones, reveted with masonry. Four of these cones are 10 feet in diameter at bottom, and are placed, one at each angle of the basement; the fifth is larger, and is placed between the others, and the foot of each cone is connected with the top of the basement by an inverted cavetto. The Tomb is supposed to have been raised over the bodies of the Horatii; but this opinion is extremely uncertain, and, indeed, is founded only upon the apparent antiquity of the workmanship. Near it is what has been taken for another Tomb, but is more generally supposed to have been a little Temple dedicated to the God Redicolus, after the retreat of Hannibal from Rome. Mr. Forsyth thinks, from the rich chiseling it exhibits, that it was erected as late as the time of Severus, and that it was destroyed soon after it was built.

The principal Tombs at Rome are those of Caius Cestus, of the Emperor Hadrian, and of Cecilia Metella. The first is a simple pyramid raised on a square plan, each side of which is 102 feet, and its height is nearly the same. In the centre of the pyramid is a rectangular cell, 20 feet long and 13 feet broad; and at one of its extremities is a small niche, which, probably, contained the sarcophagus. At each angle of the pyramid is a Doric column, seemingly intended as an ornament, for it does not support any thing.

The Tomb of Hadrian, now the Castle of St. Angelo, consisted of a square basement, the length of the sides of which is 170 feet. Above this was placed a cylindrical tower, 115 feet diameter, formed by a thin wall of tufo, and, probably, at one time, surrounded by a colonnade. The interior is crossed by the modern stairs leading to the apartments on the upper floor, which were built by Pope Paul III.

The Mausoleum of Cecilia Metella, which was built by Crassus, is a plain, circular building, 90 feet in diameter and 62 feet high, standing on a basement of the same form. The body of the tomb is of travertine stone, and, at the top, is a circular frize of marble, adorned with sculpture, representing rams' heads and garlands. In the interior is a circular cell, 19 feet in diameter, to which there is an entrance by a passage on the exterior.

Near Capua is an ancient Tomb, consisting of a cubical basement 21 feet long, and of the same height, with a door in one of the sides crowned by a semicircular arch. Above this is a lofty building, with a plain, round turret on each angle. The wall between every two turrets is cylindrical with its concavity outwards, and in its centre is a small projection, containing a rectangular window, which is crowned by a pediment, and there is a semicircular niche on each side. Above the centre of the Tomb is a small round tower, ornamented with Doric columns supporting an entablature, and the whole is covered by a low cupola. Between the columns are semicircular-headed recesses ornamented with pateræ. On what occasion this building was erected it is now impossible to form an opinion, but the workmanship is Roman.

In the *Antiquities of Magna Græcia* is given a representation of a remarkable monument, at Agrigentum, in Sicily, which is commonly considered as the Tomb of Theron. It is a pile of building about 25 feet high, in the form of a frustum of a pyramid, standing on a quadrangular basement 13 feet in length, and as much in breadth. The building is divided into two stories nearly equal in height, of which the lower is a plain stylobata, crowned by a projecting cornice. The second has a blank window, surrounded by mouldings, in each front; the angles of this story are terminated by fluted columns with Ionic capitals and bases, and the whole is surmounted by an entablature, of which the cornice is wanting. There is no regular doorway; and, no doubt, when the sarcophagus was placed in the Tomb, the aperture was built up. The columns, which, instead of being in vertical positions, incline with the walls, have Attic bases, and their capitals resemble those employed in Roman buildings. Lastly, there are triglyphs in the frize, which, also, converge towards the vertex of the pyramid.

Tomb at Valence,

At Valence, on the Rhone, is an ancient Tomb, said to have belonged to the Martian family; its plan is a perfect square and its height is equal to twice the length of each face. At each angle is a column let into the masonry and standing on a pedestal, and, on each face, is a semicircular arch springing from columns Above the latter is an entablature, and the whole is crowned by a pyramid, the height of which is about half of that of the whole Tomb. At Vienne is, also, a singular work, probably intended for a Tomb, and supposed to be Roman. It is similar to the last, but open on all sides, with a column at each angle, standing on a pedestal. In each face is a semicircular arch springing from square piers; above is a horizontal entablature, which is crowned by a lofty obelisk. The capitals of the columns and the archivolts are unwrought.

at Vienne,

at St. Remi.

At St. Remi, in Provence, is a Mausoleum which, also, bears marks of Roman workmanship; at bottom is a pedestal on two steps, with a sculptured dado, and, on this, is a square story with semicircular arches springing from pilasters. At each angle is a fluted column of an Order resembling the Corinthian, and these support an entablature with sculptured frize. Above is a circular tower with Corinthian columns on a general circular base, and, over these, is an entablature crowned by a conical dome.

Tombs at Pompeii.

The excavations at Pompeii, which have brought to light so many specimens of ancient Architecture, have, also, made us acquainted with several Roman Tombs, which are so much the more interesting, as, having been buried in the earth during so many Ages, they cannot have suffered any change of form, from the caprices of men, since the period of their construction. They are, in general, small, and are placed near together, so as to form a sort of street of Tombs. See Gell's *Antiquities of Pompeii.*

Tomb at Mylassa.

In the IId volume of the *Ionian Antiquities* is given a representation of a sepulchral monument, about a quarter of a mile from Mylassa, in Asia Minor. This work, which was, probably, executed while the Romans were in possession of the Country, is raised upon a square plan; the lower part is a general pedestal, consisting of a plain dado with a base and cornice, and, in the pedestal, is a doorway to the chamber wherein the body was deposited. Above the pedestal, at each angle, is a square pillar, and between them are two elliptical columns on each face; the pillars support a simple entablature, above which are four courses of stones, forming a frustum of a pyramid, the sides of which are in the shape of steps; the lower part of the shafts of all the pillars is plain as far as one-third of their height; the whole above is fluted, and, between the pillars, the spaces are now quite open on each face, but, originally, they seem to have been filled with marble panels. The soffit of the roof is richly ornamented, and hollowed in the form of a triple square, the sides of each interior one being inscribed obliquely within the next exterior one.

Sepulchres of the Kings.

What are called the Sepulchres of the Kings, near Jerusalem, are, by M. Chateaubriand, supposed to be the Tombs of Herod the Tetrarch, and they are described by that traveller in the following manner. In the midst of a field is an excavation similar to the abandoned work of a quarry; a long and gentle descent leads to the bottom of the excavation, where an arcade has been formed, through which is the entrance to an open room cut in the rock; this room is 30 feet long, 30 feet wide, and 12 feet high. In the middle of the South side of the apartment is a recess, cut several feet deep in the rock; its section is square, and about the aperture are ornaments resembling those of the Doric Order; over the lintel is a sort of frize, containing triglyphs and metopes; in the centres of the latter are sculptured simple rings, and these are continued down the jambs. In the left-hand angle of the chamber is an open gallery, leading to another square chamber, in the sides of which are holes cut to contain the coffins. Three vaulted doorways lead from this to seven other chambers, of unequal sizes, which are, also, cut in the rock. Some of the sepulchral monuments near this place resemble in form those in the South of France, which have been just described.

We have had occasion to mention the employment of small bells, either as ornaments, or to keep away birds from the ancient Temples of Greece and Syria; and, it is from a monumental edifice we learn that bells, for similar purposes, were used in Italy at a very early period. Tintinnabula are said, by Pliny, to have been suspended by chains about a building of this kind which, he says, was erected by Porsenna, near Clusium; this must have been about 500 years before Christ. See LABYRINTH in our *Miscellaneous Division.*

CHAPTER V.

Works of Public Convenience and Pleasure.

We class under those heads the Theatres, Amphitheatres, Circi, and Baths of the Romans, all of which were objects of the utmost importance to that people, though there is found a considerable difference in their execution, some having their details rudely formed, while in others the utmost delicacy of ornament has been profusely lavished.

The Roman Theatres resembled those of the Greeks in being of a semicircular form; but, being situated within the cities, where the natural ground did not afford the means of supporting the seats, as was the case in most of the Grecian Theatres, it was necessary to carry them upon the upper surfaces of vaults, and to terminate them, on the exterior, by a lofty wall surrounding the edifice.

Pompey's Theatre, at Rome, seems to have been the most ancient stone building of the kind, and, even of this, the seats were probably made of wood, as it was several times consumed by fire. The second stone Theatre was erected by Julius Cæsar; and Augustus, afterwards, caused one to be constructed in honour of Marcellus, his sister's son; the ruins of this last still exist. Many others were, subsequently, erected in Rome and the Provinces.

The Theatre of Marcellus

The Theatre of Marcellus consists of a semicircular part, which contained the orchestra and the seats of the spectators, and of a rectangular part, in which were the *scena*, the *proscenium*, and the porticos. The *orchestra* occupied the most central part of the Theatre, and its diameter was equal to 172 feet; round its circumference were two concentric rows of hemicylindrical vaults supporting the *podium*, or wall in front of the level space at the foot of the seats, and, probably, serving to contain the animals destined for the exhibition of combats, which seem to have taken place in Theatres before Amphitheatres were constructed. Between the vaults of the first row, at intervals, are passages by which, probably, the animals were brought into the *arena*, or *orchestra*, and, at intervals, in the second row, are steps which led to the *podium*. On the exterior of the second row is a corridor, extending along the circumference, and receiving light from apertures above. Beyond this corridor were vaults, in directions diverging from the centre of the Theatre; some of these served as passages, and others contained the steps by which the common people ascended to the upper rows of seats, and those of the Equestrian Order to their places; on the exterior is the grand corridor formed by the double arcade surrounding the building. Between the extremities of the semicircular part and the flanks of the *proscenium* are passages, which probably served as entrances for the Nobles. Behind the centre of the *scena* was a vestibule, in which were steps leading to the parts under the *proscenium*, and on each side of the vestibule were the apartments for the performers and persons who had the care of the Theatre: on each flank of the *proscenium* was a covered portico for the convenience of the spectators in bad weather. The whole diameter of the Theatre is equal to 517 feet.

The semicircular front of the Theatre was adorned with two Orders of attached columns placed vertically above one another. The lower columns are of the Doric Order, and rest upon a platform which serves as a general base to the whole edifice, and is surrounded by three steps. These columns are without bases, and the fronts of their shafts project from the face of the wall about three-quarters of a diameter; and between every two columns is a semicircular-headed archway, formed by simple voussoirs springing from imposts in the wall, at points taken about two-thirds of the height of the column from the pavement. The columns next above were of the Ionic Order, and stood on plain pedestals resting on the entablature of the lower Order; and between every two columns is a semicircular arch similar to those below. Some have supposed that there was a row of Corinthian columns above the entablature of the second Order, but of this there is no proof.

According to the dimensions given by Degodetz, when reduced to English measures, it appears that the height of the Doric columns is 24.119 feet, and the lower diameter 3.198 feet. The exterior face of the architrave is vertically over the top of the shaft; the frize is ornamented with triglyphs, and the cornice contains a row of dentels partly concealed under the inclined soffit of the corona, the face of which, also, conceals the guttæ over the triglyphs. The height of the whole entablature is equal to 6.063 feet, or nearly one-quarter of the height of the column. The span of the arches between the piers is 8.794 feet; the breadth of the latter is 6.864 feet, their thickness is about 7 feet, and their height from the pavement to the level of the foot of each arch is 17.633 feet. An elevation of one of the columns in this tier is given at fig. 1. pl. x.

The height of the Ionic columns, in the upper Order, is 23.94 feet, and their lower diameter is 2.66 feet; therefore the height is equal to nine diameters. The architrave is divided into three faciæ, the upper extremities of which incline forward; the top of the cornice is destroyed, but there remains a row of dentels over which the corona must have been placed. The bases are of the Attic kind, and the columns stand on pedestals four feet high, the tops of which are on a level with the bottom of the aperture of the arch. The volutes of the capitals are very simple, and their planes are parallel to the exterior faces of the abaci. The fronts of the shafts of these columns, also, project about three-quarters of a diameter from the face of the wall.

The ruins of other Theatres of similar forms have been noticed at Herculaneum and Otricoli, in Italy; at Taormina and Ægesta, in Sicily, besides several in Asia Minor and Syria, which were erected during the plenitude of the Roman power in those parts of the World.

struc- of the man atres.

From the descriptions of Vitruvius, and from such remains of these edifices as still exist, it appears that the principles which regulated the construction of the Roman Theatres were nearly as follows. A circle was described with any convenient radius, which was probably about one-third of the radius of the whole building; the part included between the semicircumference and the diameter was occupied by seats for persons of Senatorial rank, and a wall, extending along the circumference of the semicircle, separated this space from the seats of the other spectators; a wall coinciding with the diameter, and produced each way till it was equal to twice the diameter, formed the front of the *proscenium* or *pulpitum*. The space occupied by the Senators corresponded with the *orchestra* in the Greek Theatres, only the floor of the latter was horizontal, whereas in the Roman Theatres it was an inclined plane rising towards the circumference.

An equilateral triangle being inscribed in the circle, and having one of its sides parallel to the above diameter, the wall of the *scena* was made coincident with that side; and this determined the breadth of the *pulpitum* on which the actors performed their parts. This *pulpitum* was made not more than five feet higher than the level of the *orchestra*, in order that the spectators in this latter place might not be prevented from seeing the performances. All the seats on which the spectators sat, beyond the *orchestra*, had their centres in a vertical line passing through the centre of curvature of the wall of the *orchestra*, and the lowest seat was elevated above the bottom of this area about one-sixth of the diameter of the area, a height great enough to prevent those spectators from mingling with the Senators. The seats rose gradually, from the lowest, towards the circumference of the Theatre, in such a way that their superior edges were in a right line making an angle of about 22½ degrees with the horizon; and, at intervals, the seats were interrupted by *præcinctiones*, or level landing-places, like the *diazomata* of the Greek Theatres.

From the *orchestra* to the first præcinction were fourteen seats, which were allotted to persons of the Equestrian Order, to the Tribunes and others of that quality; all above these were the seats of the Plebeians: a covered colonnade surrounded the seats above the upper præcinction, and formed a gallery in which Augustus appointed the women to sit. The height of the seats is recommended to be from 1.2 to 1.33 feet, and their breadth between 1.94 and 2.22 feet. The circumference of the semicircle was divided into six or eight parts, and lines being drawn to these points from the centre of the Theatre, determined the directions of the steps of ascent to the different seats of the spectators; the quadrilinear division of the seats between every two præcinctions and every two flights of steps was called a *cuneus*, from its wedge-like form; the stone seats seem to have been covered by boards or cushions. The decorations of the *scena* may be traced in the remains of the Theatre at Nismes, but more particularly in some of those in Syria and the Decapolis. They consist of various Orders of columns with broken entablatures and pediments, and afford sufficient indications that richness or ornament was consulted rather than good taste.

Behind the wall of the *scena* were apartments for the performers, and from these apartments there were entrances to the *pulpitum* by three doors, of which that in the centre was called the Regal door, and those on the sides were called the Hospitalian doors. The rectilinear side of the Theatre, on the exterior, was provided with a grand portico or colonnade extending the whole length of the building.

The Flavian Amphitheatre.

The history and construction of AMPHITHEATRES having been given under that word in our *Miscellaneous Division*, it will be unnecessary to enter into many details concerning those edifices; we, therefore, confine ourselves to a general description of the plans and Architectural embellishments of the principal buildings of this kind which still exist. Of these the Flavian Amphitheatre, or the Colosseum, being the most considerable, has the first claim to our attention. The form is that of an ellipse covering about five acres of ground, and the whole edifice stands on a basement to which there is an ascent by six steps extending along its whole circumference. In the centre was the *arena*, so called from the sand with which it was strewed, the lengths of whose transverse and conjugate axes were respectively 281 and 176 feet. This was surrounded by an elliptical wall which supported the *podium* or fence above. Behind this wall was a row of cells, which continued along its whole circumference, and served to contain the beasts preparatory to their entrance into the *arena*, which entrance was made by passages cut at intervals through the wall of the *podium*. Between these passages were niches in which, probably, the combatants deposited their arms and dresses previously to engaging. In rear of the cells was a corridor, from which proceeded vaults, in directions nearly perpendicular to the curvature of the ellipse, and serving to support the first *menianum*, or the interior range of seats. In some of these vaults were the steps which led to the *podium*, and others were, simply, passages between the first and the next corridor towards the exterior. This corridor received light from apertures cut in its vault through the præcinction which separated the first horizontal division of the seats from the second. In rear of this second corridor were, also, vaults in directions nearly perpendicular to the curvature of the ellipse, in some of which were steps leading to the second division of the seats, and others were galleries leading from the corridor to the double arcade which surrounded the whole edifice. The transverse axis of the exterior ellipse is 615½ feet, and the conjugate 510 feet.

On the Northern side of the building was the lodge of the Emperor, and under it were apartments in which he gave private audiences; from these apartments a colonnade led to the Imperial Palace on the Esquiline. On the Eastern and Western extremities were the doorways by which the combatants entered, or by which the dead were conveyed away.

On the exterior of the building, about its whole circumference, there are three Orders of columns, and one of pilasters, all of equal diameter and disposed in tiers one above another; and the circumference of the wall, in each tier, is perforated by eighty semicircular-headed arches ornamented with archivolt mouldings: four of the arches in the lower Order, or tier, were for the admission of distinguished personages, and the others for the populace; these were called *vomitoria*, and from them the spectators ascended to their places by steps under the vaults which supported the seats. The piers supporting the arches are 7.329 feet wide, and each is ornamented with a half-column projecting from the wall; the distance between the piers is 14.302 feet. Horizontal mouldings at the imposts, or springing of the arches, ornament the wall and entirely surround it, except where they are interrupted by the arches and columns. A plan and elevation of this edifice is given in pl. xii.

Description of the columns.

The columns in the lower tier are of an Order resembling the Doric, but they have bases, and there are neither triglyphs in the frize nor mutules in the cornice. According to the dimensions given by Degodetz, their height is 27.631 feet, and the lower diameter 2.91 feet; consequently they are about nine diameters high, and they have a very small diminution. The base consists of a plinth, a torus, and an inverted cima recta with a fillet between the two latter; the shaft is plain and the capital consists of an ovolo, the section of which is in the form of a quadrant of a circle, with a small cima reversa at its foot. The architrave is divided horizontally into three faciæ, the frize is plain, and below the corona is a band on which a row of dentels may be supposed to have been intended; the height of the entablature is 6.644 feet; consequently the height of the whole Order, above the pavement, is 34.275 feet. For an elevation of one of these columns see pl. x. fig. 2.

The second tier of columns is of the Ionic Order, and stands on a continuous stylobata, 6 feet high, the face of which is in the same plane as that of the piers, except where it is broken under each column to form a projection, like the face of a pedestal. The height of the column is 25.731 feet; the bases are of the Attic kind, the shafts are plain, and the faces of the volutes without ornament, the eye only being marked by a circle. The height of the entablature is 6.636 feet, and its subdivisions are exactly similar to those of the entablature of the Doric Order below; the faciæ of the architrave incline inward at their tops; the cornice is without modillons, and the dentel band is uncut. The entire height of this Order, including the pedestal, is 38.367 feet.

The third tier of columns is of the Corinthian Order, and, like the tier below, it stands on a general stylobata, the height of which is 6.396 feet. The height of the columns is 25.584 feet; the bases are of the Tuscan kind, consisting of a simple torus and fillet above the plinth, and the leaves in the capitals are quite plain. The height of the entablature is 6.596 feet, and its members exactly resemble those of the two lower Orders, except that the place of the corona is occupied by a row of simple modillons which support the cymatium above. The entire height of this Order, including the pedestal, is 38.576 feet.

The fourth tier consists of Corinthian pilasters which stand upon blocks 2.788 feet high, placed above a general stylobata 7 feet high. The height of the pilasters is 27.99 feet, and they are without diminution; the bases are Attic, and the capitals are exactly like those in the Order immediately below. The height of the entablature is 7.369 feet, but it is not continuous; over the capital of each pilaster is a portion of an architrave, and above it is placed a large corbel; and in the interval between every two pilasters are placed two similar corbels in the same horizontal plane, and all at distances from each other equal to one-quarter of their length in the direction of the circumference of the building. These support a continuous cornice which projects considerably beyond the wall; and the edifice is crowned by a plain parapet 6 feet high. By adding all the vertical dimensions together, we find that the whole height of the Amphitheatre, above the steps, is 162 feet.

All the columns in the three Orders have the exterior faces of their shafts projecting from the wall, in each tier, about three-quarters of a diameter. Between the columns are semicircular-headed apertures whose breadths, though some differ considerably from others, are, in general, equal to 14.479 feet, and the breadths of the piers are 7.883 feet. The faces of the walls in the different tiers are not in the same vertical plane, but each upper face recedes a little from that immediately below it, towards the interior; and the axes of those columns which are in the same vertical planes, consequently, do not fall in the same vertical lines. The thickness of the piers is also different in the three lower tiers; reckoning from the bottom of the building upward, they are, respectively, 8.706 feet, 8.377 feet, and 7.284 feet. The arches spring from imposts and are ornamented with archivolt mouldings. The lower parts of the apertures coincide with the tops of the stylobatæ, and these seem to have been intended as parapets, since they are of a height just sufficient to be leaned over for the prevention of accidents. Between every two pilasters in the fourth Order is a square window, and between every two corbels are holes left in which were placed the beams intended to support poles carrying the canvass cover, which was occasionally drawn over the building to screen the spectators from the Sun or rain. The cloth was attached to the building round its circumference, and declined towards the interior, so that the rain might fall into the *arena* by the aperture which it left in the centre.

The magnitude and distribution of the parts of this building are such as to cause it to form an imposing spectacle, notwithstanding many defects which a critical eye may discover in it. It may be justly objected to it that the three entablatures are nearly alike, though the columns are of different Orders. And it has been observed that the dimensions of the arches and piers and the projections of the members are very irregular, which seems to indicate great precipitancy in the execution.

Amph tre at Vero

The Amphitheatre at Verona, though smaller than the Colosseum, has the advantage of being in a better state of preservation. It is of an elliptical form, 508 feet long and 403 feet broad, and the dispositions of the vaults and seats are similar to those of the Colosseum. The exterior wall of the edifice is ornamented with three tiers of Tuscan pilasters projecting before the faces of the walls, and those of the two upper tiers stand upon continuous podia; between the pilasters in each tier are semicircular-headed apertures.

The horizontal joints of the stonework in the face of the wall are marked by channels, which are also carried across the faces of the pilasters. This species of ornament, if it may be so called, has subsequently been denominated rustication. At Capua, Otricoli, and Nismes are the remains of large Amphitheatres, but as a great sameness reigns in all the works of this kind, it will be unnecessary to describe them.

Naum

Naumachiæ were buildings similar to Amphitheatres, and used for the exhibition of naval combats; the *arena* being filled with water from some river, or from reservoirs communicating with it. Those of Augustus and of Domitian are said to have been the most magnificent of these buildings, but no traces remain of them.

A Circus is a building in some respects similar to an Amphitheatre, and was generally employed for the exhibition of chariot-races. It has already been described at length (CIRCUS) in our *Miscellaneous Division*, and, therefore, it will be sufficient to state the dimensions of one or two of those edifices whose foundations, which are all that remain of them, afford the means of tracing their plans with tolerable accuracy.

The *Circus Maximus*, which is supposed to have been, originally, constructed in a rude manner by Romulus, and subsequently rebuilt by the elder Tarquin, was about 2000 feet long, and 550 feet broad on the exterior, and consisted of two parallel walls in the direction of its length, which were united by a semicircle at one extremity; the other was closed by a row of vaults disposed, side by side, in a segment of a circle, the radius of which was equal to about 430 feet. These, which were called *carceres*, were to contain the chariots previous to their starting for the race; the chord of the arc was not perpendicular to the long sides of the building, but inclined to them at an angle of about 85 degrees, and at each extremity was a square tower. In the middle of the *arena*, and parallel to its length, was the *spina*, a low wall 1300 feet long, beginning near the centre of the semicircular extremity of the building; and at each end was a *meta* or goal. The seats of the spectators were disposed in inclined planes within the walls, like those of a Theatre, with a *podium* in front; and between the *podium* and *spina*, on each side of the latter, was the course for the chariots.

The Circus of Nero was of the same form nearly as that above-mentioned; its length was 1400 feet, and breadth 260 feet; the *spina* was about 800 feet long, and the *carceres* seem to have been contained in a rectangular building.

The Circus of Caracalla was of nearly the same dimensions as that of Nero, but the two sidewalls were not exactly parallel to each other, probably on account of some local impediment. One of the sides was broken, near the middle of its length, and the two parts made, with each other, a very obtuse angle. The *spina* was not parallel to either of the sides; but, at the end next to the semicircle, it was further from the straight wall by about ten feet than at the other end. The *carceres* consisted of a row of vaults like those of the great Circus, and the chord of the segmental arc made an angle of 80 degrees with one of the long walls. The radius of curvature of this arc was equal to about 330 feet.

The Hippodrome, at Constantinople, is a building of this nature, and it, probably, remains now nearly as it stood when first constructed by Constantine.

From these descriptions we perceive that the plan of the Circus was nearly in the form of a parallelogram, the exterior length of which seems to have been equal to four or five times the breadth. A high wall surrounded the ranges of seats, and was, no doubt, pierced by semicircular-headed arcades, like those in the exterior wall of a Theatre. The length of the *spina* was equal to about two-thirds of the whole interior length of the building; this was ornamented with obelisks and statues, placed above it, and was terminated at each extremity by a *meta*, consisting of three columns, or obelisks, on pedestals. The *carceres* were, generally, vaulted chambers closed in front and rear by gates; in these the chariots remained till the signal was given for driving them round the *arena*. The oblique disposition of the plan of the *carceres*, and, sometimes, of the *spina* itself, was, no doubt, intended to equalize the spaces which all the chariots were to describe, from their place of starting to the goal.

General distribution of the Roman Baths.

The *Thermæ*, or Baths, were public buildings in which the citizens, who had not conveniences for bathing in their private houses, could assemble and enjoy that luxury. They contained a suite of apartments for men, adapted to the several circumstances attending the performance of that operation among the Ancients, and a corresponding suite for women. Some remains of the public Baths of Nero, Vespasian, Titus, Caracalla, Dioclesian, and Constantine are still in existence at Rome. Those buildings were generally of a rectangular form; each was surrounded by a *peribolus* or enclosure, and contained all the different apartments for bathing; peristyles and arcades, for the purpose of promenading; *xysti*, for the exercises of the *athletæ;* Theatres; *exedræ*, or apartments for conversation; and Temples, either in the *peribolus* or in the wings of the building.

In the restorations, given by Palladio, of these edifices, we find apartments open towards the exterior, in the fronts of which are rows of columns supporting horizontal entablatures; the open fronts terminate at the roof in segmental arches with low pediments above them, and without a horizontal cornice. He supposes the *xysti* to be covered by groined vaultings, the middle of the interior peristyles and arcades to be without roofs, and the galleries, between the columns or piers and the walls, to be covered by hemicylindrical vaults.

Baths of Dioclesian.

But the Baths which exist in the best state of preservation are those of Dioclesian, which seem to have been also the most extensive and magnificent in Rome. They form a rectangle 744 feet long, and 454 feet wide, and were surrounded by a *peribolus* 1050 feet long, and 908 feet wide. In various places about this enclosure were supposed to be *exedræ* of a semicircular form, besides small rectangular Temples; and, in the middle of the longest side, a semicircular Theatre.

In the front of the building is an open court, 300 feet long, and 170 feet wide, on the right and left of which are vestibules, open towards the court and covered with groined vaultings; these lead, on each side, into a saloon supposed to have been intended for the distribution of prizes, and to the Baths for the use of those persons who did not exercise in the *xystus*. In the centre of the front, opposite the open side of the court, was the grand entrance which led to the *xystus*, a rectangular space 176 feet long, 73½ feet wide, and 90 feet high, and covered by three groined vaults supported by Corinthian columns. On the right and left of this were apartments for the spectators, vaulted in the same manner, and beyond these, on each wing, was a magnificent peristyle 229 feet long, and 114 feet wide; the surrounding galleries were roofed by semicircular-arched vaults; and at the extremities of the galleries were *ephebei*, or large apartments, open towards the peristyles.

On the side of the *xystus* opposite the grand entrance are doors leading to a circular building, which might have served as an *apodyterium;* it is 62 feet diameter, with a rectangular recess on each side; and beyond this building were the baths of the *athletæ*, in a rectangular saloon, 148 feet long, and 68 feet wide, covered with a groined vaulting. Where the apartments open into each other, the aperture is occupied by four columns, or two columns and two pilasters, and the entablature over the two middle columns is in the form of a semicircular arch. In the walls of the *xystus* are semicircular or rectangular niches, between which are columns supported on corbels projecting from the walls.

We have given, from Chambray's *Parallel of the Orders of Architecture*, an elevation of a Doric column said to have belonged to these Baths. Its height is equal to eight diameters, and the principal moulding in the capital differs from that in all the older examples of the Doric Order, in having the form of a cymatium, and below it is an astragal sculptured in the form of a rope; the cornice has no mutules, but contains a row of dentels between two curvilinear mouldings, of which the upper one is cut to resemble a bundle of leaves. See pl. x. fig. 3.

In the grand Saloon, which has been since converted into a Church by M. Angelo, the columns are of the Composite Order, and an elevation of one is given at fig. 7. pl. xi. The height of the column is 45.182 feet, and the lower diameter is 4.619 feet. The architrave is divided into three faciæ separated by sculptured mouldings, and the upper extremities of all the faciæ incline towards the interior; the cornice contains both dentels and modillons, and both the corona and the cymatium above it are richly sculptured. The height of the whole entablature is 10.725 feet, or about one-quarter of the height of the column.

General construction of the Roman Baths.

In constructing the bathing apartments, a floor of tiles seems to have been laid on the ground; on this floor were placed pillars of brick, about two feet high, at intervals, and above them was laid another floor of tiles; between these floors, under the place where the water was heated, a fire was made, and this part seems to be that which was called the *hypocaustum* or furnace; the heat from this extended itself under the floors of the different apartments which were intended to be warmed. Above the *hypocaustum* were placed three vessels, one, called *frigidarium*, contained the cold water which came from the reservoir; another, called *tepidarium*, received the water which flowed through a pipe from the former vessel, and in it the water received a certain degree of heat; the third, called *calidarium*, received the water from the *tepidarium* by a pipe, and in it the water acquired the greatest heat; from hence a pipe conveyed the hot water to the Bath.

One apartment for each sex was allotted for undressing, and called *apodyterium*. Another, called the *unctuarium*, contained the oils and ointments; and in this the people anointed themselves. Two apartments were occupied by the hot and cold Baths, and sometimes there was another apartment containing a small bathing-vessel, perhaps for children. Near the hot Bath was a warm room, called *sudatorium*, for promoting perspiration after bathing; and another, called *tepidarium*, which served as a drying room, and as a place for exercise before going into the open air; besides these, there was a grand Saloon, called *ephebeum*, for exercise and conversation.

In the floor of the *sudatorium* there seems to have been an aperture through which the heat issued from the *hypocaustum*: it was covered by a *clypeus*, or dome-shaped vessel, which might be raised or lowered at pleasure, in order to regulate the degree of heat in the room. This aperture, with its cover, was called *laconicum*, and it was probably invented by the Lacedæmonians.

The apartments just mentioned are recommended by Vitruvius to be sheltered from the Northern and North-Eastern quarters of the heavens, and the hot Baths to be placed on the South-Western side; a disposition which is found to exist in such remains of the ancient Baths as have been discovered. In those at Baden, the *baptisteria* or bathing-places are of a rectangular form, about 27 feet long, and 19 feet wide, and are excavated in the floor to the depth of 4 feet: at either end were four steps, each 1 foot high, by which the bathers descended, and on each of the long sides there were two steps, 2 feet high. The rule given by Vitruvius is, that the breadth of the basin should be two-thirds of its length, and that there should be a passage not less than 6 feet wide between the basin and the wall, that there might be room for those persons to stand who were waiting for their turn to descend into the water; he mentions a *pulvinum* about the Bath, which was, probably, a coping surrounding the basin.

In their Baths the Romans seem to have indulged an unlimited taste for magnificence; they employed, in them, the most ornamental of the Orders of Architecture, which they covered with the richest sculpture, and they adorned the walls and ceilings with splendid paintings. But, however, much as these edifices exceeded the ancient buildings of Greece in richness of embellishment, they seem to have wanted the good taste which characterised those classical works. Unfortunately a taste for variety led to a departure from the sound principles of Art in the application of the most important members of an edifice, which was not perceived amidst the profusion of ornament employed about them; and succeeding artists, copying the general style without having the talent to execute the embellishments, produced those rude edifices which, in a later Age, prevailed so generally in Europe. In the Baths of Titus are still to be seen paintings exhibiting delineations of slender twisted columns, broken entablatures, and curvilinear pediments; and if to these we add the columns supported on corbels attached to the faces of walls, and a profusion of sculpture, in which animal figures and foliage, in the most fantastical forms, are displayed, we shall, perhaps, be led to recognise the originals of most of those extravagancies which subsequently prevailed in the Moorish and Gothic buildings, executed in what are called the Middle Ages.

Portic

Colonnades covered with roofs, and quite unconnected with any building, were often raised by the Romans to serve as public promenades; these were called by the general name of Portico, and, though none of them are now in existence, yet traces of them have been found in many of the cities of the Empire. The building at Rome which is considered as the Portico of Pompey, had, probably, a similar destination, but it is differently formed. This is a rectangular area 374 feet long, 154 feet wide, and open on all sides; it is covered by a groined vaulting which rests on square piers, and above this is a second story covered by the general roof of the building. Between the arches, on the exterior of the four sides of the building, are attached Tuscan or Doric columns supporting an entablature above the crowns of the arches. In the middle of the area, and parallel to the long sides is a wall, in each face of which

Portic
Pomp

is a row of semicircular niches; and between these, in the thickness of the wall, are several circular staircases, which led to the upper story. According to Durand, this was situated before the house of Pompey, and was one of the most delicious promenades of Rome, being ornamented with alleys of trees and fountains.

CHAPTER VI.

Characteristics of the Roman Orders of Architecture.

The proportions of the several parts of the columns and their entablatures, which form the different Orders of Architecture employed by the Romans, are to be obtained from the writings of Vitruvius, and from the several edifices remaining within the limits of the Empire; and these are chiefly such as have been already described.

propor- s of the an r.

The Tuscan Order is that which presents the greatest simplicity of character; and though it does not seem to have been much used by the Romans, and no example of an Order like that which Vitruvius calls by that name is now in existence; yet, as that ancient author has given a description of such an Order, it will not be proper entirely to omit noticing it. He makes the height of the whole column equal to seven times its diameter, including the base and capital, which are each equal to half a diameter in height; and he determines the absolute height of the column by making it equal to one-third of the breadth of the Temple for which it is destined. The upper diameter of the shaft is made equal to three-quarters of the lower; consequently, the difference of the two diameters is one-quarter of the latter, and the difference of the semidiameters is $\frac{1}{56}$ of the length of the shaft. The base consists of a plinth, the height of which is about a quarter of a diameter, and of a torus, above the plinth, with an apophygis and fillet. The plinth is remarkable for being of a circular form on the plan, the semidiameter being perhaps equal to $1\frac{1}{3}$ of that of the shaft at bottom. The profile of the torus was perhaps a semicircle, and its height may have been equal to four-fifths of the height of the plinth; one-fifth of the latter may have been the height of the fillet.

The capital consists of a rectangular abacus, an ovolo, or curvilinear moulding, the profile of which is a quadrant of a circle, an apophygis and fillet, and the hypotrachelion. The whole was divided into three equal parts, of which the abacus and ovolo were each equal to one part, the apophygis and hypotrachelion were together equal to the third; and the breadth of the abacus was equal to the lower diameter of the shaft. The word hypotrachelion being used by Vitruvius, it would seem that there must have been some member to separate it from the rest of the shaft, and perhaps this was an astragal, consisting of a small semicircular moulding with its fillet.

The architrave was laid over the columns, and this consisted of two beams of timber placed side by side, with an interval of $1\frac{1}{2}$ inch between them, that the air might circulate there, and prevent the decay which Vitruvius supposes would take place if they were put close together. Perpendicularly to the architrave were placed horizontal beams which projected beyond the faces of the building as much as one-quarter of the length of the column; and this being a much greater projection than exists in any other Order, some have supposed that there is an error in the text of the Latin author; but it is possible that this may be what he intends, for such a projection accords very well with the description he gives of the Tuscan Temples, and would afford a good shelter under the colonnade. Above these cross-beams there must have been a cornice, and the inclining rafters of the roof were placed in vertical planes over the beams. For an elevation of a Tuscan column, see pl. x. fig. 4.

The massive character of the Tuscan column, and an absence almost total of ornament, caused Sir Henry Wotton to compare it to a sturdy labourer in homely apparel; but its simplicity makes it harmonize admirably with an assemblage of low wooden buildings; and, of course, there are many situations in which it may be applied with advantage.

The Roman Doric Order.

The Doric Order seems to have been seldom employed by the Romans, and in passing through their hands, it underwent a considerable change of character; particularly, it became less massive than that which is exhibited in the Grecian examples. The rules given by Vitruvius for determining its members are probably derived from the practice of the Architects of his day, but we shall not find them accord accurately with such examples of the Order as have been measured; in fact, he himself makes a difference in the essential terms of height and thickness of the columns when applied to different buildings; in Temples he prescribes that the whole height of the column should be seven times its diameter, and, in Theatres, that it should be half a diameter more; the reason of which, he says, is, that in the former, there should reign more of majesty, and less of elegance than in the latter. In order to make the triglyphs in the frize fall into their proper places, by preserving a constant proportion between the diameter of the columns and the extent of the intercolumniations, he prescribes that, if the Temple is tetrastyle, the diameter of the columns should be $\frac{1}{14}$ of the breadth of the Temple, by which means the intercolumniations will be each equal to $3\frac{1}{3}$ diameters; if hexastyle, it should be $\frac{1}{22}$ of the breadth, by which means the intercolumniations will each be $3\frac{1}{3}$ diameters; that is to say, in both cases, the species of intercolumniation is diastyle, but the proportion must vary according to the extent of the intercolumniations. The above rule permits two triglyphs to be placed over the intervals of the columns, and causes the metopes to be rather greater in breadth than the height of the frize. The diameter of the column being regulated by such considerations, the dimensions of its members may be all determined with relation to that magnitude.

The columns of the Roman Doric Order may be considered as having no base, for Vitruvius does not describe one; and of the only remaining examples of the Order, *viz.* the columns in the lower tiers at the Theatre of Marcellus, and at the Amphitheatre of Vespasian, the former are without this member, and though the latter have it, their difference in other respects from columns possessing the essential characteristics of the Doric Order, will hardly allow us to consider them as exceptions to the rule. The Doric capital consists of an abacus, ovolo, and hypotrachelion; each of these is of the same height, and the height of the whole is equal to half the diameter of the column.

Vitruvius prescribes that the diminution of the shaft of the column, or the difference of the upper and lower diameters should be from $\frac{1}{6}$ to $\frac{1}{8}$ of the latter, according to the height of the column, which he limits between 15 and 50 feet. And if we suppose the length of the shaft to be equal to seven diameters, this will make the difference of the semidiameters equal to between $\frac{1}{84}$ and $\frac{1}{112}$ of the length of the shaft. Now in the Theatre of Marcellus, and in the Colosseum, the columns are respectively 24 and 28 feet high, yet the diminutions, when compared with the diameter, are $\frac{1}{5}$ and $\frac{1}{11}$ respectively; and when compared with the length of the shaft are $\frac{1}{70}$ and $\frac{1}{180}$ respectively. Here, since the situations of the columns are similar, while the proportions are so different, it is probable, though from the want of examples we cannot positively affirm it, that no general rule for the diminutions was followed in practice.

The entasis, or swell of the shaft, is recommended to be equal to about $\frac{1}{30}$ of the diameter; and the shaft to be channelled longitudinally, with twenty grooves forming segments of circles equal to quadrants, and intersecting each other in single edges along the column.

The height of the epistylium or architrave, including the tenia, or fillet above, is equal to half a diameter, and the face of the architrave is nearly in a vertical plane passing through the upper part of the front of the shaft. The height of the frize is three-quarters of a diameter, and the triglyphs, which extend from top to bottom of the frize, have their breadth equal to half a diameter. The metopes are generally square, that is, their breadths are equal to the height of the triglyphs. The surfaces of the metopes seem to have been intended to be in the same plane with that of the architrave, and the exterior faces of the triglyphs to project forward about $\frac{1}{20}$ of the diameter of the column. The centres of the triglyphs were exactly opposite the axes of the columns, and a space was left between the outer edge of the extreme triglyph and the angle of the frize, the breadth of which was about equal to that of half a triglyph, or to one-quarter of the diameter of the column.

Above the frize is a horizontal moulding of a rectangular form in profile and broken at intervals to form projections over the triglyphs and metopes; its height is $\frac{1}{12}$ of a diameter; but whether this is to be included in the three-quarters of a diameter given to the height of the frize, does not appear from Vitruvius, and the existing examples of the Order differ in this respect. Above this moulding comes the corona, which is a plain beam projecting nearly half a diameter beyond the face of the architrave; it rests upon a small bed-moulding in the form of a cymatium, placed on the capitals of the triglyphs, and terminates above in a similar moulding; the height of the corona, including those two mouldings, is about one-quarter of a diameter. Above the corona comes the epitithedas, or crowning member of the Order, which is in the form either of a cymatium or cavetto, and its height is about equal to that of the corona; this completes the entablature.

According to Vitruvius, the soffit, or under surface of the corona, is in an inclined plane, as if it coincided with the directions of the rafters, and there are mutules over the triglyphs and metopes as in the Greek examples; but the practice of the Romans seems to have been variable in these respects; for, in the Theatre of Marcellus, it is conformable to the method of Vitruvius, but from the fragments at Albano, it appears that the soffit of the corona, and the mutules, were in horizontal positions; and both in the Colosseum, and in the fragments found at the Baths of Dioclesian, the soffit is horizontal, and there are no mutules. The general projection of the corona beyond the axis of the column is above nine-tenths of the diameter of the column.

Compari between Grecian Roman ric Orde

In the details of this Order, Vitruvius professes to have followed the practice of the Greeks; but the character of the whole is considerably lighter than that of any Grecian example we are acquainted with, if we except those at Cora and Pompeii. The shaft of the column is more slender, and the entablature lower. In the capital, the Greek echinus is changed for the ovolo, or moulding, the section of which is a quadrant of a circle, except in the example found at the Baths of Dioclesian, where this moulding is a cymatium, which, as well as the ovolo in the capital at Albano, is ornamented with sculpture.

The Roman triglyphs differ from those of the Greeks in their projection from the axis of the columns; for the latter, except in the Temple of Apollo, and in the Portico of Philip, both in the Island of Delos, have their surfaces all in the same vertical plane with the face of the architrave; whereas, according to Vitruvius, and the existing examples, we find the former project beyond the general surface of the architrave and frize about as much as the metopes were sunk within the frize in the Grecian Order. The practice of the two people, also, further differs in the position of the triglyphs at the angles formed by the meeting of the entablatures of the front and flanks of the building; the Greeks making one side of the triglyph coincide with the extremity of the entablature, while the Romans, according to Vitruvius, made the centres of such triglyphs as well as of the others correspond with the axes of the columns, as has been said.

In the Grecian examples of this Order, we found the height of the columns, taking a mean of several, to be equal to about 5.25 diameters, and the mean height of the entablature to be nearly one-third of the height of the column. In the Roman Doric, the height of the column is about 7.5 diameters, and of the entablature one-quarter of the height of the column; or if, as in the Greek examples, we do not include the epitithedas, it will be found that the height of the Roman entablature is about one-fifth of that of the column.

The Vitruvian architrave seems rather small considering the strength required in that part of the edifice; on the other hand, the frize seems too high. In the Doric entablature of the Colosseum, the architrave is divided into three faciæ, and in the cornice of the Theatre of Marcellus there are dentels in place of mutules; these circumstances detract much from the apparent solidity of the Order; nevertheless, in the latter building, it possesses a masculine character, and this example appears to have been much imitated by the Moderns.

There is reason to believe that, occasionally, the Roman artists made use of columns which had been executed in Greece, or which had formerly belonged to Grecian edifices, and that they altered the forms of such columns to suit their own taste or convenience; it is also possible that, in some cases, during the later period of the Empire, when the intercourse between Italy and Greece had become frequent, the Roman Doric Order might affect a Grecian character. An example of a modification of the Grecian Doric occurs in some columns which are supposed to have been taken from the Baths of Dioclesian, and are now situated in the nave of the Church of S. Pietro in Vincoli. These are of

Cipoline marble; their heights are equal to 8.8 diameters, and their shafts, which begin to diminish from one-third of their heights, are ornamented with shallow flutings, like those in the Greek columns. The profile of the principal moulding in the capital, instead of being an ovolo, is nearly in the form of an inverted frustum of a cone, and appears to have been originally an echinus, but brought to this form by rubbing away its surface; the sides of the abacus have also been rubbed, so as to leave no margin between those sides and the top of the echinus. The columns have a sort of Tuscan base, consisting of a plinth and torus, which have, perhaps, been added to the original shaft.

Of the Ionic Order few examples executed by the Romans remain, but the description of it given by Vitruvius is nearly as follows. The height of the column is equal to 8.5 diameters, and it has a base and capital peculiar to itself. The height of the former, from the bottom of the plinth to the top of the upper torus, is half a diameter, and the height of the plinth is equal to one-third of that of the base. Above the plinth are two scotiæ separated from each other by a double astragal with fillets, and upon the upper scotia is placed a torus moulding, whose height is equal to that of the plinth; this must be considered as a specimen of extremely bad taste, for the massive torus, which ought to have been the lowest moulding, seems to crush those below it by its weight; happily for the credit of the Roman artists, this construction does not seem to have had many followers, and Milizia, speaking of it, says, *Ne' monumenti Romani non si è finora trovato vestigio alcuno di sì brutta base.* Instead of it we generally find that the bases of the Roman Ionic columns resemble that which is called the Attic base.

The diminution of the columns seems intended by Vitruvius to be the same as in the Doric Order, and, like it, to depend upon the height of the column. The height of the capital, reckoning from the top of the abacus to the bottom of the volutes, is equal to half a diameter, and the vertical section of the abacus is not a simple rectangle, as in the Doric Order, but has a cymatium and fillet at the top. The centre of the volute is in a vertical plane passing through the top of the front of the abacus, and in a vertical line drawn in that plane at a distance from the middle of the abacus equal to 0.489 diameter of the column. The whole height of the volute is 0.842 diameter, measured in the vertical line passing through the centre; and this line, being divided so that the ratio of the whole to the parts shall be as 1 to 0.56, and as 1 to 0.44, respectively, and the larger division, set down from the top, will give the centre of the volute; the diameter of the *cathetus*, or eye of the volute is one-eighth of the height; within this cathetus the centres are to be found for describing the several spirals, which, evidently, he supposes to be portions of circles, whereas the Greek spirals seem to have been a sort of transcendental curves. Below the abacus, at a distance equal to two diameters of the eye, is the top of an ovolo, which is sculptured with oves and arrows; the height of the ovolo is equal to two diameters of the eye, and at a distance below the ovolo, equal to one diameter of the eye, is the upper surface of an astragal which crowns the shaft, and separates it from the hypotrachelion. The projection of the top of the ovolo beyond a vertical plane passing through the top of the abacus is also equal to a diameter of the eye. The shafts of the columns are fluted with twenty-four channels of a semicircular form, and between every two is a fillet equal in breadth to the entasis of the column, that is, to about $\frac{1}{30}$ of a diameter.

The height of the epistylium or architrave is made to depend on that of the column; when the latter varies from 12 to 30 feet, the former varies from $\frac{1}{17}$ to $\frac{1}{12}$ of the height of the column; and this increase of the height of the architrave is to compensate for the apparent diminution of magnitude produced by the elevation of the object above the eye of the observer. The architrave is crowned by a cymatium, exclusive of which it is divided into three faciæ, the breadths of which, from the bottom upward, are respectively in the ratio of the numbers 3, 4, and 5; each upper face projects a little over the lower; the lowest is nearly in a vertical plane passing through the top of the exterior surface of the shaft, and the highest nearly in a vertical plane passing through the foot of that surface. The height of the frize is equal to $\frac{3}{4}$ of that of the architrave, if plain, but if sculptured it should be equal to $\frac{5}{4}$ of that member; and the frize, like the architrave, is crowned by a cymatium. The cornice is divided into three equal parts, of which the lower is occupied by the line of dentels, the middle by the corona, and the upper by the epitithedas. The height of the dentels is equal to that of the middle face of the epistylium; their projections are equal to their heights; their breadths equal to half their heights; and the intervals between them are each equal to two-thirds of their breadths. The whole height of the entablature, according to the dimensions above given, will vary from about $\frac{1}{6}$ to about $\frac{1}{4}$ of the height of the column; and Vitruvius recommends that the faces of the architrave and frize should not be in vertical planes, but should incline forward at top as much as $\frac{1}{12}$ of their height, in order to counteract the apparent receding of the upper parts of vertical objects when viewed by an eye situated below them. He makes the corona project as much as 1.131 diameter from the axis of the column, and 0.656 diameter from the face of the frize.

The comparison between the proportions assigned by Vitruvius to the principal parts of this Order, and those actually adopted by the Roman artists will be best effected by means of a Table, showing the dimensions of the only existing examples of Roman Ionic columns, which are those belonging to some of the buildings we have already described. The dimensions are in English feet, and in the height of the cornice is included that of the crowning member.

Names of Edifices.	Height of base.	Height of shaft.	Height of capital.	Lower diam.	Upper diam.	Height of architr.	Height of frize.	Height of cornice.
The Temple of Fortuna Virilis........	1.592	24.335	1.421	3.109	2.72	1.834	1.489	3.461
The Temple of Concord.............	2.243	38.375	2.243	4.486	3.701	2.12	2.65	2.43
The Theatre of Marcellus............	1.33	21.72	0.89	2.66	2.24	1.906	1.622	2.832
The Colosseum..................	1.358	23.015	1.358	2.91	2.424	2.25	1.67	2.716

From these we find that the Vitruvian column is rather less slender than those actually constructed, for a mean being taken of all, shows the height of the columns to be equal to nine diameters. In every other respect the proportions are nearly the same. The height of the capitals and bases are equal to about half a diameter. If we measure the diminution by the ratio of the difference of the upper and lower diameters of the shaft to the lower diameter, Vitruvius makes it from $\frac{1}{6}$ to $\frac{1}{8}$, and the mean diminution in practice is $\frac{1}{6.1}$; or if we measure it by the ratio of the difference of the semidiameters to the length of the shaft, his rule for columns of the same height as those in the above examples, makes the diminution equal to $\frac{1}{112}$, and in practice it seems to have been $\frac{1}{107}$ of the length of the shaft. The rules given by Vitruvius for the dimensions of the entablature make this member rather larger than it is found to be in the existing examples; since for columns of about the same heights as these, the height of his entablature is equal to 2.313 diameters, while the mean height of those in the examples is but 2.12 diameters. It may be remarked that the faciæ of the architraves in the Theatre of Marcellus, and in the Colosseum, have that inclination forward which is prescribed by Vitruvius.

Comparison between the Grecian and Roman Ionic Orders.

If we compare together the examples of the Grecian and Roman Ionic Orders, it will appear that the columns of the latter are scarcely more slender than those of the former, since their mean height is equal to nine diameters, and that of the Greek examples is 8.95 diameters. The diminution of the shafts, if we take it with relation to the diameter of the column, is nearly the same in both; but if we estimate it with respect to the length of the shaft, we shall find the diminution of the Roman columns is less than that of the Grecian; in the former it being equal to $\frac{1}{107}$, and in the latter to $\frac{1}{90}$ of the length of the shaft. The height of the entablature among both Romans and Greeks is equal to about two diameters, or to about $\frac{1}{4.3}$ of the height of the columns; but, in the Greek columns, the epitithedas is not included; now the only Roman Ionic example which we can consider in this way is the Temple of Fortuna Virilis, and if, in this entablature, we leave out the epitithedas, its height will be equal to $\frac{1}{5}$ of the height of the column; consequently, if, as is probable, there were at one time, in the Empire, many specimens of the Order similar to this, by which the general character of the Order might be determined, it would follow that the Roman Ionic entablature may be considered as much lighter than the Grecian. The height of the architrave is nearly equal to that of the frize in both the Roman and Greek examples, but there is a considerable difference in the proportion of the cornice to either of the other members. In the Roman Order the height of the cornice exceeds that of the architrave in the ratio of 1.25 to 1; and in the Grecian Order, it is only equal to $\frac{1}{2.6}$ of the height of that member.

We find a considerable difference in the capitals of the Grecian and Roman Ionic Orders; the volutes of the latter are smaller than those of the former, and consist of but one spiral baltheus which is bent down from the under side of the abacus, while the Grecian spiral is double or triple, and the curves are continued in the form of festoons on the front of the capital. The sides of the Roman capitals present the appearance of bundles of leaves bound in the middle, except in the Temple of Concord, where all the four faces are of similar forms, the planes of the volutes being situated obliquely to the sides of the abacus, instead of being in a plane parallel to its front. This disposition certainly has the advantage of producing uniformity of appearance on the four faces of the capital; but the unequal foreshortening of the spirals, which occurs when the eye is not opposite the middle of the capital, gives an irregularity to their figures, and the apparent ellipticity of their curves makes them seem disagreeably compressed.

Pa

The R
Corint
Order.

Of the Corinthian Order, Vitruvius gives no other account than of its origin, and the dimensions of its capital. He makes the whole height of the capital, including the abacus, equal to one diameter of the column; the plan of the abacus is not a square, but the faces of it are cut in the form of arcs of circles, concave outwards, and described upon the sides of a square the diagonal of which is equal to two diameters of the column, and the versed sine of each arc is equal to $\frac{1}{9}$ of the side of the square. The bottom of the capital has the same diameter as the top of the shaft of the column, and under it is an astragal and fillet. The height of the abacus is equal to $\frac{1}{7}$ of the diameter, and the remainder of the height of the capital is divided into three equal parts; these divisions determine the heights of the two courses of leaves, and the upper of the three spaces is appropriated to the caulicoli or stems from whence spring the volutes which curl under the angles of the abacus. We may suppose him to mean that the proportions of this Order, in other respects, should be the same as those of the Ionic Order.

The Corinthian Order may be considered as exhibiting the highest degree of refinement in Architecture; and though it is distinguished for the richness of its ornaments, yet, as a whole, it may be considered, perhaps, as the most simple of all the Orders, and admitting of greatest facility in its execution. The construction of the volutes in the capitals of the Ionic Order, and the embarrassment arising from the disposition of the triglyphs, together with the sculpture in the metopes of the Grecian Doric Order, render these more complex than the Corinthian; so that it would seem as if the ancient artists, while, in the Orders of later invention, they aimed to obtain more beauty than existed in the earlier Orders, endeavoured also to procure more simplicity and elegance. Among the Romans, the Corinthian Order became the general favourite; it seems to have entirely superseded the two more ancient Orders, and to have gone on increasing in richness of decoration till it arrived at the highest degree of luxury in the works erected by that people in Asia Minor and Syria.

It is uncertain whether or not the Greeks invented that form of capital which is so generally employed in the Roman buildings constructed according to this Order; and which is found in Greece itself, in edifices constructed by Roman or native artists at times subsequent to the Roman conquest of the Country. Be that as it may, it is to Italy, and to the different Provinces of the Empire, that we are to look for examples of the Corinthian Order, of which many remain to this day in a state of good preservation. The following Table exhibits the dimensions of columns belonging to the six principal edifices; and from them we shall be enabled to deduce the proportions which may be considered as characteristic of the Order. We have added to the Table the dimensions of the three principal examples of the Composite Order; in order to avoid making a

hitec-
ture.

Part II.

separate Table of examples the proportions of which do not differ materially from those of the former Order. The dimensions are all in English feet, and we have included the epitithedas in the height of the cornice.

Names of Edifices.	Height of base.	Height of shaft.	Height of capital.	Lower diam.	Upper diam.	Height of architr.	Height of frize.	Height of cornice.
Portico of the Pantheon	2.398	38.995	5.636	4.797	4.102	3.396	3.396	4.325
Interior of the Pantheon	1.821	29.211	3.642	3.642	3.157	2.579	2.493	3.128
Temple of Jupiter Tonans	2.325	39.391	5.368	4.598	3.99	2.772	3.189	3.553
Temple of Jupiter Stator	2.445	39.973	5.228	4.841	4.313	3.389	3.389	5.501
Façade of Nero	3.646	53.514	8.34	6.568	5.801	4.875	4.842	6.307
Arch of Constantine	1.757	23.1	3.18	2.902	2.562	2.176	1.935	2.829
Arch of Titus	2.345	17.056	2.664	2.07	1.836	1.588	1.552	2.105
Arch of Severus	1.444	23.1	3.303	2.887	2.549	2.166	1.227	3.296
Baths of Dioclesian	2.405	40.605	5.466	4.619	3.746	3.426	3.373	3.926

By a mean of the first six examples, we find the height of the Corinthian column to be equal to 9.81 diameters, a proportion rather more slender than that assigned by Vitruvius, (ch. i. book iv.) who makes the height equal to 9$\frac{1}{6}$ diameters The mean height of the base is equal to 0 527 diameter, and of the capital, is 1.135 diameter. The diminution, or difference of the upper and lower diameters is $\frac{1}{8}$ of the latter, and the difference of the semidiameters is $\frac{1}{140}$ of the length of the shaft. The height of the whole entablature is equal to 2.296 diameters; that is to $\frac{1}{4.3}$ of the height of the column. The heights of the architrave and frize are nearly equal to each other, and each is equal to 0.667 diameter; and the height of the cornice is equal to 0.962 diameter. So that while the proportions of the Corinthian shaft and base remain the same, nearly, as in the Ionic Order, the height of the capital is twice as great. The proportions of the architrave, frize, and cornice to each other, and to the diameter of the column, remain also nearly the same as in the Ionic Order. The projection of the corona from the axis of the column is equal to 1.226 diameter, and from the frize is 0.749 diameter.

The Attic base is sometimes employed in the Corinthian Order, but, frequently, it consists of two tori, having two scotiæ between them separated from each other by a double astragal and fillets, and the whole supported on a square plinth, the projection of which from the axis of the column is, by a mean of the above examples, equal to 0.695 diameter.

The generality of the capitals in this Order consist of a bell-shaped vase surrounded by two rows of foliage, one above the other, the upper row springing from the intervals of the lower; and from the intervals of the upper row proceed cauliculi or stems, which, curling under the angles of the abacus, form small volutes; each principal leaf is composed of clusters of small leaves resembling those of the olive, and the bases of the shoots which form the volutes are ornamented with the same kind of foliage.

mo-
in
er.

It is in the entablature of the Corinthian Order that the Roman artists have deviated most considerably from Nature and from the practice of their Grecian masters, and even from the precepts of Vitruvius. In the cornices of all the Roman examples of the Order we find both modillons and dentels employed, and the former are invariably placed above the others; whereas if the modillons represent the ends of the principal rafters, and the dentels those of the smaller, the latter should have been placed above the others; it is true that the dentels would not be seen to advantage by an eye near the ground if they were placed above the modillons, but there is no reason why one or the other of them should not be omitted; and to retain both, thus misapplied, is a sacrifice of good taste to ostentation. The modillons are sometimes of a rectangular figure, or are divided into two faciæ, as in the entablature of Nero; but, in almost every case, their under-surfaces are cut in the form of a scroll or curve of contrary flexure, the thicker extremity of the member being nearest to the face of the cornice in which they are inserted. Under this inferior surface is attached a piece of sculpture in the form of a leaf, and the profiles of the modillon represent the curve continued and forming a spiral ornament. There are some examples, as the entablature of the Maison Quarrée at Nismes, and even the interior cornice of the Temple of the Winds at Athens, in which the smaller end of the modillons is placed next to the wall; but it is evident that this disposition is improper, since it takes away from the member its essential character, which is that of a support to the corona, and makes itself appear to want support.

It has been said, in describing the Pantheon at Rome, that on the interior surface of the cylindrical wall, the vertical sides of the modillons and the corresponding sides of the lacunaria or coffers in the soffit of the corona, instead of being parallel to each other, tend towards the axis of the building; by this circumstance the symmetry of the work is preserved, while no rule of propriety is violated in consequence of one extremity of the modillon being smaller than the other, since the larger end is that next to the wall, which is the place wherein the greatest strength is required. But on the convex exterior of the same building, the vertical sides are made parallel to each other, in order, no doubt, to avoid the bad effect which would have been produced by making the outer extremity broader than the other, and thereby giving to the modillon an appearance of weakness.

The magnitude and disposition of the dentels and modillons in Roman Architecture follow no general rules; by taking a mean of the dimensions of these members in several buildings, we find, for the dentels, the height equal to 0.158 diameter of the column; the breadth equal to 0.119 diameter; the projection, 0.141 diameter; and the interval of every two, 0.053 diameter, or about half the breadth: for the modillons, the height 0.156 diameter; the breadth, 0.192 diameter; the length, 0.344 diameter; and the interval of every two, 0.428 diameter. In some examples the centre of a dentel or modillon corresponds nearly with the axis of the column; in others one of the vertical sides corresponds with it; and there are again others in which the middle of the interval falls in that position. It is evident, therefore, that convenience only has been attended to in disposing those ornaments.

The Composite Order.

The Composite Order differs so little from that which has been just described, that it can hardly be considered as entitled to a distinct appellation. In the Arches of

Titus and Septimius Severus, which are the principal examples of the Order, if it may be so called, the profiles of the entablature and of the base of the column as much resemble some of those of the Corinthian Order, as many examples of the latter resemble each other; and, perhaps, the writers on Architecture are no more justified in treating this as a fifth Order, on account of its capital, than they would be in considering as so many different Orders, all the columns made subsequently with capitals which are not exactly identical. It must be observed that the Composite columns in the Baths of Dioclesian are remarkable for as great a diminution as is found in many of the Grecian Doric columns, the difference of the diameters being equal to $\frac{1}{5.3}$ of the lower, and the difference of the semidiameters, to $\frac{1}{86}$ of the length of the shaft.

When the Triumphal Arches were first noticed, at the time of the revival of learning, on account of the Historical subjects sculptured on them, the capitals of the two above-mentioned were observed to be compounded of the leaves of the Corinthian, and of the volutes of the Ionic Orders; and this seems to have induced Scamozzi to consider them as appertaining to an Order distinct from either of the other four. The Composite capital consists of two rows of leaves surrounding a bell-shaped vase; the stems of the leaves of the interior row rise in the intervals of the leaves of the lower row, and the tops of the former leaves are as much above those of the latter, as these are above the bottom of the vase. The foliage is richer than that of the Corinthian Order in general, and seems composed of leaves of the acanthus. Above the upper row is an ovolo moulding which resembles the exterior of a shallow vase, and from this vase, about the middle of the face of the capital, spring two stems which diverge to the right and left and form large volutes diagonally under the angles of the abacus.

This kind of capital, which may be said to have a greater appearance of strength and even less of elegance than the Corinthian, has been employed chiefly on the columns which adorn the Triumphal Arches of Italy; and Serlio supposes that the Romans used it to express their dominion over the people who invented the Orders of which it is composed.

In the Roman Architecture, when columns are attached to the walls of buildings, the entablature, as we have seen, is frequently broken so as to make it project over each column; this practice is generally condemned, because it is said to be inconsistent with the intention of an entablature, which is to express a continuous line of beams resting on the columns. It would be easy, however, to find a prototype for such a mode of construction; for the projecting parts of the entablature may represent the extremities of beams supposed to be situated perpendicularly to, and carried out beyond the face of the building.

Irregularities in the proportions of the Orders.

In comparing the different Orders of Architecture together, and contemplating the different examples of each Order, we cannot avoid observing that the Ancients did not bind themselves to any constant proportions between the parts of an Order, but, perhaps, made them depend upon the situation or destination of the edifices. In the Ist Chapter of the IVth Book, Vitruvius, describing the Orders separately, makes the height of the Doric columns equal to seven times their diameter; the height of the Ionic columns equal to 8½ diameters; and of the Corinthian to 9½ diameters. But in speaking of the intercolumniations, (book iii. chap. ii.) he states, that in aræostyle Temples, the height of the columns should be equal to 8 diameters; in the diastyle and eustyle, it should be 8½ diameters; in the systyle, it should be 9½ diameters; and in the pycnostyle, it should be 10 diameters; and these proportions are given without any regard to the particular Order employed. He thus makes the proportion of the diameter to the height of the column depend upon the intercolumniation, a circumstance which was, perhaps, not attended to by the Greeks. Again, the proportions are made to differ according to the character of the building; the columns which ornament a Theatre being more slender than those of the same Order which surround a Temple.

Finally, the diminutions of the columns of the Roman Orders, like those of the Grecian, are subject to great irregularities if we compare the individual examples; thus a column 34 feet high has the same diminution as one 47 feet high; a column 24 feet high has the same as another of 34 feet; and a column which is 47 feet high has less diminution than one which is 65 feet high, contrary to the general rule which gives to the taller column less diminution than to the shorter one. But on taking the mean diminutions of columns belonging to the different Orders, we find that the Doric columns are more diminished than the Ionic, and these more than the Corinthian; from which circumstance we are disposed to conclude that the degree of diminution was made to depend, not upon the absolute height of the shaft, but upon the proportion that the diameter of the column bore to its height; and that this rule was subject to great modifications, with the causes of which we are not well acquainted.

Depe
of the
ral pr
sions
interco
lumni

It seems as if Vitruvius intended the general proportion between the diameter and height of a column to be employed only when the intercolumniation, or distance between the nearest parts of the surfaces of two columns, is of the kind called pycnostyle; for, in the IId Chapter of the IIId Book, he proposes, when the intercolumniation is increased, to augment the thickness of the columns, so much as from $\frac{1}{10}$ to $\frac{1}{8}$ of the diameter of the column, in passing from the pycnostyle to the aræostyle. Now, we are probably to understand that the intercolumniation is to be regulated by the augmented diameter, and not by the original diameter of the column; for, in the former case only, will the ratio between the diameter and the interval be that which is prescribed by the rule of the intended intercolumniation. This may be easily perceived; for in the aræostyle intercolumniation, the ratio of the diameter to the interval may be as 1 to 4; and by augmenting the diameter, retaining the same distance between the centres of the columns, the ratio will become as 1 to 3.5 nearly, which would reduce the intercolumniation to the diastyle kind nearly, and render the rule of the aræostyle intercolumniation useless. This could not have been the intention of Vitruvius, and it is probable, therefore, that he meant to increase the diameter of the column, in order to give it such additional strength that the intercolumniation might be made equal to four diameters without danger. Sir William Chambers objects to this rule of Vitruvius that it does not answer the intention, since the diameter and intercolumniation are both increased in the same proportion; the objection, however, only applies to the apparent strength, for the intercolumniations are proportional to the diameters of the columns simply, while the real strength of the columns in supporting incumbent weights, are proportional to the squares of their diameters, which is a higher ratio than the former, as that author admits. (See Gwilt's edition of Sir W. Chambers's *Architecture*, vol. ii. p. 268.) A more serious defect would arise from the increase of the intercolumniations, *viz.* that the architrave over the interval would become weaker, and, in order to remedy this evil, it would be necessary to give proportional thickness to that part of the entablature.

It is probable, as Sir W. Chambers supposes, that Vitruvius intended the five intercolumniations mentioned in his IIId Book, to be applied only to the Ionic and Corinthian Orders, which, according to him, differ only in their capitals; for, in the IIId and VIIth Chapters of the IVth Book, he establishes other intervals for the Tuscan and Doric Orders, regulating the latter by the triglyphs, of which there were generally two over each intercolumniation; the monotriglyph and aræostyle interval being only used in cases of necessity.

A regard to the first principles of Architecture would lead us to suppose that, in the same story of a building all the columns should be of equal height; but the inequality of the ground, or the different levels of the parts of the roof have prevented the Ancients from adhering always to this rule. Pedestals were resorted to in order to correct the former inequality, and bring the bases of all the columns on the same floor to the same horizontal plane, but no remedy could be found for the other, and the columns were made of different heights.

In the Propyleum at Athens, the columns of the exterior portico are lower than those in the vestibule; the former are of the Doric, and the latter of the Ionic Order. In the ruins of Balbec there is a contrary example, for the columns in the front of the portico are higher than those within; and a remarkable case, in which the entablature of a line of columns has been made to rest, at one extremity, on a corbel attached to the shaft of a higher column, has been mentioned in speaking of the ruins in the Decapolis.

CHAPTER VII.

General Description of the other Ornamental Parts of Roman Edifices.

The employment of pilasters in the buildings of the Romans was very general, and specimens of them may be seen in the Pantheon, the Temple of Mars the Avenger, the Baths of Dioclesian, and other works; sometimes they were attached to the faces of walls, and projected but a little way from them, as in the interior face of the first-mentioned building; but at other times they formed a sort of square column, having the same kind of bases and capitals, and having the diminutions of their shafts and all their other proportions nearly identical with those of the round columns which belong to the same Order, as in the porticos of the Pantheon and of Mars the Avenger.

In these buildings the pilasters are of the Corinthian Order; of the Ionic Order, the Baths of Dioclesian afford one example. The height of this pilaster is equal to 8.5 times its breadth; the shaft is made without diminution contrary to the general practice, and each face is furrowed by five channels with vertical fillets between them; between the volutes of the capital the plan of the ovolo forms an arc of a circle, and this member is sculptured with oves and darts as usual; the base and capital are each equal in height to about half a diameter, and the former is of the Attic kind. The height of the whole entablature is equal to 1.8 times the breadth of the pilaster, or to $\frac{1}{4.72}$ of its height. The architrave is divided into three faciæ, the frize is swelled in a cylindrical form, and there are dentels in the cornice. The Greek antæ differed from the Roman pilasters in being always placed at the extremities of walls, from which they projected but little, in having no diminution of shaft, and mouldings quite different from those of the columns with which they were connected in the same building.

Pedestals.

In the ancient Grecian Architecture, pedestals were not employed as supports of columns, but in Roman Architecture they enter as an important feature and were often highly embellished. The principal part of a pedestal is a dado or die, in the form of a rectangular parallelopiped, and either plain or ornamented with sculpture; this is crowned by a cornice consisting of an alternation of plain faciæ and curvilinear mouldings, generally cymatia; and under it is a base composed, in most cases, of a torus moulding with an inverted cymatium above; the whole rests upon a plain plinth. The mouldings both of the base and cornice are more numerous in proportion to the richness of the Order, though this rule is not universal; in the Arch of Severus, for example, the dados of the pedestals are plain and the mouldings are few, though the columns are of the Composite Order.

The dimensions of the Roman pedestals are various, but, by taking a mean of those employed in the Triumphal Arches, we find the height of the dado to be equal to 2.41 diameters of the column, and its breadth, 1.41 diameter, or nearly the same as the length of each side of the plinth of the column. The height of the cornice is 0.45 diameter, and its projection from the face of the dado, 0.35 diameter. The height of the base, not including the plinth, is 0.5 diameter, and its projection 0.41 diameter; and when the plinth rests immediately on the ground, its height is equal to about half a diameter; so that the whole height of the pedestal, in the Roman examples, may be considered equal to 3.86 diameters, or to more than one-third of the height of the column.

A stylobata is a sort of general pedestal serving for the support of a whole range of columns, and its profile is the same as that of a single pedestal; under each column in the range the stylobata is generally broken so that its face projects a little forward, and this gives to the whole the appearance of a number of pedestals connected together by low walls.

Equal attention seems to have been paid by the Ancients to the apparent form of a stylobata and of the shafts of columns; for Vitruvius directs (book iii. ch. iii.) that the upper surface of the former should be raised higher in the middle than at the extremities, in order to correct the optical deception which causes a long line, when perfectly horizontal, to appear lowest in the middle, as it causes the sides of a conical shaft to assume a concave figure. Small pedestals were sometimes placed over the walls, one at each angle of a building, with their upper surfaces above the sloping sides of the roof; and a similar one on the apex of the pediment; these, which were called *acroteria*, were probably intended for the support of statues; they were ornamented with a moulding above, and Vitruvius prescribes that the tops of those at the angles should be in a horizontal plane passing through the middle of the tympanum, and that the height of the acroterion at the vertex should exceed that of the others by about one-eighth.

Arches. The arches built by the Romans, both for their bridges and to serve as apertures in buildings erected on land, were almost invariably semicircular, and were formed either of plain voussoirs, as in the Theatre of Marcellus; or, as in the arcades of the Colosseum, the exterior front of the arch was divided into faciæ, and ornamented with mouldings resembling those on the horizontal architrave of a building, and hence called an archivolt. The arches which cover the apertures in Roman works are, in almost every case, made to rise from the upper surface of a sort of cornice, or impost, in the wall on each side; but, in the decline of Art, we find that some ill-founded perception of beauty, or some vain attempt to excite admiration by an appearance of boldness, led to the practice of making them spring from the capitals of columns, or from the extremities of the horizontal entablature placed over a colonnade, the entablature being interrupted under the arch. Such caprices exist in the Architecture of the Roman Baths and in the Palace of Dioclesian; from whence they were copied in the edifices of Europe in later times, and became the origin of a style unknown to the ancient artists of Greece and Rome.

In the later Ages of the Empire, when small and slender columns were employed for the support of arches, a practice arose of increasing the projection of the capitals in order to afford room for the foot of the archivolt on each side: and the intrados of the latter coming over the lateral extremity of the capital caused the breadth of the aperture to be less than the intercolumniation; and this is one of the distinguishing features of the arcades in the Ecclesiastical edifices of the time of Constantine, and in the buildings derived from them.

In the Theatres and Amphitheatres of the Romans, and in their Triumphal Monuments, the arches are important features; and by taking a mean of the dimensions in several examples, we find that the proportion between the height and breadth of an aperture covered in this manner is nearly as two to one; consequently the height of the top of the impost from the foot of the aperture is equal to three-fourths of the height of the whole aperture. The intrados and extrados of the voussoirs of an arch were originally made concentric with each other, but it has been observed that after the time of Vespasian, the voussoir at the foot of the arch was frequently made the longest, and the others diminished in length gradually to that at the vertex. Where great weight was to be supported several courses of voussoirs were placed one above another, and their joints, in all the courses, united in lines tending to the centre of the arch.

Impost. An impost, we have said, is a sort of cornice forming the ornament of the tops of piers which are connected by arches, and resembling, generally, the crowning member of a pedestal. At a small distance below the mouldings of the impost is an astragal and fillet, the interval between which and the lowest part of the mouldings is frequently plain, but sometimes it is ornamented with sculpture, and constitutes a sort of hypotrachelion; these mouldings give to the whole pier the appearance of a broad pilaster of which the impost is the capital.

The impost of the great Arch of Constantine has a corona with modillons and dentels, like the regular cornice of a building; and that of the great Arch of Severus is ornamented with dentels, but has no modillons. By a mean of the dimensions, in several examples, it appears that the height of all the mouldings of the impost, including the hypotrachelion, is $\frac{1}{11}$ of the span of the arch, or $\frac{1}{16}$ of the height of the pier, and the projection of its upper moulding is $\frac{1}{13}$ of the same span. When the piers of an arcade are ornamented with attached columns, the projection of the imposts from the face of the wall is not permitted to exceed that of the centres of the columns, lest the mouldings should interfere too much with the vertical lines produced by the surfaces of the columns.

Archivol The ornaments of archivolts appear to have been derived from those of the architrave in a horizontal entablature, the fronts of the arch stones being broken into two or more concentric faciæ, and terminated at the extrados by a cymatium and fillet; and as the faciæ of an architrave in general incline forward, so also in the archivolts, the upper extremities of the faciæ project further from the face of the wall than the lower. In the Doric and Ionic Orders of the Colosseum, the divisions which separate the faciæ are plain chamfers; but in most of the Triumphal Arches those divisions are formed in mouldings, generally astragals, either cut in beads or ornamented with foliage; the cymatium above the exterior faciæ is also sculptured in a similar way. The intrados of the arch spring from a point vertically over the side of the pier; and by a mean of several examples we find the breadth of the archivolt is equal to $\frac{1}{13}$ of the span of the arch.

Pedimen In the generality of the Roman buildings we find that the height of the apex of the pediment above the top of the horizontal cornice, is one-fifth of the whole length of that cornice in the front of the building; which makes the angle of inclination of the rafters to the horizon equal to 21° 49′; in the Grecian buildings, the angle of inclination was found to be about 12° 40′. The surface of the tympanum is in a vertical plane coinciding with the face of the architrave. The corona of the inclining sides of the pediment is like that over the columns, and it is surmounted by a cymatium the height of which is nearly the same as that of the corona. This cymatium does not occur over the horizontal cornice of the pediment, but is generally continued, in Roman buildings, over the entablature of the flanks; and on this account we have, in describing the Roman Orders, included the height of the cymatium in that of the cornice: the case was different with the Grecian Orders, for in them, generally, a horizontal cymatium over the cornice of the flank of a building either had not been formed, or had been subsequently destroyed, so that its dimensions could not often be ascertained.

Dome The circular and polygonal buildings of the Greeks have been shown to be covered by roofs of solid stone; but the Roman domes are formed of bricks, or pumice stones of small dimensions; and the Pantheon is the earliest edifice of the kind of which we have any knowledge, though it is not likely that a work of such magnitude should have been the first of the kind. In building it, the lateral pressure round the base, which arises from the weight, must have been appreciated, since we find it is resisted by making the lower courses of voussoirs thicker than the others, and by disposing several horizontal courses of materials round the exterior of the foot of the dome; the mechanical conditions of its stability, also, must have been known and distinguished from those of the stability of a cylindrical vault; since an aperture is left at the vertex which, if attempted in a vault of the latter description, would have rendered it incapable of supporting itself for a moment.

The domes which serve as coverings to Roman Temples or Tombs may be considered as forming, universally, segments of spheres; yet one example remains in which a vertical section of the dome presents the appearance of two arcs of circles meeting in a point over the centre; this is the brick Temple, said to be of Proserpine, on the Lake Avernus. Its plan is octagonal on the exterior, but within, circular, and the beds of the courses forming the dome are horizontal: the figure of the latter certainly differs but little from a hemisphere, and it might be supposed that some partial sinking of the materials had given it the pointed form; but we learn that no such failure is visible, and that the work is undoubtedly of Roman execution.

es.

Niches or recesses were, generally, formed in the interior of Roman buildings, particularly of Temples and Baths; those of smaller dimensions serving to contain statues, and the greater intended as oratories, or exedræ, in which persons might retire for conversation apart from the rest of the company. In almost every case they were half-cylinders, terminated above by vaults in the form of quadrants of spheres; though, occasionally, they were rectangular on the plan, and then their covering was hemicylindrical. The decorations of recesses, when the latter were small, resembled those about doors or windows; and, when large, the principal ornaments of the interior of the building were continued or repeated within them.

led ns.

In the ruins of Palmyra have been found examples of columns coupled together, with two sides of their plinths nearly in contact, and the intervals of the pairs of columns equal to between three and four diameters. Hence it has been concluded that this practice was not unknown to the Ancients, though nothing of the kind has been found in any Grecian building; and no other ancient example of coupled columns exists, except in the Temple, called of Bacchus, at Rome; and in this building, which, as has been described, is circular, the columns are coupled in the direction of the radii. In such a situation as this, the coupled columns are not destitute of utility, because they serve for the support of a roof, and have a lighter appearance than single columns of an adequate bulk. But when columns support an entablature on the exterior of a building, the reason of coupling them must have been to gain large intervals opposite to doorways and windows; and it may have been supposed that, by so doing, equal strength might be obtained with greater extent of intercolumniation between the pairs, than single columns would afford. This, however, does not appear to be just; for, though the number of points of support may be equal whether the columns be single or double, yet, bringing some of the columns nearer together in order to increase the intervals of others, will cause the entablature over the greater intervals to be weakened in proportion to that increase.

In the Temple at Palmyra, and in a peribolus at Djerash, two columns are joined together by their shafts; these are, perhaps, the only ancient examples now in existence of that practice. But they are sufficient to show that the clustered columns, which afterwards became such an important feature in buildings, were not unknown to the Romans; and may have been often executed by them, though the edifices thus ornamented may have been destroyed.

Orders superimposed on each other.

The great examples which the colonnades of the Roman Temples and Fora would have exhibited, of Orders superimposed on each other, are so completely ruined, that we are compelled to draw the few notions we can obtain respecting the rules of their construction from the writings of Vitruvius, and from the columns on the exterior of the Theatre of Marcellus and of the Amphitheatre of Vespasian.

According to Vitruvius, (chap. i. book v.) the following rules should be observed. The lower Order of columns should be higher than the Order next above by one-fourth; and the height of the second Order, if there are more than two, should exceed that of the third in the same ratio; by which the height of the third Order will only be equal to $\frac{9}{16}$ of the lowest; the height of the podium, or continued pedestal, which, in each Order, supports the columns, should also diminish upward in the same proportion. But there would be this inconvenience attending an adherence to these rules, *viz.* that the smallness of the diameters of the upper columns, caused by the diminished length of shaft, will render the intercolumniations of the upper Orders too great; for if the intercolumniation of the lowest Order is equal to three diameters, that of the second Order will be $4\frac{1}{4}$ diameters, and that of the third will be $6\frac{1}{9}$ diameters, contrary to the precepts of Vitruvius himself with respect to the intercolumniations.

Such an inconvenience could not have escaped the notice of an Architect who had actually designed an edifice in which two or more Orders were placed one on another; and accordingly, in the Theatre of Marcellus, and in the Colosseum, we find that the columns in the upper Orders have nearly the same height and diameter as those of the lower Order; and, consequently, the intercolumniations in all the Orders remain nearly the same.

In these buildings we remark, that the strongest Order is placed below, and the others increase in delicacy upward; a method of construction which is perfectly justified by the consideration that the strength of bodies should be proportional to the weight they have to support; and that those which have the least weight to support should be the most ornamented, provided their height above the eye is not so great as to prevent the ornaments from being seen.

The first principles of stability teach us that the axes of the upper and lower Orders of columns should be vertically coincident; yet this rule was violated in the interior of the Pantheon, where the pilasters of the upper Order stood over the intervals of those below; and in the portico of the Temple of the Sun, at Palmyra, where two columns stand over the aperture of a doorway. Many similar improprieties in the practice of the Ancients are mentioned by Serlio.

Greek sculpture superior to the Roman.

The Greeks and Romans had a great propensity to embellish their Architectural works with sculpture and painting; and the edifices of the Romans are particularly distinguished by an unsparing application of the chisel: every part susceptible of ornament being often entirely covered with representations of foliage, animals, or historical subjects. But the embellishments of the Grecian, though less profusely bestowed than those of the Roman buildings, almost invariably exhibit a superiority of taste in the design, and of skill in the execution; and it is in the sculpture of the later works of the Romans that the decline of Art is particularly observable.

Sculptured ornaments on Roman columns,

In the Roman examples, the shafts of the columns, though sometimes plain, are in general fluted, and some are even covered with sculptured foliage; in the first case they are usually formed of a different material from the bases and capitals, in order to produce a variety which may compensate for the want of other ornament. The shafts of the columns of Trajan and of Antonine are covered with figures in the directions of spiral lines round them, from bottom to top. Besides the constant ornaments of the capitals of columns, we also, occasionally, find the mouldings of the bases, and even the faces of the plinths, ornamented with guilloches, or with foliage, in single leaves, in bundles, in scrolls, or in festoons. In the Temple of Augustus, at Mylassa, the bases of the columns are ornamented above the plinths with foliage, which gives to the shaft the appearance of standing on the root of the plant, like the columns in some of the Egyptian buildings. Similar, but richer foliage, is cut above the mouldings of the bases of columns in the Baths at Nismes, and in the Baptisterium of Constantine.

on the frize,

The frizes of the Roman entablatures are distinguished by some of the best specimens of ornamental sculpture. In the Temples of Vesta, at Tivoli, and of Jupiter Tonans, at Rome, this member is adorned with ox-heads, having in the intervals festoons of flowers, or axes and vases, which are evidently intended to represent the accompaniments of a sacrifice; and in the Triumphal Arch of Titus, the same are expressed in a more elaborate manner by the entire figures of the animal, and of the persons concerned in that rite. In the Temple of Antoninus and Faustina, at Rome, and of Æsculapius, at Spalatro, are representations of griffins and vases; in the entablature of Nero are large scrolls of the richest foliage, the execution of which is equal to that of the Grecian sculpture in its best time; and at Palmyra and Balbec, the frizes are ornamented with Eagles, Cupids, and other figures, having festoons of flowers between them. It must be added that sometimes the frize is filled with inscriptions, and, in a few cases, these are contained in a tablet which occupies the height of both frize and architrave.

on the soffits of entablatures,

In the soffit of the architrave between every two columns is generally a rectangular sunk panel, either plain, or having the interior occupied by fretwork, and sometimes surrounded by a guilloche, as in the Temple of Antoninus and Faustina. In the ceiling, between the entablature of a peristyle and that of the wall of a building, are usually square panels formed in two or more depths, so that the sides have the appearance of inverted steps; these sides are usually sculptured with oves, and the panel itself is ornamented with an elegant cluster of foliage in the form of a rose. Sometimes between every two such panels is a plain square, surrounded by a rich fret in relief, as in the Temple of Mars the Avenger. In circular buildings two of the sides of each panel are in the direction of radii from the axis of the building, the other two are arcs of circles concentric with the face of the entablature, of which the Temple of Vesta, at Tivoli, affords an example. The inferior surface of the corona, in the intervals of the modillons, is commonly ornamented with square panels of small depth having a rose in the centre of each; at other times, though rarely, the soffit is plain. The inferior surface of a modillon is, generally, ornamented with a leaf resembling one of those in the Corinthian capital.

on the ceilings d buildings.

But the sculptured ornaments on the ceilings of buildings present the finest examples of elaborate workmanship. The general manner of ornamenting these parts of an edifice was by a system of panelling in circular, polygonal, or rhomboidal forms, though, occasionally, the ornaments were executed in relief. From fragments of the vaulting which once roofed the Temple of Venus at Rome, it appears that its surface was covered with square and rhomboidal panels, deeply sunk, with ornamented sides, and with a rose in the centre; in the intervals between the panels are bands of guilloches, crossing each other at right angles, and having roses at their intersections. The interior of the dome of the Pantheon is occupied by square, sunk panels in horizontal courses; and, in a similar way, the soffits of the niches and the ceilings of triumphal arches are ornamented. The ceilings of the Temples at Balbec and Palmyra are profusely decorated with panels of circular and polygonal forms, the interiors of which are filled with figures, and the margins are enriched with fretwork or elegant foliage.

Paintings the ceili and wali

The paintings on the ceilings of the Roman Baths are in general remarkable for elegance of design, and are disposed in square compartments about the centre, or along the margins of the apartments; they consist of representations of divinities and human beings; of birds, beasts, griffins, and centaurs; of medallions, and an endless variety of foliage in festoons. The sides of rooms were ornamented with perspective representations of slender shafts, like rods, supporting light entablatures, or canopies with circular or triangular pediments above: among these are representations of statues, tripods, and vases, with drapery and foliage in festoons, and in some places are views of gardens. The Baths of Titus and those at Herculaneum afford great abundance of these paintings.

CHAPTER VIII.

Practice of Roman Building.

Manne describi the Ro mouldi

The mouldings used in the Roman Architecture are mostly of the same denominations as those in the Grecian, but the profiles and elevations of the first are formed by arcs of circles, whereas the latter are portions of conic sections. See pl. ii.

The torus and astragal are both semicircles, the diameters of which are equal to the height of the moulding, and they only differ from each other in their magnitude.

The ovolo is a quadrant of a circle, the convex surface of which is outward; its semidiameter is equal to the height of the moulding, and its centre is in a horizontal plane passing through the upper extremity. This moulding generally occupies the place of the echinus in the Grecian Architecture.

The cavetto is described in the same way, being also a quadrant of a circle, but its concave surface is outward, and its centre is in a horizontal plane passing through the lower extremity.

The apophygis, if it is a quadrant of a circle, is also described in the same manner as the former mouldings, but it, generally, does not exceed an arc of 60 degrees; in which case the centre is at the vertex of an equilateral triangle formed on a line joining the two given points through which the curve is to pass; it is necessary, however, that the centre should be in a horizontal plane passing through the column in the place where the apophygis joins the shaft, otherwise the profile of the column will appear broken at that place.

The cima recta may be described by dividing the line joining the extremities of the fillets above and below in two equal parts by a line parallel to the fillets, and describing a quadrant of a circle on each half, on contrary sides of the first line; the centres for describing the quadrants will be in the second line; and this construction supposes that the projection of one fillet beyond the other is equal to the height of the curvilinear moulding.

The scotia is sometimes described by joining the extremities, *a b*, of the fillets above and below; (see pl. x. fig. 9.) and upon *a b*, as a diameter, describing a semicircle, in which case the upper surface of the lower fillet is rendered a little concave; but usually the scotia consists of portions of two circles, which may be described in the following manner. Draw the indefinite lines *b m* and *a n* parallel to the axis of the column; upon *a b* describe a semicircle as before, and draw *b c*, making the angle $m\,b\,c = 60$ degrees, to cut the semicircle in *c*; lastly, draw *c d*, making the angle $b\,c\,d = 60$ degrees, and meeting *a n*, *m b*, in *e* and *d*; *d* will be the centre of the arc *b c*, and *e* the centre of the arc *a c*; and these arcs form the scotia required. The curves will not appear broken at *c*, because a line at *c*, perpendicular to *d c*, will be a tangent to both.

The Ionic volute is an ornament which is required to be drawn with considerable exactness; and methods have been given for describing it, by Vignola, Sir William Chambers, and Goldman, on the supposition that the spirals are formed by the union of several circular arcs. The rules delivered by Goldman seem to afford the most elegant form, and therefore we may confine ourselves to them. See pl. x. figs. 7 and 8.

He supposes the whole height A B of the volute to be divided in C, in the ratio of 9 to 7, then the point C becomes the centre of the volute; about this point a circle, *a b*, is described with a radius equal to $\frac{1}{18}$ of A B, and this forms the eye of the volute. On the diameter *a b*, he takes from the centre C, the distances C *m*, C *n*, each equal to one-fourth of *a b*, and divides each of these into three equal parts in the points *o*, *p*, *q*, *r*; on *m n*, *o r*, and *p q*, he forms squares, and produces their sides indefinitely, as in figure 7; then *m*, *s*, *t*, *n*, *o*, *v*, &c. become the centres for describing the several quadrants of the volute.

Having determined the breadth A D of the baltheus or listel at the top of the volute, he makes A *z* equal to half the side of the square *s n*, and joins *z* C; through D, he draws D *d* parallel to A *z*, and divides it into three equal parts; he then makes C m', C o', C p', respectively equal to D *d*, D *e*, D *f*, and sets equal spaces below C, and forms squares on $m'\,n'$, $o'\,r'$, $p'\,q'$; the angular points of these squares become the centres for describing the interior quadrants of the volute.

When the volutes are formed obliquely to the face of the abacus, as are those of the Temple of Concord, of the angular columns in the Temple of Fortuna Virilis, and those in the capitals of the Composite Order, the spirals, when represented on paper, become portions of ellipses; the vertical axes of the ellipses, that is, those which coincide in direction with A B remain of the same length as when the planes of the volutes are parallel to the face of the abacus, but the horizontal axes are all diminished in the ratio of radius to the cosine of the angle of obliquity; the several horizontal axes being thus determined, the spirals may be traced by the usual rules for describing ellipses.

The ornaments in the Corinthian and Composite capitals must be traced by hand; and it will be only necessary to observe that the leaves of the former resemble those of the laurel, or of the olive; those of the latter, of the acanthus, or of parsley.

Optical modification of a profile.

Vitruvius observes, that the magnitudes of objects should be changed according to their situation with respect to the eye; and it can be conceived that this must be true, when some of the projecting members might conceal others which, from their essential character, or their embellishments, ought to be visible. In such a case we immediately conclude that the projection should be lessened, or the parts above and below should be increased in height beyond the quantities assigned by the general rules; and that the faces which are usually vertical should be made with their upper extremities inclining forward or backward, in order to cause them to be seen to advantage. For the same reason the superior surfaces of mouldings which have considerable projection, instead of being horizontal, should be in planes inclining upward towards the face of the building, or in the form of a curve concave outwards; as is often the case with the fillet between the architrave and frize. Such deviations from the general rules are observed in the great works of the Romans; but it is necessary to understand, as has been observed by Newton, the translator of Vitruvius, that they should only take place when the object is viewed from a situation to which the spectator is unaccustomed; for, in most ordinary situations, however the eye may be elevated above or depressed below the object, the mind has the power of rectifying the perceptions produced by the images actually transmitted to the eye; and the objects appear, not as we see them, but as we have found them to be by previous experience.

Rules for the foundations.

In the Vth chapter of his Ist Book, Vitruvius, describing the building of walls, says, the ground is to be dug down to, and even into the solid earth; the foundation walls to be thicker than those which are built above ground, and executed in the firmest manner. And in chap. iii. book iii. he says, the stereobata, or the walls above ground, on which the columns stand, are to be thicker by half than the diameters of the columns themselves. He adds, if the ground is soft and marshy, it must be excavated, and piles of scorched wood driven in very close together, and the intervals filled with charcoal. No rule, however, is given by Vitruvius for the depth of the foundations below the ground, but the general practice of the Ancients seems to have been to make it equal to one-sixth of the whole edifice. He recommends to sink the wells, cisterns, and drains, previously to laying the foundations, as well to ascertain the nature of the ground, as to supply the wants of the inhabitants.

Dimensions of walls.

Besides the general rule that the thickness of a wall should be proportional to the magnitude of the edifice, Vitruvius directs, in the XIth chapter of his VIth Book, that buttresses should be erected in front of the foundation-walls, in order to resist, as he says, the expansion of the included earth when swollen by rain; and he directs that the distance between every two should be equal to the depth of the substructure below the general level of the ground. Their thickness he recommends to be the same as that of the foundation-wall; their upper extremities, probably, coincided with the surface of the wall at the level of the ground, and their lower extremities projected from the surface of the wall as much as the thickness of the wall itself. He also proposes that walls should be built as high as the level of the ground within the interior space, and disposed in triangular forms on the plan, one side of each wall coinciding with the interior face of the building itself, the better to enable the side of the building to resist the outward pressure of the included earth.

Methods of building walls.

The ancient Etruscan or Latin walls were constructed of large, square masses of stone without cement; but during the existence of the Republic, this method of building seems to have given way to the formation of what was called the *incertum opus*, which consisted of small stones mixed with mortar; and specimens of it are still to be seen in the Temples of Vesta, at Tivoli, of Fortune, at Præneste, and in many other edifices; but Mr. Ramage observes, that this species of work must not be confounded with that formed of large stones in the shape of irregular polygons, as may be seen in the walls at Cora, Præneste, and other ancient cities of Latium, which is of an older date. The Roman *emplecton* was employed, probably, during the same period; it was similar to that of the same name, which was in use among the Greeks; but seems to have been executed less carefully, the rubble stones being thrown promiscuously with mortar between the faces of the wall; and Vitruvius justly gives the preference to the method of the Greeks. To these succeeded the *reticulatum opus*, which must have been fashionable in the time of Vitruvius; it was composed of stones or bricks made in the form of rectangular prisms, and disposed with their diagonals in vertical and horizontal positions, so that the face of the wall had the appearance of network. When this was used, bricks or rectangular stones in horizontal courses were employed at the quoins, or angles of the walls, in order to give it stability. Vitruvius seems to consider this as beautiful; but certainly from the oblique pressures which the bricks must have exerted against each other, in consequence of the weight of the mass above them, it must have been very liable to give way, and perhaps it could hardly have stood a moment, but for the cohesive power of the mortar. This species of wall is said by Mr Ramage to have continued in fashion till the time of Caracalla, and examples of it are to be seen in the Garden of Sallust, near the Quirinal Hill, and in the Palace of Mecænas, where it is mixed promiscuously with brickwork.

In great works, like the towers and walls of towns, we find that the general method of construction was to dispose the rubble stones as regularly as the nature of the material would admit, in horizontal courses; and at distances of three or four feet above each other were placed horizontal courses of broad flat stones to bind the whole together. Remains of this kind of masonry are very abundant in England, and examples of it may be seen in the walls of Richborough castle, in Kent, and of Silchester, in Berkshire; in these places the rubble is disposed in alternate courses of rough rag-stone, large flat bricks, and layers of solid mortar; the whole has been mixed with liquid mortar, which united the materials in a hard and strongly coherent mass.

To connect the parts of a wall together, or perhaps to lighten the pressure on particular parts of the foundation, it seems to have been customary to form, in the thickness of the walls, one or more rows of arches, like those in the walls of the Pantheon, consisting of two or more concentric courses of voussoirs; and within the intrados of the arch are horizontal courses of masonry, as in the rest of the wall.

Kinds of stone employed in Roman buildings.

Mr. Ramage observes, that the stone employed in the buildings of ancient Rome is of five different kinds. The first, called by Vitruvius *Lapis ruber*, and by the Moderns *Tuffa*, is a volcanic production, and is employed in the foundations and walls of buildings; the Temple of Fortuna Virilis and the Aqueduct of Claudian are built of this stone; which, in the latter building, is cut in large masses, that it may better resist the action of the air, by which it is liable to be decomposed. The second, called *Lapis Albanus*, or *Peperino*, is also volcanic; the more ancient Italian buildings, as the *Cloaca Maxima*, and part of the Tullian walls under the Quirinal Hill, are built of this stone, which is more solid and less subject to decomposition by the air than Tuffa; it is also capable of resisting the action of fire. The third, called *Lapis Tiburtinus*, or *Travertino*, is a calcareous concretion which was brought from the neighbourhood of Tibur: it has the quality of hardening by exposure to the air, but is decomposed by fire; when employed in building it is cut in large quadrangular masses, which are put together without cement. The Temples at Pæstum, the Colosseum, and the Sepulchre of Cecilia Metella, are built of this stone. *Silex* was frequently employed in paving streets, and filling up the interior of walls; and Pumice-stone, obtained from Asia, Spain, and Marseilles, so light as to float in water, was, on that account, used in the formation of vaults: those of the Colosseum, and the dome of the Pantheon, are partly constructed of this last material. The Silex was a basaltic, and the Pumice-stone a vesicular lava, but neither of them are of the same species as the stones which now go by those names.

Brickw

Brickwork continued in use till the fall of the Empire, and, at first, it was nearly equal in strength to stonework; but, in the later times, it had not its former solidity, on account of the greater quantity of mortar employed. Vitruvius says, that the Greeks used square bricks equal to 5 palms, or 15 inches in length and breadth, in their public works, and others equal to 4 palms, or 12 inches in length and breadth, for their private dwellings; they also used half-bricks, and placed them with the whole bricks in alternate courses. The Roman bricks, or tiles, were of finer quality than those made at present, and were either square or parallelogramic; the former were sometimes 18 inches long and broad, and the latter 12 inches long and 6 inches broad; and in the times of Augustus and Tiberius, the bricks were occasionally made of a triangular form, as may be seen in part of the remaining walls of Rome. Vitruvius does not specify any thickness for bricks, but it was in general small, in some cases not greater than one inch. It may be added that this author describes only unburned bricks, and he recommends that they should not be employed till after they had been made at least two years.

It seems to have been the opinion of the ancient Romans that an edifice of brick was more durable than one of stone; for Milizia says, they estimated the value of a stone-building every year less than in the preceding year, by one-eightieth part of the whole, supposing that it would last only eighty years, whereas they estimated the value of a brick-building always at the same sum, as if it were indestructible. It is probable that the stone here supposed to have been employed was of a very inferior character.

The Romans used a species of mortar now called *Pozzolana*, from Pozzuoli, anciently Puteoli, the name of the place wherein it was first made; it had the valuable quality of hardening in water, so as to form with the stones or bricks a solid mass uniformly consistent. The harbour at Antium and the mole at Pozzuoli, the latter of which was probably erected near the Augustan Age, afford the best proofs of the durability of this material.

It seems unnecessary to dwell longer upon the detail of the practice of the Ancients in the mechanical construction of their edifices; because, though it was in general good, and it even forms the basis of the practice of Architects in the present day; yet the progress of improvement and the circumstances of climate and of manners, have necessarily brought on such changes as render an adherence to their rules impossible.

tec-

The Grecian artists produced simplicity and unity in their most magnificent designs by forming a system of unbroken horizontal lines in the lower and upper parts of the buildings; these occur in the steps and in the divisions of the entablature, and give to those members the appearance of bands uniting the extremities of the columns in one entire system, while they indicate at a glance the whole length and breadth of the building. The sides of the columns present also a system of lines, nearly vertical, which serve to mark its height. The system is completed by adding a low pediment which forms a cover to the whole just sufficiently raised in the middle to throw off the gentle showers of rain which fall in a climate in which the atmosphere is seldom troubled by violent storms, without interrupting the general effect of the vertical and horizontal lines of the building.

Abundant in well-executed sculpture as are the members of the Grecian buildings, the variety of form produced by the chisel is not suffered to interfere with the outline, being sunk within the general face of the building. The mouldings only of the capitals and entablatures break the rectilinear character of the edifice, and diversify a style otherwise too monotonous, by the graceful curves which they exhibit in profile. Large masses of shadow, projected by the peristyle and its entablature, fall upon the walls of the building, and powerfully contrast with the light reflected from the curved surfaces of the columns themselves which surround the building, and produce a long succession of alternate lights and shades which change every moment with the position of the Sun and the eye of the observer.

Rome, in the zenith of her prosperity, copied, with some modifications, the Architecture of Greece; but though her works might sometimes surpass their originals in magnificence, they almost always remained inferior to them in purity of taste. Vitruvius, indeed, professes to have formed his rules from the buildings and writings of the best Grecian artists, yet he laboured under the disadvantage of not having seen the former; and perhaps the latter were the works of men who lived near his own times, when a considerable change had taken place in the style of the Architecture, even of Greece herself; and, lastly, from the loss of the drawings, which originally accompanied his manuscript, we remain in doubt of the precise meaning, and the effect of many of the rules he has delivered.

In the best times of the Roman Architecture, the Temples of Italy might be little inferior, in merit, to those of Greece; a similarity of form was adhered to, and perhaps the modification of the proportions of the columns and their entablatures was but of small moment; it might even happen that this was rather to the advantage of the Roman Architecture by rendering those members of the edifices lighter than the corresponding ones in the Greek examples. The almost general adoption of the Corinthian Order in Italy was also the means of producing a degree of embellishment superior to that of the Doric Order which had formerly prevailed on the opposite shores; but a great difference took place in the exterior forms of buildings by the construction of brick-domes, high pediments, and the piling of one Order upon another. Of the domes it may be said that they afford a convincing proof of high mechanical skill; and that they constitute a feature which is capable of exciting sublime emotions, by the view of an immense mass of solid materials suspended in the air; and which, by the application made of it in later times, has given to buildings a degree of magnificence superior perhaps to that of any production of the ancient schools. We have shown how much the inclination of the sides of the pediment of the Pantheon exceeded those of the Grecian Temples; and though the Romans did not always give so great an inclination as we find in that example, yet such was the general case. These high-raised roofs are far from producing so pleasing an effect as the others, either because they interfere too much with the system of horizontal and vertical lines in the building, or because they afford indications of less skill in resisting the lateral pressure of the rafters, which in low roofs is very considerable; though in a climate more rude than that of Greece, the utility of the higher pediments is undoubted.

The supraposition of Orders is not without a reasonable excuse, if it have not, in some cases, the plea of necessity. In Theatres, and such buildings where great height was required for the exterior wall, it would have been impossible to make one Order of columns extend from bottom to top; and an obvious measure was to consider the building as divided into several stories, and to mark each story by a particular Order, the entablature of which might correspond with the floor in the interior. Single Orders are employed in the peristyles of the cavædia; but there the floor is supported by *parastatæ*, or posts attached to the shafts of the columns, a mode which can hardly be considered as exhibiting either skill or science: the great column is evidently unfit for its purpose, and two Orders in such situations would have been more natural than one thus broken.

We have had occasion to mention the magnificent works of Augustus, Vespasian, Trajan, and Hadrian; and we may also add, from Gibbon, that it was not only the Sovereigns of Rome by whom the Empire was adorned; this honour was shared with them by the Governors of Provinces, and even by private individuals. Among the works of the latter he enumerates those executed by the munificence of Herodes Atticus, a citizen of Athens, from which a notion may be formed of the encouragement given to Architecture by the wealthy subjects of the Empire. But when the extravagant follies of the Emperors had diverted the treasures of the State from their legitimate uses; *viz.* the defence and embellishment of their dominions; and when the insecurity of property prevented even individuals from displaying their taste in the erection of public or private edifices, then the cessation of the demand for the talents of the artists necessarily led to a neglect of the study of the principles which are the foundation of a pure taste in the Arts of design; so that when, at the command of a Prince more enlightened than many of his predecessors, a new edifice was to be constructed, nothing remained in the power of the artist, if he did not copy mechanically the whole of some building already in existence, but to introduce in his design the different members employed in some similar work. This seems to have been often done without regard to their connection with each other; and from ignorance of their just proportions, they have been altered and distorted according to the fancy of the artist; while the surface of the work has been covered with a profusion of ornament equally destitute of propriety and elegance.

The patronage of Dioclesian and Constantine, it has been observed, produced a gleam of taste which shone with faint lustre for a short time; but from the death of the latter may be dated the period of a complete corruption of the Art. Symptoms of decline are exhibited, principally, in the Triumphal Arches of Severus, Gallienus, and Constantine; in the edifices of Palmyra and Balbec; and in the Palace of Dioclesian at Spalatro. In all these we find the members overloaded with ornaments badly sculptured; in some we find columns have been taken from other edifices and cut to the required length, when too long, without making a corresponding diminution in the bulk of the shaft; or, when too short, they have been mounted on pedestals. The entablatures are often broken, and form projections over the capitals of the columns attached to the walls; thus destroying the unity of the horizontal band, and the fine effect arising from the long lines of shadow above the columns; while the pedestals interrupt and spoil the effect of the continuous basement; and the frize, instead of presenting a vertical face, is cut in a cylindrical form, and resembles a beam crushed by the weight of the cornice above. In some cases, columns with spiral flutings were capriciously employed, in direct contradiction to the first principles of stability, and exhibiting the appearance of ropes employed as props to sustain the roof of a building. Pediments are inscribed in each other; some have not the horizontal cornice; others are bounded by a curve at top; occasionally the tympanum is broken vertically into three different faces; and finally, there are some in which the inclining sides are not continued to the apex. All these circumstances are so many gross deviations from the classic styles of Greece and Rome; and like the gilded statues and colossal figures of the same period, are indications that, in Architecture and Sculpture, the minds of men were then disposed to run into the wildest excesses.

In the Arch of Hadrian, at Athens, the archivolt rises from the top of a short pilaster attached to the wall. But it is in the Palace at Spalatro that we find the earliest examples of arches springing from the tops of columns; a practice which afterwards became common in Ecclesiastical edifices, but which, applied as it is in this building, is a signal example of a corrupt taste; for whatever may be the real strength of a column, it does not appear adequate to the support of an arch and the building above it; nor is it in reality capable of resisting the thrust which every arch exerts in a lateral direction outward upon its points of support; piers alone, which may have any breadth required, appear adapted to these purposes. It may be observed that Sculpture declined before Architecture, and this is what might be expected; since though to design a building may require a greater effort of genius than to form a statue, yet it is obviously much easier to copy the proportions of an edifice than those of a human figure; and, in fact, some of the most magnificent edifices of Rome were erected in an Age when Sculpture had ceased to exist as a Fine Art. We may remark here that the corrupt style of the later Ages of Roman Architecture, and even the forms and proportions of that since denominated Gothic, are visible in many of the representations of buildings depicted on the walls of Herculaneum and Pompeii.

CHAPTER IX.

Ecclesiastical Edifices of the Western and Eastern Empires.

Probabiliy that Christian Churches existed before the time of Constantine.

Before Christianity became the established Religion of the Roman Empire, the Christians seem to have had regular Churches for the performance of divine worship; for Eusebius relates that in the beginning of the reign of Dioclesian, they both repaired the older edifices, and built new ones of considerable magnitude. The anger of Dioclesian, also, is said, by Lactantius, to have been excited by a new Church which had been built at Nicomedia; and the edict issued by Constantine for repairing as well as rebuilding the Churches is a proof that such must have existed before his time.

The heat Basilicæ used as Churches in the We

It is reasonable to believe that in the infancy of the Religion, and subsequently, in times of Persecution, those who had embraced its tenets, and had thus rendered themselves obnoxious to the Civil power, would hold their assemblies in private houses, and even, as they are said to have done, in the public catacombs, in order to elude the vigilance of their persecutors. But this secrecy was not likely to be continued, by a people zealous in the cause of their Master, longer than they were compelled to it by necessity; and as soon as their increasing numbers required more space, or the storm of persecution was abated, it might be expected that the Faithful would endeavour to obtain possession of public buildings for the purposes of Religion. That opinion, therefore, is probably not correct, which has been asserted; *viz.* that the Christians had no public Churches till the time of Constantine. But the intervals of the Persecutions being short, it would perhaps not often happen that buildings could be purposely erected to serve as Churches; and the people would be induced to avail themselves of a species of building already existing, and which could easily be adapted to their circumstances. This was the Basilica, or Court erected for the administration of justice, of which we have already spoken generally, in our *Miscellaneous Division, ad v.* We shall here more particularly describe their construction. Even after Constantine had delivered the Church from her enemies, and a public profession of Christianity could be made with safety, the Heathen Temples were rejected, and the Basilicæ were preferred, probably because they had not served for any superstitious purposes, and were more convenient for the celebration of Christian worship. Afterwards the Churches purposely erected, at least in the Western Empire, were designed in accordance with the plan of such buildings; and hence the first Churches were called Basilicæ, and that name has been since retained, though the forms of the more recent Churches often differ entirely from those of the buildings from which they are derived.

Convenience of the Basilicæ for Religious ervice.

The celebration of Heathen worship was accompanied by the slaughter of animals, which was most conveniently performed in the open air; where, or under the colonnade surrounding the Temple, the bulk of the worshippers remained; therefore there was no necessity for great capacity in the interior of the Temples. But the Christian worship consisted in public prayer, and catechetical exercises, accompanied by the delivery of lectures; and these, being best performed under cover, required Religious edifices large enough to contain a numerous congregation; such were the Basilicæ, being spacious buildings roofed over and abundantly lighted by windows.

General rm of the Basilicæ.

The great Basilicæ of the Heathens were of a rectangular form, and divided into three or more parts by rows of columns parallel to the length of the building; another colonnade, at each extremity, crossed the former at right angles, and in the middle of one of the end walls was a hemicylindrical recess in which was situated the tribune of the Judge; the colonnades of the aisles being discontinued when they arrived near the tribune, there was formed a transverse division at that end of the building; and, thus, the interior division assumed the figure of a cross. The recess, formerly occupied by the tribune, was found a convenient place for the altar; which continued to occupy that station till the desire of giving to the plan of the Church, on the exterior, the form of a cross, induced the artists to add to the original rectangle, of which the plan consisted, another crossing it at right angles at or near the middle of its length; then the altar was placed in the intersection of the two, which, from this time, became the most important place in the Church; and, as a mark of distinction, was subsequently covered by a dome or cupola, rising above the general roof of the building.

The circular recess at one extremity of the Basilica gave the building something like the appearance of a ship; and from this circumstance, probably, the body of the Church or Basilica was called the *nave*, a term which was afterwards confined to the central division between the parallel rows of columns. The lateral divisions were called *aisles*, and the two arms of the transverse rectangle, which crossed the principal building at right angles, *transepts*. In the Churches of Italy, and all those which were copied from them, this transverse building was placed at or near one extremity of the main body of the edifice; but in Asia, Constantinople, and Greece the forms of the Churches, at least of those which were erected in, or subsequently to the time of Justinian, were rather different; the plan of most of them consists of two rectangular parallelograms intersecting each other perpendicularly in the middle, in such a way as to make the four arms of equal length; and the centre, like that in the Italian Churches, is covered by a dome. This plan bears the name of a *Greek cross*, to distinguish it from that of the Western Churches, which is called a *Latin cross*.

The ancient Basilicæ frequently had upper galleries between the columns and the interior of the walls; and when these buildings were dedicated to the service of Religion, or Churches were erected according to the plan of those buildings, the upper galleries were frequently appropriated to the female part of the congregation, which in the ancient Christian Church was separated from the male part: and the ascent to them was by steps in the thickness of the walls, so that the women could arrive at their places without being seen by those persons who were in the lower part of the Church.

Constantine promotes the building of Churches at Rome.

The Religion of Christ becoming, in the reign of Constantine, the Religion of the Empire, that Prince directed a portion of his own wealth and that of the State, to the noble purpose of erecting, for its service, edifices which might be worthy of the Roman name. Seven Churches, built or consecrated within or near the city of Rome, are described as the fruits of his zeal; and though not one of them remains in its original state, it is incumbent on us to mention some of them, because they were, in their time, objects of great importance, and were also the first works of magnitude which were appropriated to the celebration of Christian worship.

The Basilica of St. John de Lateran.

The first of these is the Basilica of St. John de Lateran, which was originally part of the Palace of Plautius Lateranus, and subsequently of the Emperors of Rome. Constantine, to whom it belonged, caused it to be dedicated to the Saviour, to St. John, and St. Peter. Being now entirely modernized, it is impossible to give an accurate description of it; but, according to Rasponi, it was of a rectangular figure, except at the Eastern extremity, where was a semicircular recess; the body of the Church was divided longitudinally, by four parallel rows of columns, into five parts, forming a centre, or grand nave, and two aisles on each side.

The Baptisterium of Constantine.

Contiguous to this, and forming part of the ancient Palace, is a building serving for a Baptistery, and supposed also to have been built by Constantine. The plan is a regular octagon, and there is a descent by four steps to the bottom of what was originally the basin, a superb vessel of basalt for the immersion of the converts. Eight columns of porphyry surround the central part in the interior of the edifice, and above the entablature are eight smaller columns of white marble; these bear a heavy entablature, above which, at the angles, are pilasters supporting the dome of the edifice; and a remarkable circumstance is, that between these Orders there is no ceiling, either over the centre or over the gallery between the columns and the wall. The materials of which this edifice is composed seem to have been taken from other buildings, and the borrowed columns appear to have been put up in haste, without even reducing them to one size of shaft.

The Basilica of St. Peter,

The Basilica of St. Peter was built on the North side of the Circus of Nero, perhaps with the materials of the Circus itself, and was consecrated by Constantine in the year of Christ 324. This edifice is supposed to have had the figure of a cross on the plan, and was, probably, the first of the kind. The body of the Basilica is said to have been 200 feet long from East to West, and 154 feet wide, according to the measurements of the Abbé Uggeri; and to have been divided into five naves by four parallel rows of columns. The transept, if it may be so called, was at the Eastern extremity, and equal in length to 208 feet from North to South; in the middle of the Eastern face was the semicircular *chalcidia* or *apsis*, which was about 43 feet in diameter;

and at the Western extremity, in front of the doorway, was a grand rectangular peristyle. The whole building is described as exceeding in magnitude and splendour any Temple before seen, having in it an hundred marble columns; but it is allowed to have had small pretensions to architectonic merit. Being destroyed by the Saracens in 846, it was restored by Probus, probably on the traces of the more ancient building. It was again demolished by Pope Nicholas V., and the present grand Cathedral of St. Peter was subsequently built on the same spot. For a plan of this Basilica see pl. xiv.

of St. Laurentius,

The Basilica also of St. Laurentius, at Rome, was one of the seven Churches built by Constantine. It is now of a rectangular form, and without the chalcidia or semicircular tribune; therefore, probably, the plan has been changed since the original construction. Its interior length is 296 feet, and breadth 70 feet. In front is a pronaos with six Ionic columns between the antæ. The nave beyond is divided into three parts longitudinally by two rows of Ionic columns, and within the centre division, or grand nave, are two *ambones* or pulpits, one on each side, elevated above the level of the pavement with steps to ascend to them; at the further extremity of the grand nave is the Presbytery, or division appropriated to the officiating Priests, which is enclosed by a rail. Beyond the nave is the Choir or Sanctuary, of a rectangular form, elevated above the general pavement of the Church, and having an aisle on each side on a lower level. This elevation seems to have been made at a time posterior to the building of the Church in order to obtain a space below for a Crypt or lower Chapel. On each side of the Choir are five fluted Corinthian columns, the bases of which are on the pavement of the aisles. The capitals of these are of different kinds, and they carry an entablature ornamented with sculpture, good and bad; above these is another Order of Corinthian columns of smaller size, with spiral flutings, and over them are arches and a wall pierced by windows. Between the extremity of the Choir and the Eastern end of the Church is a Chapel, the pavement of which is on a lower level than that of the nave; and it is supposed by some that this was originally the vestibule of the building.

of St. Paul,

The Basilica also of St. Paul, on the banks of the Tiber, was built originally by Constantine; it was subsequently enlarged, but according to the same plan, by the Emperors Valentinian, Theodosius, and Arcadius. This building also, which still exists, has the figure of the cross, and the transept is placed at the Eastern extremity, but its length only exceeds the breadth of the body of the Church by a few feet. The length and breadth of the latter are 296 feet and 215 feet respectively, and it is divided into five aisles longitudinally, by four rows of columns of the Corinthian Order; twenty-four of the forty columns in the two interior rows are supposed to have been taken from the Mausoleum of Hadrian, and the rest are of the time of Theodosius and Honorius. The entrance from the central nave to the transept is covered by a grand arch, springing from two columns of the Ionic Order with Attic bases. The transept, which is 79½ feet wide from West to East, is divided into two equal parts by a wall and columns in a Northern and Southern direction; in the centre of this wall is an arched entrance opposite to the former, and, as in that, the arch is supported on two columns. At the Eastern extremity is the tribune or apsis, in the form of a segment of a circle on the plan, and lined with mosaic work. All the columns of the nave support arches; above those on each side of the central division are high walls, adorned with Paintings which are divided into two rows; and at the top of this wall, on each side, is a tier of arched windows filled with plates of Parian marble and pierced with round holes in several rows. Almost every column is formed of a single block; the shafts are fluted and the channels are cabled, or filled as far up as one-third of their height; but the flutes and capitals are badly cut, and the former are not even straight.

of St. Agn

The Church of St. Agnes, without the walls, is another of the works of Constantine; its plan is rectangular, 99 feet long and 53 feet broad, and it has no transept, but there is a semicircular recess at the Eastern end. The Church is divided into a grand nave and two aisles by two rows of columns, each consisting of two Orders one above the other; and over the aisles is a gallery on each side, as was usual in the Heathen Basilicæ. The walls of the recess are covered by plates of white marble, ornamented alternately with little bands of porphyry in the form of small pilasters; of these two are curious in the two angles of the apsis, with capitals of the Corinthian Order; they have very little relief, and are executed in the bad style of the Lower Empire; one of them has also an Attic base as badly executed as the capitals.

Dr. Milner has given a copy of a mosaic picture executed by order of Pope Honorius, about A. D. 621, representing this Church in its original state; from which it appears that the walls of the nave were carried up higher than the four exterior walls of the Church, and were pierced by semicircular-headed windows along the sides and front. The Church seems to have been covered with tiles; the roof of the nave terminated in a ridge extending longitudinally over the middle of the building, and in the gavel, or triangular front at the Western end, was a circular window. At the Western extremity of the body of the building was the *narthex*, or porch for Penitents; the entrance to which from the street was closed merely by a curtain.

of St. Stephen

We may conclude this account of the ancient Roman Churches with a description of the circular building dedicated to St. Stephen, which bears marks of having been executed in the latest period of the Roman Empire; probably on the ruins and with the materials of a Temple dedicated to Claudius. The exterior wall is 211 feet diameter; within this is another the diameter of which is 80 feet, in the interior circumference of which are eight pilasters at unequal distances from each other; and between these are alternately four and five columns half sunk in the wall; some of the columns are larger than the others, and have Corinthian capitals; the capitals of the others are of the Ionic Order. The shafts of some are plain, of others fluted, and all of them support a small cornice which is broken so as to project over each column. Above these columns is a cylindrical wall with arcades. Within this colonnade is another, 77 feet in diameter, which consists of isolated columns all of the Ionic Order, supporting an architrave, and having bases of all sizes and kinds. At the extremities of a diameter of this colonnade are two piers ornamented with Corinthian pilasters, the faces of which are towards the centre; and in the interval between them are two large Corinthian columns, which, with the pilasters, support three arches in the direction of a diameter of the building; on them rests the timberwork of the roof. The Grand Altar is in the centre, and there are other altars in the circumference of the exterior colonnade.

Ecclesiastical edifices must have been erected in Syria and Greece in the very infancy of Christianity, and before any were erected in Rome; those Countries being so much nearer to the place whence the Religion emanated. Of those edifices the erection of which was anterior to the time of Constantine not a trace now remains by which we can judge of their forms; but Mr. Whittington supposes, in his *Ecclesiastical Antiquities of France*, that they were generally of an oblong figure, and that near each of them may have been a lodging for the officiating Priest.

Works of Constantine at Byzantium.

When Constantine removed the seat of Empire to the city which he called by his name, he adorned his new residence with so many stately edifices that it became nearly equal in magnificence to the ancient Capital itself. Besides a Cathedral dedicated to Sancta Sophia, or Holy Wisdom, and a Church to the Apostles, he built a Forum of an elliptical form, surrounded by colonnades and statues, having its opposite entrances formed by Triumphal Arches, and a lofty column in its centre; a Circus or Hippodrome, about 400 paces in length and 100 in breadth, having the space between the metæ or goals filled with statues and obelisks. And, within a century after its foundation, Constantinople is said to have contained a School of Learning, a Circus, two Theatres, eight public and one hundred and fifty-three private Baths, fifty-two Porticos, fourteen Churches, and as many Palaces.

hurch of e Holy epulchre.

The pious Helena, mother of Constantine, about the same time, caused several edifices for Christian worship to be executed in the East; the most celebrated of which seems to have been the Church of the Holy Sepulchre at Jerusalem. According to M. Deshayes, Helena only built that part which covers the sepulchre, and succeeding Princes augmented it so as to include Mount Calvary. Its form is very irregular, being subject to the inequalities of the ground, but it nearly resembles a cross; its length is 120 paces, and breadth 70 paces. M. Chateaubriand shows that the whole building consists properly of three Churches, *viz.* that of the Holy Sepulchre, that of Calvary, and that of the Invention of the Cross. The first is of a circular form, and constitutes the grand nave of the whole edifice; its interior circumference is ornamented with two tiers of marble columns, sixteen in each, supporting two tiers of arches. The columns of the upper tier are smaller than those of the lower, and form the front of a circular gallery; and a row of niches is formed in the interior circumference of the wall, corresponding to the apertures of the lower arcade. This part of the building is, or rather was, covered by a timber-dome in the form of a frustum of a cone, 30 feet diameter, with an aperture at the top like that of the Pantheon at Rome. The Sepulchre is under the middle of the dome, and consists of a rectangular excavation in the rock, the entrance to which is by a low aperture; the interior is nearly square on the plan, 5 feet 10 inches long each way, and about 8 feet high. The Choir of this Church is on the Eastern side of the tomb, and is divided into two parts; in the first are the stalls for the Priests, beyond this is the Sanctuary which is raised a little above the level of the former part, and on each side of it is an aisle, in which several small Chapels or Oratories have been formed. In the right aisle are two entrances, one of which leads by a vaulted staircase to the upper part of the rock of Calvary, where is formed the Church of that name; and the other, by a descending staircase, to the Church of the Invention of the Cross; and both these Churches are covered by small domes. The Architecture is of the Age of Constantine, and it is probable that it has not been essentially changed since the time of its first erection. The columns, which are of the Corinthian Order, are mostly heavy and ill-proportioned. The Church has no peristyle, and perhaps it never had any exterior ornament. M. Chateaubriand relates that since his return from Syria, the Church of the Holy Sepulchre, perhaps he means its timber-dome, has been destroyed by fire.

Church of the Nativity

The Church of the Nativity, at Bethlehem, which seems to have been executed in this Age, is of a rectangular form; the body is divided into three parts by two rows of Corinthian columns, and in the walls of the central division, above the columns, are semicircular-headed windows. But what is remarkable in this Church is, that the walls between the windows are covered with mosaics, representing buildings in which are twisted columns, and others the shafts of which are ornamented with zig-zag grooves across them, very much in the style of those employed in the Saxon or Norman Churches erected about the Xth century.

Distribution of the interior of the ancient Churches.

The façades of the primitive Greek Churches are said to have been originally turned to the East, in order that the Priest in celebrating the service might have his face turned that way; but the practice was not general, for in some cases, as in the Church at Antioch, the principal façade was towards the West; and among the Latins this last disposition was that generally adopted. The semicircular recess at one extremity of the Basilica had the name of apsis, from a Greek word which signifies an arch; and this was the place destined for the throne of the Bishop. In front of the apsis or tribunal, was the Sanctuary or Chancel, a part surrounded by a balustrade in which was the Grand Altar, and into which only the Ministers who officiated had permission to enter: this was elevated a few steps above the pavement, and, according to Eusebius, it was divided from the rest of the Church by a lattice-work of wood. The Chancel and Altar were generally situated at the Eastern extremity of the building, in order that the congregation might, in prayer, have their faces towards the Altar, when, agreeably to the custom mentioned by the early Fathers, the people turned to the East in that act of devotion. Near the Sanctuary were the *ambones* or pulpits, which were placed one on each side of the central division of the nave; these were also elevated above the general pavement, and from them the Epistle and Gospel were read to the people. In the central division of the nave was also the *presbyterium*, a place enclosed and appropriated to the Deacons and Chanters, corresponding to the Choir of the present day: between the presbyterium and the entrance was the *narthex*, or, as it was afterwards called, the *Galilee*, a station assigned to the Penitents, to whom also, or perhaps to those who were more guilty than the rest, was allotted the portico on the exterior of the Church. One aisle of the Church was appropriated to the male, and the other to the female part of the congregation, these, in the ancient Church, being kept separate from each other. Over the aisles were generally galleries corresponding to those which, according to Vitruvius, were constructed in the Heathen Basilicæ; the arcades in front have been supposed to be intended to screen the people in the galleries from the rest of the congregation; but it is more probable that they were merely formed for the purpose of supporting the roof, where a horizontal entablature could not be obtained on account of the wide intervals of the columns.

The Constantinian Churches at Rome had generally, before the Western extremity, quadrangular courts with interior peristyles or arcades, as well for the Penitents as for the convenience of the congregation while waiting for the hour of prayer.

The transepts were probably added to the original rectangle in order to obtain room for a greater number of persons to get a sight of the High Altar, which was in the body of the Church; and in buildings thus constructed it was generally, though not always, placed at the intersection of the nave and transepts. In addition to this there was, sometimes, a smaller altar in the hemicycle at the Eastern end of the Church: the latter seems to have been the original place of the altar, the Bishop's throne only being behind it. Mr. Green, in his *History of Worcester*, supposes the other arrangement to have taken place when the doctrine of Transubstantiation was introduced in the Christian Church.

The Cathedral of Sancta Sophia.

The Cathedral of Sancta Sophia, at Constantinople, which had been built by Constantine, having been twice destroyed by fire, was rebuilt finally by Justinian about A. D. 532. His Architect Anthemius gave the design, and the Emperor every day superintended the work, which was completed in about six years from the time of laying the foundation: the magnificence of the edifice so well satisfied the Emperor that he is said to have glorified himself with the reflection that in it he had exceeded Solomon himself. For a plan and elevation, see pl. xiv.

The plan of the interior is that of a Greek cross, the four arms of which are of equal length; the central part is a square, the sides of which are each about 115 feet long. At each angle of the square, a massive pier of travertine stone has been carried to the height of 86 feet from the pavement, and four semicircular arches stretch across the intervals over the sides of the square and rest upon the piers. The interior angles between the four piers in the central square are filled up, from the springing points of the four arches, in a concave form, to a horizontal plane passing through their vertices, which are at 143 feet above the pavement; so that, at the level of the vertices, the interior edge of the part filled up becomes a circle, the diameter of which is equal to the side of the central square. Upon this circle, as a base, is raised the principal dome, the form of which is that of a segment of a sphere, which is said to be equal in height to one-sixth of the diameter of the base. On both the Eastern and Western sides of the square, in the centre of the Church, is a semicircular recess, the diameter of which is nearly equal to the side of the square · it is carried up to the same height as the piers, and terminates in a half-dome or quadrant of a sphere, its base resting upon the hemicylindrical wall of the recess, and its vertical side coinciding with the arch raised between the piers on that face of the building; the flat side of each recess and dome being open towards the interior of the Church. These quadrantal domes were intended to resist the lateral thrust of the arches raised on the Northern and Southern sides of the Church, but they were found insufficient, for the arches pushed away the half-dome on the Eastern side twice, and it could only be made to stand by constructing the great dome of pumice-stone and very light bricks obtained from Rhodes, by filling up the arches with others of smaller dimensions, and by carrying an enormous arch-buttress from a massive wall beyond the building to the foot of the dome.

At the extremities of the semicircular recesses, in a line running East and West through the centre of the Church, are smaller recesses, the plan of one of which terminates in a semicircle, and of the other in a right line; these recesses are built to the height of the springing of the four principal arches, and are crowned by quadrantal domes, which, as well as the recesses, are open towards the interior. In each of the two principal hemicylindrical recesses between the great piers and the other recesses just mentioned, are formed two other cylindrical recesses, open towards the interior and covered by quadrantal domes. All the recesses and domes are perforated by rows of small windows to obtain light.

On both the Northern and Southern sides of the square, in the interior of the Church, is a grand vestibule forming a square on the plan; the roof of each consists of three hemicylindrical vaults extending from North to South, and of another vault of the same kind crossing the former at right angles through the middle, and forming by their intersections three groined arches; these vaults are supported by massive pillars which have bases but no plinths; the upper part of their capitals resemble the volutes of the Ionic Order, but the lower part seems to be a barbarous imitation of the Corinthian base. Above these vestibules are galleries exactly similar to them, and, probably, appropriated to women during the performance of divine service. The whole Church is surrounded by cloisters and enclosed by four walls, forming one great rectangle on the plan.

The exterior does not correspond with the internal grandeur of the edifice, being surrounded by clumsy buttresses. The entrance is by a portico as long as the Church, and about 36 feet wide; this is ornamented with pilasters, and communicates with the interior by five doorways of marble, sculptured with figures in bas relief. Contiguous to this vestibule, and parallel to it, is another which has nine doorways of bronze.

After twenty years, the Eastern dome was thrown down by an earthquake, but it was immediately restored by the persevering industry of Justinian; and it now remains, after a lapse of thirteen centuries, a stately monument to his fame. Besides this Cathedral, Justinian is said to have built in Constantinople twenty-five Churches to the honour of Christ, the Virgin, and the Saints: he also built a Church to St. John, at Ephesus, and another to the Virgin, at Jerusalem, besides bridges, hospitals, and aqueducts in various parts of the Empire.

Christi favour to the

The Christian Religion may be said to have rendered an essential service to the Fine Arts, as is observed by the Abbé Uggeri, (*Edifices de la Décadence*,) in having contributed to the revival of the genius of the artists after a period of barbarism, by the opportunity it afforded them of raising Temples worthy of the Divine Majesty; and to the preservation of many remains of ancient Architecture, which became embodied in the buildings they erected. While the Arts were tending fast to ruin, Constantine ascended the Throne, and under his protection were raised at Rome the works we have mentioned; the execution of which might have been impossible from the want of materials and workmen, if the fragments of the Heathen Temples had not furnished a supply of the former, and, in part, superseded the latter.

st of e and Jexhi- d in the istian dice.

The style of building employed in the Churches erected during the time of Constantine and his immediate successors would necessarily resemble that of the Basilicæ themselves; for the materials employed must have had an influence on the design, and columns taken from other buildings could only be applied in one which resembled that from which they came. And though some of the Basilicæ, which had been erected at an early period of the Empire, might equal in merit the best works of the Augustan Age, yet it is probable that most of them, and consequently the Churches of which they were the prototypes, were executed under the influence of that bad taste which characterises the Baths and Triumphal Arches. This is visible in a disregard of the proportions established by the more ancient artists, in a multitude of minute divisions and ill-executed ornaments destroying the simplicity which the designs of edifices of that class should possess. In several instances the columns which adorn the Churches have been taken from other edifices, either on account of the haste with which the buildings were constructed, or from incapacity on the part of the artists to execute any thing equal to them. These have been fitted to their places by the Procrustean expedient of cutting off the ends of those which were too long, or mounting on pedestals those which were too short; the rude artists seeming quite indifferent to the alterations which were thus made in the original proportions of the members of the Order. In some cases we find columns of different forms and proportions, not only in the same edifice, but in the same range, with bases, capitals, and entablatures mingled in the utmost confusion, and one substituted for another, seemingly because it came first to hand. A striking example of the capricious style which was occasionally employed in the ancient Christian edifices may be seen in the Tomb of Zacharias, at Jerusalem, a work of the time of Constantine. In its porch is a great torus moulding placed over a Doric frize, and above this is an Egyptian cavetto serving as a cornice.

ess of me of

Amidst all this inattention to the principles of sound Architecture, a taste for that which might excite surprise by its magnitude and dazzle by its splendour prevailed in the East: to this taste we may ascribe the erection of the edifice of Sancta Sophia, which seems to have been intended to unite the characters of the Temple of Peace and of the Pantheon at Rome. An example of a magnificent, hemispherical dome already existed in the latter of those buildings, but this was raised on a cylindrical wall, and the horizontal thrust at its base, which is not considerable, could be counteracted by a sufficient hoop of masonry surrounding it; but the dome of Sancta Sophia is of a different character, and presents what must have been then a daring novelty, being raised on the tops of four piers; its form, also, is that of a flat segment of a sphere, consequently the horizontal pressure outwards at the base would be very great, and this could only be resisted by masses raised about the four piers: the difficulty of adjusting this resistance to the pressure, must, in those days, have been considerable, and it is not wonderful that the dome should have failed twice before it could be rendered secure.

The masses of materials which fill up the four angles in the interior of the building, to serve as supports for the base of the dome, are called *pendentives;* these, if we except the very small ones in the Palace of Dioclesian, are the first works of the kind with which we are acquainted, and their construction displays great skill in the Art of building.

The external effect of this dome is entirely lost by the enormous buttresses which prop it up, but persons who have seen it from the interior describe it as producing a most imposing effect.

Probable origin of high and narrow windows.

The hemicylindrical recesses, which were almost universally adopted in Religious edifices from the time of Constantine, may have led to the formation of the high and narrow windows, which also are found in many of those edifices; for the convexity of the wall would not permit broad windows to be made with either horizontal or arched tops, on account of the voussoirs projecting obliquely outward between their abutments; and, consequently, not being properly supported. Narrow windows are less subject to this evil, therefore such would naturally be preferred; and to obtain a sufficient quantity of light it would be necessary to increase their length in proportion to the diminution of their breadth. The windows of the Church of the Holy Sepulchre, at Jerusalem, are of this kind, with semicircular heads. This change in the form of windows seems to have been a step towards a greater change which, not long after this period, affected the whole style of Ecclesiastical edifices.

The construction of the Cathedral of Sancta Sophia seems to have been very generally adopted both in the West and East. At Corfu a small Church still remains which was built in the Constantinopolitan style, on the plan of a Greek cross, with a dome over its centre; and from an inscription over the doorway, it appears to have been erected in the VIIth century. The great Ecclesiastical structures of Italy, which were erected soon afterward, and even the Mosques of the Mohammedans, present nearly a similar appearance.

We terminate here our account of the Architecture of the Roman school. From the time of Justinian an entirely new manner of building arose, which gradually superseded the former, and for several Ages prevailed universally in every Country which had been subject to the Roman dominion.

CHAPTER X.

Arabian or Saracen Architecture.

Departure from the Greek and Roman Architecture.

We have now arrived at a time when a considerable change took place in the Architecture both of the East and West: instead of the Grecian and Roman porticos with their long, horizontal entablatures and pediments of low elevation, we find arcades supported on very massive or very slender columns, and lofty roofs crowned by cupolas; and instead of that majestic simplicity of building which, in general, was indebted only to the correctness of its proportions for the admiration it excited, we find an effort to produce surprise and extort applause, by boldness of form and a profuse display of elaborate and fantastical ornament.

But the new styles which arose in the East and West, though possessing some points of resemblance, differ materially from each other; and as the latter suffered several modifications in different places and in process of time, which it will be advantageous to pursue in an uninterrupted course, we think it convenient to describe, first, the Architecture of the people of the East during the decline of the Constantinopolitan Empire; in order that nothing may interfere with the account we purpose to give of the rise and progress of those styles of building which then, and afterwards, prevailed in Europe.

The Kaaba, at Mecca.

Those Sciences of which the Arabs, or Saracens, from the earliest times were in possession, they probably learned from their Egyptian and Babylonian neighbours. Strabo informs us that they had magnificent Temples and private dwellings built in the Egyptian style, and a Temple, at Mecca, is mentioned by Diodorus as existing in his time; we are ignorant of its form, but it was rebuilt, or, at least repaired, by Mohammed, and became the chief Temple of his Religion. This is now called the *Ka'beh*, or Square building, and a description of it will be found in our *Miscellaneous Division*, under HEDJAS. It is likely enough that this building, originally, did not differ much from an ancient Egyptian Temple; and it is also reasonable to suppose that the cupolas and turrets which rise above the roof were imitations of similar works erected in Syria by Justinian or his successors; or they might have been at once adopted from the Cathedral of Sancta Sophia itself; of which the Arabian Prophet might have been informed by those who are said to have assisted him in compiling the Koran.

Mosque of Omar, at Jerusalem.

On the ruins of the ancient Temple at Jerusalem, the Caliph Omar, about A. D. 640, raised a superb Mosque, which, by the Mohammedans, is considered as next in sanctity to that at Mecca, and of which, till lately, no particulars were known to the Christian world. We are indeed still ignorant what was the nature of the edifice originally erected by Omar, because many additions have been made to it, at subsequent periods; but the following account of it has been drawn partly from the *Itinéraire à Jérusalem*, by Chateaubriand, partly from other sources.

The whole is contained in a quadrangular area, about 500 paces long and 460 paces wide, surrounded by walls in which are twelve entrances through as many porticos at unequal distances from each other, and consisting of arcades supported on pillars in one or two tiers; and it is probable that the high towers about the building, mentioned by William, Archbishop of Tyre, were situated at the angles of this enclosure. On the exterior of the wall, towards the East and South, are the walls of the city; on the West are some Turkish houses; and on the North are the buildings called the *Prætorium* of Pilate, and the Palace of Herod.

The edifices within the enclosure consist of two Temples, or Mosques, called respectively *El Achsa* and *El Sachara;* the former is divided into seven aisles by rows of cylindrical columns, each 16 feet high and 2½ diameter; these support arches each formed by two segments of circles meeting in a point at the vertex, but the whole differing little from a semicircle. Above the arches are walls 13 feet high, and pierced with two rows of windows; at one extremity of the central division are four piers disposed at the angles of a square on the plan, and surrounded by marble columns; and from the piers spring four arches, above the crowns of which is a cylindrical tambour 32 feet diameter, containing two rows of windows, and supporting a dome in the form of a segment of a sphere, the interior of which is ornamented with gilding and painting of that kind which has been since called arabesque. Near this edifice, and within the enclosure, is a terrace 460 feet long, 400 feet broad, and raised 6 or 7 feet above the court, from which there is an ascent on each side by marble steps: in the centre of this platform is situated the Mosque *El Sachara*, a building of an octagonal form; and, according to the information given by the Turks to Deshayes, containing in its centre the stone or portion of rock on which Mohammed mounted when he ascended to Heaven. About this stone, are four piers surrounded by columns supporting an octagonal lantern, and crowned by a dome similar to that of El Achsa; this was formerly covered with gilt copper, which the Caliph El Louid had taken from a Church at Balbec, and it is terminated above by a spire and crescent. The walls of this building are faced on the exterior with little squares of coloured bricks and marble, and ornamented with arabesques and texts of the Koran; and in the lantern are round windows of coloured glass. There is said to be an entrance on each face of the Mosque, and each doorway is ornamented with mouldings and columns. The columns of the interior, which are placed on pedestals, and crowned by capitals, have probably been taken from Christian edifices.

Mosque near Cai

We may add to the above account of the Arabian edifices, that there exists an abandoned Mosque, seemingly of ancient date, near the walls of Cairo. According to the description given by Pococke, it must have resembled that at Jerusalem; at the angles are square pavilions which terminate in minarets, and along each face is a row of arches with pointed vertices; the walls are crowned with battlements of a triangular form, having each side cut to resemble steps. In the centre of the building is a square tower with a polygonal lantern crowned by a cupola, the form of which is that which would arise from the revolution of a pointed arch about its vertical axis. From certain inscriptions in the Cuphic character, the origin of the building is referred to some period more remote than the Xth century, but this is extremely uncertain.

Scarcity the re of Sarac building

Considering the great extent of the dominions acquired by the Arabians shortly after the establishment of the Religion of Mohammed, the magnificence of the Courts of Cairo and Bagdad, and the patronage bestowed by the Caliphs on men of Science, it is surprising that so few public buildings should remain, the construction of which can be referred to the times in which those Princes flourished. We can hardly ascribe this scarcity to any devastations produced by the wars which subsequently took place in that part of the World; for except the Crusaders, whose conquests did not extend much beyond the sea-coasts of Syria, and who alone from Religious motives might have destroyed the buildings of their enemies, all other invaders of the Empire of the Saracens were men of the same Faith with themselves, and would naturally consider the public edifices erected by the Caliphs as property common to all the Moslems. But whatever be the cause, it is certain that, except the Mosques at Mecca and Jerusalem, nearly all the remains of the Architecture of the Eastern Saracens have disappeared.

Tomb Abda

Of the few that are still in existence we may mention the Tomb, said to be of Abdallah, one of the twelve disciples of Mohammed. According to the description of Cornelius Le Brun, its plan is a square of 32 feet, and the entrance is in front at an aperture covered by an arch formed of two segments of circles meeting in a point at the top, the radii of which are about equal to the span of the aperture. If this Tomb were really erected immediately after the death of Abdallah, it would afford an important evidence in favour of the Saracenic origin of the species of arch with which it is ornamented; but this is extremely improbable.

The same species of arch occurs also in the Castle of Cairo, and in the ruins of an edifice, in the same city, called the Hall of Joseph; both of which are supposed to have been works of Saladin. The latter is a quadrangular area surrounded by tall columns of porphyry, or granite, without bases, but having circular plinths; the capitals resemble those of the Corinthian Order, but are more simple; and from them spring arches with pointed tops, like that above mentioned. The uncertainty, however, respecting the period during which these edifices were erected, does not permit us to consider them as affording any data by which to determine the antiquity of the pointed arch; a member which, as we shall presently see, forms so distinguished a feature in the Architecture of Europe during what are called the Middle Ages.

The Empire of the Saracens extended from the banks of the Indus to the Western extremity of Europe, and it is a remarkable circumstance that the most splendid specimens of their Architecture should be found so remote from the seat of their Government as Spain; in fact, the principal building from which we derive our knowledge of the Arabian Architecture is the Mosque at Cordova, for a description of which we are indebted to Mr. Swinburne. It was begun in the year 786 by Abdoulraham, King of the Moorish dominions in Spain; and the style of it was, no doubt, copied from such Arabian buildings as existed at that time in the East. It is a large rectangular edifice, 510 feet long from East to West and 420 feet broad, and is divided into two parts by a wall parallel to its greatest length. The Northern part is an open court in which the worshippers performed their ablutions previously to their entrance into the body of the Temple; its length from East to West is equal to that of the whole building, and its breadth is 240 feet; a covered colonnade, 25 feet wide, consisting of sixty-two pillars, occupies three of its sides in the interior, and on the fourth is the wall before mentioned, in which are several doors communicating with the other part, which may be considered as the main body of the Mosque.

This latter part is divided into seventeen aisles by nearly a thousand columns of various-coloured marble, disposed in rows extending from East to West, and about 20 feet asunder. Of these rows there are two, consisting of columns attached one to each face of a square pier. These cross each other at right angles, and divide the Mosque into four rectangular portions, three of which were allotted to the populace, and the fourth, which was the South-Eastern quarter, contained apartments for the Priests and Nobility, and the thrones of the Caliph and Mufti. All the columns are about 18 inches diameter, but they are not of the same height, and seem to have been taken from Roman buildings, which, probably, at a more ancient time, existed in the neighbourhood; those which were found too long for the purpose had their bases cut off, in order to reduce them to the required size; others, which were too short, were lengthened by giving them tall capitals, cut to resemble those of Corinthian columns, but badly executed. The aisles are covered by low vaults, and an arch, in the form of a segment of a circle, springs from the top of every two columns in the direction of the length of the building. The interior receives light chiefly from the doorways, and from apertures in the roof.

The exterior walls of the Mosque are plain, and the roof is hid from view by battlements cut in the shape of steps. The Eastern wall is supported by buttresses, and, on this front, are several semicircular-headed windows, with archivolts springing from short pilasters or columns, approaching the Tuscan form; some of these windows are double, and consist of two semicircular-arched tops, which rest upon three short pillars. The doorway is crowned by an arch composed of two segments of circles meeting in a point at top, and continued below the horizontal line passing through their centres; so that the aperture at the foot of the arch is less in breadth than at some distance above it; a form which, though not always assumed by Moorish arches, has never been employed in those of any other people

Bath at Gerona.

At Gerona, in Catalonia, are the remains of an Arabian Bath, of considerable, though uncertain antiquity, but deserving mention in this place, as it is the only known example of a species of building which must have been as generally constructed by the Arabians as by the Greeks and Romans. It consists of a square apartment, having in the centre a space enclosed by a low octagonal wall, on the periphery of which were placed eight columns, with capitals resembling those employed in the ancient Egyptian Architecture. From these capitals spring eight arches in the form of segments greater than semicircles; a kind of arch which, from its resemblance to a horse-shoe, is generally called by that name. These support an octagonal wall, from which spring cylindrical vaults to the four sides of the apartment, and to four faces formed diagonally at its interior angles. Above the wall is an open lantern formed by eight short columns, which support an octagonal cupola with a pointed vertex. In one of the sides of the room are recesses, the entrances to which are crowned by pointed arches.

The Alhamra at Grenada.

We may conclude this account of the Saracenic buildings by a reference to the description of the ALHAMRA, or Palace of the Moorish Princes of Grenada, given in our *Miscellaneous Division, ad v.* This edifice, though it was not erected till near the end of the XIIIth century, appears to have been built according to the same style as the earlier works of the Arabians, but with a greater degree of ornament.

Elevations of a column and one of the arches in the Court of the Lions there described, are given in pl. xv.

Character of the Saracenic Architecture.

The Arabian or Saracenic Architecture seems to have undergone some change during the time in which that people enjoyed a political existence. The style of the original examples has some resemblance to that which prevailed in the Byzantine Empire. The cupolas formed in the earliest buildings are probably copies, on a small scale, of those which crown the Church of Sancta Sophia; and, of the columns which were employed in the same buildings, those not actually taken from edifices of more ancient date, were formed, though rudely, in imitation of such as had been executed by Roman artists. The later style of the Arabians seems to be distinguished by cupolas formed of portions of cylinders springing from a square or octangular base, and meeting in a point at top, like what are called cloistered vaults; by arches in the form of segments greater than semicircles; by slender, square minarets, terminating in a ball, or pine-apple; and by the painted tiles and mosaic work with which the walls of the buildings were covered.

The buildings we have described are those which have first given us occasion to introduce the cuspid arches, or those formed by segments of circles meeting in a point at the vertex; and could we be certain that they were constructed at the time of the erection of the oldest buildings in which they are found, there would be no hesitation in admitting that they are the originals of that kind of arch which from the XIth to the XVIth century prevailed almost universally in Europe. Considerable doubt, however, is thrown by travellers, on the antiquity of those arches, and it is generally believed that the date of their construction is posterior to that of the buildings themselves; and, consequently, they afford no proof that the Arabians have a just claim to the invention of the pointed arch. With respect to those of the horse-shoe form, there is little difficulty in admitting that they may have been the inventors of it, as no example of a precisely similar form is to be found in any part of Europe, except Spain. This construction must have originated in the mere love of novelty; for the least attention to its form will show that it does not possess the essential property of an arch, stability, since the pressure in the direction of the curve is entirely unresisted at the foot; and therefore, the wall over the aperture is prevented from falling only by the means employed to bind together the stones, both in the arch and the wall above it.

In Saracenic arches we find the adjacent sides of the voussoirs cut in notches, like the teeth of a saw, the projections of one fitting the rentrant parts of the other; a construction which indicates an apprehension on the part of the builders that plain sides would not have had sufficient divergency to permit the blocks to keep their places. But this serrated form subsequently became a species of intricate scarfing, the projections and the corresponding notches being cut in the form of complex curvilinear mouldings; these might have been introduced merely for the sake of ornament; but it is also possible that it was intended to unite all the voussoirs together, so as to constitute an archivolt capable of standing vertically without any lateral pressure; this, in the horse-shoe form, must have been an object of importance, as there is nothing to counteract the inward pressure at the lower extremities of the arch.

The Moorish arches about a doorway are frequently ornamented in the most splendid manner; the faces of the voussoirs are marked with arabesques, and surrounded by a moulding, which is not, in general, concentric with the intrados; the whole is enclosed in a rectangular panel, the mouldings and surface of which are elegantly enriched with scrolls and foliage; and commonly, the foot of the arch rests on a small column on each side of the aperture. In pl. xv. is given an elevation of part of the highly ornamented entrance to the Sanctuary of the Koran in the Mosque at Cordova; this may, perhaps, be considered as the richest example of the manner in which the Arabian artists embellished their edifices.

The Religion of Mohammed forbidding the representation of animals, the sculpture of the Arabians consists of foliage, or texts of the *Koran* inscribed on the walls. To the first they gave every variety of form that the most fertile imagination could devise; and hence, all ornaments of a fantastic character have, from this people, obtained the name of *Arabesque* or *Moresque*.

M. Durand observes that the Mosques of the Arabs contain, in a quadrangular enclosure, an immense quantity of columns ranged in files like plantations of trees, among which the people might enjoy that coolness, which, in the climates of the East and South, was not to be obtained in the open air; and M. Chateaubriand perceives, in the heavy, majestic, and durable style of Egyptian Architecture, the germ of the light Saracenic; he considers the minarets as imitations of obelisks; the arabesques as hieroglyphics painted instead of sculptured; and he gives the Temples of Egypt as examples of the forests of columns composing the interior, and bearing the flat roofs of the Arabian Mosques. But it may be observed that, with this sort of license, no difficulty need be experienced in justifying any hypothesis whatever.

The minarets, or lofty slender turrets, which always accompany the Religious edifices of the Mohammedans, are supposed by D'Herbelot to have been first erected by the Caliph Walid about the beginning of the VIIIth century.

PART III.

GOTHIC AND INDIAN ARCHITECTURE.

CHAPTER I.

Ecclesiastical Architecture of Italy before the XIVth Century.

We revert now to the Architecture of Europe; and, taking it up at the time which immediately followed the erection of the Cathedral of Sancta Sophia, at Constantinople, we proceed to trace in Italy, and subsequently in the North of Europe, the imitation of the style exhibited in that edifice; and, finally, to develope the character of a style of unknown origin, the principal features of which differ considerably from those of any edifice before constructed.

he employ-
nt of the
ch cause
change in
oman
ilding.

The introduction of the arch seems to have been the first step towards that complete change which took place in Roman Architecture at the time of the decline of the Empire. In the ancient buildings the columns employed to divide the internal area, or to support the roof, had their distances from each other necessarily regulated by the length of such stones as could be procured to form the entablature, since the extremities of each stone were to rest on the two nearest columns, or upon other stones which project but little beyond the interior sides of those columns. But an arch, the extremities of which were supported on two piers, could be made to cover an interval more considerable than the extent of a regular intercolumniation; and, therefore, would be a great improvement in a public building where the frequency and closeness of the columns would render it impossible for the eye of a spectator to command a good view of the interior. As soon as this construction had been adopted, it would not, probably, be long before an effort would be made to diminish the massiveness of the piers, which, as the arches counteract each other's lateral pressures, have evidently to support only those in the vertical directions. It is, therefore, conceivable that the next step would be to make the arch rise from the top of a column. The arcades thus formed constitute one of the principal features of the style which succeeded the ancient Roman, and in the above manner their origin may be accounted for.

ined
lts sup-
ed by
mns.

Another feature is that which is called groined vaulting, a species of covering which could not escape the notice of any person who had been employed to execute a common cylindrical vault; since the intersection of two such vaults would produce that particular kind of which we speak; and the idea being once obtained, the method of construction would be sufficiently obvious.

At first the diagonal ribs of the groined vaulting may have been made to rise from the interior angles of the walls of a building, or from the square piers left by the intersections of the passages which cross each other at right angles within the area; but the employment of columns to support simple arches, subsequently led to the practice of making the ribs of the groins rest also on the columns. The modifications of this system of arches and vaults springing from pillars, constitute the differences in the character of that species of Architecture which we are presently to consider.

The communication between Greece and Italy favourable to Architecture.

The intercourse which subsisted between Italy and Greece after the fall of the Western Empire, gave rise in the former Country to specimens of Architecture and Sculpture of the purest kinds, long after the irruption of the Northern Nations had annihilated the Arts and artists in other parts of Europe. The merchants of Venice, Genoa, and Pisa, together with the natural productions and manufactures of Greece, imported from that Country the materials of its ancient buildings, with which they adorned their own cities; and from the dearth of artists which then prevailed in the rest of Europe, natives of Greece are supposed to have been employed to construct the Ecclesiastical edifices of Italy with the ruins of the Temples of their Heathen ancestors. It is thus that in the IXth, Xth, and XIth centuries, the Cathedrals of Venice and Pisa and the old Church at Ravenna were built, by artists from Constantinople, or by Italians formed in their school, in imitation, and according to the disposition of the Cathedral erected by Justinian, in the latter city; but with members which bear the marks of the good taste of the ancient Greeks. Even where such materials were not actually employed, the imitations of them would be less unworthy of the ancient masters than the rude works of persons left to the indulgence of imagination, without taste or skill to guide them in the design or execution of their own fantastic conceptions.

Extension of the old Italian Architecture to the North of Europe.

The Ecclesiastical Architecture of Italy would naturally be carried into the Northern part of Europe by the Clergy of the different nations of Christendom, who, from the time that the Papal influence became general, visited Rome on a spiritual or a temporal account. These persons would observe the style of building in that city, and take delineations of the edifices; by these they would erect similar works in their respective Countries, with such variations as their several tastes might dictate; and hence, though there would be a general conformity with the Italian models in the outline of their edifices, yet the details may be expected to vary considerably. This is, no doubt, the reason of the differences in style observable in the Churches of Germany, France, Spain, and Britain, which some have considered to be as strongly marked as those in the Doric, Ionic, and Corinthian Orders. In those Countries the artists, having before them few examples of the antique Roman Architecture on which to form their taste, were naturally inclined to improve upon the contemporary style of Italy, which had been transplanted thence in the way we have described. This improvement they continued till they raised out of it another style, very different, but perhaps equally beautiful with that from which it had, at first, degenerated.

The Ecclesiastical edifices which, in Italy, have been executed according to the style so prevalent in the

Causes of the small influence of the Northern Architecture in Italy.

North of Europe from the XIIIth century, are probably modified imitations of the Cathedrals of Germany and France. The Architecture of these buildings may have been introduced into Italy by the power of example, and in spite of the monuments of Roman Art on which the taste of the Italians had before been formed. But these monuments being far more numerous in Italy than in the North of Europe, it is easy to perceive that such a predilection for the antique would exist in the former Country, that the Northern style would hold but a subordinate rank. And when, at the revival of the Arts, the Roman Architecture was more diligently studied in Italy, it became a standard for the buildings subsequently erected in that Country, and the Architecture of the Dark Ages, which appeared to be a corruption of the former, was held in contempt. Finally, in the XVIth century, the artists of Italy succeeded in bringing the Architecture of the rest of Europe within the pale of the Roman school.

Impropriety of the terms Gothic,

The style of building which prevailed in Europe from the fall of the Roman Empire till the XVIth century is classed under the general name of *Gothic*, as if it had been invented or introduced by the Goths in the different Countries which they conquered. Nothing, however, it must be owned, is more erroneous than such an opinion; for the Barbarians who overwhelmed the Empire do not appear to have had either the inclination or the means to execute any one of those works which are called by their name. Indeed History informs us that when the Goths adopted the Religion and the manners of the polite Nation which they had subdued, they adopted also its style of Architecture, and built Churches according to the examples which they saw in Rome; which they, most probably, would not have done had they possessed any thing like a style of building peculiar to themselves.

and Saracenic Architecture.

It has been proposed to apply the term *Saracenic Architecture* to that style which prevailed in Europe from the Xth to the XVIth century; from an opinion that its principal features were derived from those employed in the Architecture of Syria and Egypt about the commencement of that period. This opinion, and with it the name, is now abandoned. It is true that the Arabs or Saracens brought a particular style of building into the South of Europe, which, no doubt, was either identical with, or a modification of that which had, perhaps, long prevailed in the East; but the Arabian Architecture differs considerably from that which prevailed in the North of Europe at the same time, and the latter appears to have been a gradual developement of some preexisting mode, which would not be the case if it had been adopted at once from that of the Orientals.

The *Architecture of the Middle Ages*, and the *Christian Architecture*, are terms which have been also applied to the class of buildings now under consideration; but, though not destitute of propriety, they are yet liable to some objections. The first because its application will, in the course of time, cease to be just; as the period of its existence will not be a Middle Age for a remote posterity. And with respect to the other term, it may be thought to comprehend too much, for the sacred buildings of the Christians have not been confined to this, nor to any other particular style; they were first constructed in the manner which prevailed in Italy when the Arts were at a low ebb, and subsequently in imitation of the purest style of the edifices of Rome and Greece.

Reason
retaining
the term
Gothic A
chitectur

To the Architecture of Europe in the period before mentioned, the term Gothic seems to have been given by those professional men who have since laboured to revive the Architecture of ancient Rome, as a mark of reproach, indicating that it was as destitute of architectonic merit as the Goths were of Science; and though those persons probably were mistaken, and their censure too severe, yet, as the term has now become general, it will answer the purpose of distinction as well as any other; and may, therefore, be employed, provided we agree to consider the style to relate to the Goths no otherwise than as the first specimens of it existed in Europe about the time when that people performed an important part on the same theatre.

Different classes of Gothic Architecture

The division which the Italians made of the general Gothic style seems sufficiently proper, and shows, at the same time, the Countries in which the distinguishing characters originated. That particular style which prevailed in the North of Italy, they called Lombard Gothic, *Gotico Italico;* that which prevailed on the North of the Alps, they called German Gothic, *Gotico Tedesco;* and that in Spain and some other Countries, they called Arabic or Moorish Gothic, *Gotico Moresco.* In England, where different styles prevailed at different times, and the features of each are strongly marked, it is considered as of three kinds; *viz.* the *Saxon* and *Norman* Gothic, the *full* or *simple* Gothic, and the *florid* Gothic. This last style had hardly arrived at perfection when taste suddenly made a revolution in favour of the ancient Roman style, and the Gothic Architecture was completely abandoned. A different classification has been made of the ancient English Architecture by some writers on the subject. The Saxon is considered as a style distinct from the Norman; and that which succeeded, and which is designated by the general term *Gothic*, is divided into the *lancet-arch* Gothic, the *complete* Gothic, the *ornamental* Gothic, and the *florid* Gothic; but the Norman style seems to be only a modification of the Saxon; and the epithets applied to the others sufficiently indicate that these differ only in the degrees of ornament applied to the same or similar features; and, therefore, that the distinctions are hardly necessary.

It is probable that between the VIth and Xth centuries, the Ecclesiastical edifices of Italy were imitations either of the ancient Basilicæ, or of the Cathedral at Constantinople, and the few remaining Churches of that time have evidently been formed upon the model of the last-mentioned building; hence these edifices are considered as belonging to the *Constantinopolitan*, or, as some call it, the *Greco-Italico* style. After the Xth century, the characters of the Eastern and Western basilican Churches seem to have been united, and the style thence resulting is that which is usually designated the *Lombard* Gothic.

Cathedr
St. Mark
Venice.

The greatest of the Italian Churches built in the Constantinopolitan style, is the Cathedral of St. Mark, at Venice, which is said to have been erected in the IXth century by a Greek artist whose name is unknown. Its plan is that of a Greek cross, and each arm is roofed with a hemicylindrical vault; these meet in the centre of the building, and terminate in four semicircular arches on the sides of a square about 42 feet long in each direction. From the angles of the piers between these arches rise pendentives, similar to those of Sancta Sophia, and terminating at top in a circle which forms the base of a cylindrical wall; in this is contained a row of windows to give light to the interior, and on it is raised the central or principal dome, which is of a hemispherical form. The Church is divided, longitudinally and transversely, by rows of columns supporting semicircular arches; and the aisles of the body of the building and of the transept intersect each other in four places about the centre of the cross; over these intersections are constructed domes similar to that of the centre, but smaller, so that there are five domes on the roof of the Cathedral; the exteriors of the domes are covered with lead and surmounted by crosses.

The façade of St. Mark consists of three stories: in the centre of the lower one is the entrance, which is covered by a great semicircular arch, and on each side are two other arches of the same form; all these have plain archivolts, which spring from the upper of two Orders of columns placed one above another. At each extremity of the façade is a square tower, in each face of which is an arch, supported also on the upper of two Orders of columns. Over the lower arcade is an open platform, with a balustrade which is continued round the exterior of the Church; in front of this platform, and occupying the centre of the façade, are the four famous horses of Corinthian metal, which once belonged to the Arch of Nero.

The second story contains four blank semicircular arches, placed two on each side of a central aperture, which is higher than the four arches and forms a window; all of them are covered by pediments in the form of curves of contrary flexure, and ornamented with foliage; and over the spandril between every two arches is a turret terminating in a small pyramid or pinnacle. The building has undergone many alterations since its original construction, and the ornaments just mentioned are certainly of much later date than the rest of the edifice. The general style, however, seems to have been constantly preserved.

The Campanile or Bell-tower of St. Mark, which was built by Buono, an Italian architect, in 1154, is a brick building, the plan of which is a square, 40 feet in extent in each direction, and which rises to the height of 330 feet. It is celebrated for its strength and firmness, not having declined from a vertical position as so many other similar buildings in Italy have done.

In Certosa, one of the Islands of the *Lagune* at Venice, is a Church, erected, as appears by an inscription, in 1108, which on account of its great antiquity, and for a certain singularity in its interior, deserves to be mentioned in this place. The plan is a simple parallelogram, having no transepts, but at one end is a hemicycle or semicircular recess, in the centre of the curvature of which is the altar; concentric with the curve of the wall, and rising gradually towards it, are rows of seats like those of a Theatre. A flight of steps proceeds from the back of the altar, in a direction parallel to the sides of the building, to the level of the uppermost seat, where was situated the throne of the Bishop. The body of the Church is divided longitudinally into three parts by two ranges of columns which support arches taller than semicircles, the curvature of the archivolt commencing at a small distance above their capitals. The height of the throne is such that, when the Bishop was seated, his head must have been on a level with the tops of the same columns.

The Church of St. Vitale at Ravenna, which was built probably about the same time as that of St. Mark, is nearly in the same style. The exterior walls are formed upon a regular octagon, the diameter of which is 128 feet; within these are eight piers disposed at the angles of an octagon concentric with the former, and 54 feet in extent from one side to that opposite. The height of these piers is 55 feet; above them, and crowning the whole edifice, is a hemispherical vault covered by a conical roof of timber. This dome is remarkable for the spandrils being filled with empty vases of potters'-clay, and round the exterior of its base are semicircular-headed windows, each of which is divided into two apertures of similar forms. Between every two piers is a hemicylindrical recess formed on each side of the octagon, and covered by a half-dome, the vertex of which is 48 feet from the pavement; each of these recesses contains two windows divided into three parts by two Corinthian columns supporting semicircular-headed arches. Between the piers and the exterior walls of the building are two corridors surrounding the whole, one above another, and each covered by a hemicylindrical vaulting. The upper corridor has a sloping roof of timber above the vault.

of St. Anthony, at Padua.

The Church of St. Anthony, at Padua, is in a mixed Gothic style, and is crowned by domes like that of St. Mark; but this building is particularly distinguished for two slender towers or minarets, which give it much the air of a Saracenic edifice.

The Cathedral at Pisa.

The Cathedral at Pisa, with the Baptistery and Belfry belonging to it, form a group of buildings not only the finest in Italy, but possessing in an eminent degree those features which particularly distinguish the Lombard-Gothic style of Architecture, and, therefore, claim a particular description. The Cathedral was built, in 1016, by Buschetto, a Greek or Italian artist, for it is uncertain which; its plan resembles a Latin cross, of which the principal part is 304 feet long, and 107 feet wide; and the transverse branch is 234 feet long, and 55 feet wide. The former is divided longitudinally into five parts, of which the grand nave is 40 feet broad, and 128 feet high; this is separated from the nearest lateral aisles by twenty-four Corinthian columns of Oriental granite, of which there are twelve on each side. Semicircular arches spring from the capitals, and carry smaller columns forming the front of an upper gallery appropriated to the women. The columns which separate the lateral aisles are smaller than those of the nave, but are raised on pedestals to an equal height. The nave is roofed with timber, but the aisles are vaulted and painted. The transept is composed of a nave 107 feet high, and two aisles, each 60 feet high, and formed by columns of the same size as those of the aisles before mentioned. In the intersection of the naves are four pillars supporting four great arches, above which is a polygonal wall adorned with eighty-eight columns supporting arches, and on this rests a corona of marble; above the corona is a cupola 70 feet high, the interior of which is lighted by one hundred windows The exterior of the wall on which the cupola is built is ornamented with two tiers of arches, of which those in the upper tier are small and crowned with decorated pediments with pinnacles between them; but these are probably of later date than the original structure.

The Western façade consists of five stories; the lower one is composed of seven arches supported by six Corinthian columns and two pilasters; the second contains nineteen arches, supported by eighteen columns and two pilasters; the third has nine arches in the centre, all of equal height; but on the right and left of these, where the façade is limited by the sloping roof of the galleries over the aisles of the nave, are columns which diminish in height according to the inclination of the roof. The walls of the central division of the nave are carried vertically above the level of these roofs, and terminate in a roof with sloping sides, forming a longitudinal ridge in the middle, and the corresponding part of the façade is ornamented with two tiers of arches, supported by columns as in the tiers below; the arches in the upper tier are supported by columns, which also diminish from the centre towards the extremities, on account of the inclination of the sides of the roof. The sloping sides of the pediment or gable are ornamented with foliage, supposed by Dr. Milner to have been added when the Cathedral was repaired after the fire of 1569, which burned down the roof from the cupola to the Western end. The arches and columns in the lowest tier of the façade are attached to the wall, but all those above are detached from it, and have a narrow open gallery in their rear.

Along the exterior of the walls of the nave and transept are three tiers of attached arches and pilasters, corresponding in situation with the lower, the second and fourth tiers of the façade. In the middle of the Eastern end of the Cathedral is a semicircular projection towards the exterior, ornamented with three tiers of arcades corresponding also with those of the Western front; this projection terminates at the height of the roof of the aisles, above which this face of the building is flat; it is ornamented with two tiers of arches, and terminates in a gable. Similar projections are formed at the extremities of the transepts. The whole edifice stands on a basement which is ascended by five steps. In pl. xvi. is a perspective view of this Cathedral. See also a superb Work on the Architecture of the Middle Ages, by Cresy and Taylor.

The Baptistery, at Pisa.

The Baptistery, which was begun, in 1152, by Diotti Salvi, is a cylindrical building of marble, 129 feet in diameter, and raised on three steps. On the exterior, are two Orders of Corinthian columns engaged in the wall, and supporting semicircular arches; the columns of the upper Order are more numerous than those of the lower, each arch below bearing two columns above it. Between every two arches of the upper row is a pinnacle; above each arch is a sharp pediment enriched with foliage, and over these is a horizontal cornice surrounding the building. Above the second story is a cylindrical part ornamented with semicircular arches, crowned by pediments; and between the arches are pilasters which carry a horizontal cornice like the former; over this is a pear-shaped cupola, 179 feet high, and covered with lead. The convex surface of the dome is divided by twelve ribs of copper which unite at the vertex, and these are ornamented with knots of foliage, or, as they are called, *crockets*, executed in marble; between every two ribs are windows ornamented with little columns and terminated by small open pediments. The whole forms a mixture of the round and pointed styles of ornament; the features of the latter, *viz.* the pinnacles and pediments, are generally supposed to have been introduced subsequently to the original construction of the edifice; but this seems doubtful, except so far as concerns the decorations which accompany them.

The dome is double, being composed of two shells, and the interior one is a frustum of a pyramid of twelve sides; its upper extremity forms a horizontal polygon, which is finished with a small parabolic cupola, having twelve small marble ribs on the exterior. The outer vault is of brick, of a hemispherical form, terminating above at the base of the small cupola, which, like a lantern, stands over the aperture. The height of the cupola from the pavement is 102 feet. The entrance to the Baptistery is by a grand doorway, and there is an interior descent by three steps round the building; the space between the steps and the wall was for the accommodation of the persons assembled to witness the ceremony of baptism.

Round the interior circumference of the Baptistery is an aisle or gallery, formed by eight granite columns and four piers, from which spring semicircular arches supporting an upper gallery; above this tier of arches, are twelve piers, on which rest the semicircular arches supporting the pyramidal dome. On the ground story are four entrances, and between each two, on the exterior, are five columns; that story is, therefore, surrounded by twenty. The capitals of these columns support semicircular arches decorated with foliage; above is a second story with semicircular arches, in the same style, resting on piers and leaving a gallery behind them which forms a walk round the building.

Mr. Cresy states, in Britton's *Architectural Antiquities*, vol. v., that above the floor of the inner gallery is an inscription showing that this part was rebuilt in 1278; the same gentleman adds, that the mouldings of the interior correspond with those of the Campo Santo built at that time by John of Pisa, and that one of the shields on the windows of the dome bears an inscription, dated 1396, to the memory of the operarius or architect; and he attributes to this person all the work in the pointed style, together with the domes.

The Cam nile, at Pi

The detached Tower or Belfry, which was built, in 1174, by two Architects, an Italian and a German, is of a cylindrical form, 50 feet diameter, and 180 feet high, and consists of eight stories of columns supporting semicircular arches, forming as many open galleries. It has a flat roof, and the upper story contains a peal of bells. A remarkable circumstance in this Tower, as well as in several other Italian Belfries, is that they have sunk on one side considerably; in the present instance so much that the top overhangs the base about 13½ feet. There is no doubt this has been caused by a defective foundation, and that it sank when only partly erected; for, on one side, at a certain height, the columns are made higher than on the other side, showing that the builders, after the failure, endeavoured to bring the upper part of the Tower nearer to a vertical direction. See pl. xvi.

The Ca Santo, Pisa.

The Campo Santo, or public burying-place, at Pisa, was built, in 1278, by an Architect of that city. It is a great quadrangle, 403 feet long, 117 feet wide, and surrounded by a corridor 32 feet broad on the interior of the enclosure, in which the bodies of the dead are deposited; the corridor is roofed, but the interior area is open to the sky; in the side of the corridor next to the area are semicircular-headed windows, which at first were simple apertures extending down to the pavement, but each has been subsequently divided into smaller apertures by vertical columns, which from the level of the foot of the arch form intersecting ramifications. These enrichments have been added to the structure by some later Architect; probably by Burgundio Taddi, who, in 1303, added new members to the exterior of the building; or by Antonio Jacopo, a Pisan Architect, who, according to an inscription on the North side, executed four open arches and twenty-eight windows, in 1464.

The Cathedrals of Orvietto and Sienna, the Churches of St. Francesco, at Pisa, and of St. Michael, at Lucca, are all similar in form and general style to the Cathedral at Pisa.

thedral at enna.

The Cathedral of Sienna, however, is distinguished by a mixture of the circular and pointed arches; and, therefore, resembles in some respects the Gotico Tedesco. Its construction is marked by some singularities; the centre of the dome is not over the centre of the intersection of the nave and transept, but is nearer the Western end. The dome itself, which has a pointed vertex, is raised upon a base of twelve sides, and this is supported on six pointed arches formed over a hexagonal plan.

e Cam- nile at cca.

The Bell-Tower, at Lucca, is a perfectly square prism, consisting of five stories in height, of which the three lower are ornamented respectively with one, two, and three semicircular-headed windows; over the windows in each story are small semicircular-headed ornaments like arches, and the upper story is crowned with notched battlements.

haracter the nstanti- opolitan hurches.

The Churches erected in the Eastern division of the Roman Empire appear to have been in the form of a Greek cross, on the plan; having the four arms divided into aisles by piers, ornamented with pilasters or columns, and covered by hemicylindrical or groined vaults, and the centre crowned by a large cupola or dome, supported by pendentives at the angles of the four central piers. Semicircular recesses were formed at the extremities of the arms of the cross, and covered with half-domes; sometimes small domes were placed about the principal or central one; over the intersections of the side aisles of the building, and above the aisles of the nave or of the transepts, or of both, were galleries for the accommodation of the female part of the congregation.

The Churches of Italy, which appear to have been the work of Greek artists, as those of St. Mark and St. Vitale, resemble in many points the Churches before mentioned; most of them are covered in the interior, at intervals, with mosaic-work, of which the figures are in colours on a gold ground. The ornamental foliage is long and pointed, and appears to be a corruption or modification of that on the early Greek rather than that on the Roman edifices, and the monogram of Constantine is frequently found on the walls. The arches are invariably semicircular.

aracters the Lom- d-Gothic urches.

The plan of the Lombard Churches was a Latin cross; the longer arm, in which was the principal entrance, was usually on the Western side, and at the extremity opposite the entrance was the apsis or semicircular recess. The interior of the Church is divided into one central and two or more lateral naves, by parallel ranges of columns in the direction of the length of the building. These columns support semicircular arches; and over them are the side walls of the central division, which are carried up to a considerable height above those of the body of the Church. The ceilings of the side aisles are covered by roofs sloping down towards the exterior, and that of the centre by a high-ridged roof forming a pediment or gable at each extremity. In general, these Churches have no galleries above the side aisles, and in this also they are distinguished from the Churches of the denomination last-mentioned; another distinction appears in the figure of the dome, which generally, instead of being hemispherical, is formed in faces rising from the sides of a polygon, and terminates with a pointed top. The principal decorations of the façades and side walls, on the exterior and interior, are ranges of small semicircular arches, which rise from columns or pilasters, and are either attached to the wall or stand before it so as to form galleries open towards the exterior. It must be observed that originally there were no buttresses or pinnacles about the walls, though these were subsequently added to the other features of the style.

It may naturally be inquired why such a profusion of arches should be employed on the exterior of a building merely for ornament; and, perhaps, the solution of this question may be found in the taste for open galleries, so prevalent in the ancient World, which shows itself in the peristyles and porticos of the ancient Greeks and Romans, and in the upper galleries of the Heathen Basilicæ. In the progress of improvement, a row of semicircular heads over the apertures between columns might, not unreasonably, be considered as more ornamental than a simple rectilinear entablature, which, at first, crowned those apertures; and, at least, by lessening the height of the columns themselves it would permit a smaller diameter, and thus give the arcade a light appearance. That which was employed in the interior of Churches would soon be adopted as an external feature either for convenience or ornament; and, as there is always a disposition in Man to carry every thing to excess, the arcades were soon multiplied till the whole appeared to be merely the frame of an edifice, to which buildings thus ornamented have been compared. The ornamental foliage on these buildings appears more rounded than that on the Greco-Italico Churches, and seems to have been more directly copied from the ornaments on the ancient Roman edifices.

The most ancient Churches of Italy have a lofty tower, detached from the building, but in its immediate vicinity, perhaps to distinguish the sacred edifices from other public buildings of the city; and in these were placed the bells which served to notify the times of prayer.

In addition to the Church itself it was necessary, in the early Ages of Christianity, to have a building in which the baptism of the people who were converted from Heathenism might be performed. This rite being performed by immersion, and the number of persons being considerable, because in general it took place only at the two most solemn festivals of the year, a spacious building for the purpose was required, and one was usually erected in the vicinity of the Church. The Baptisterium of Constantine is the earliest example of this species of building.

Among the ancient Romans a law existed that no one should be buried within the walls of the city; but after the establishment of Christianity, a practice arose of enclosing a piece of ground near the Church to serve as a place of public interment, and the enclosing walls were sometimes ornamented with features resembling those of the Church itself. The Campo Santo, at Pisa, which we have described, is one of those cemeteries.

The style exhibited in these Italian buildings seems to have been nearly the same as that which prevailed in the North of Europe at the same time, and the parent of that which followed it, and which flourished till the XVIth century. The latter was chiefly distinguished from it by a modified form of the arch, and an excessive enrichment of all its members.

Lombard Tombs.

In various parts of the North of Italy are some remarkable Tombs, which appearing to have been executed about the period of which we are now speaking, may not improperly be made to terminate this Chapter.

One of the most remarkable is that of Theodoric, at Ravenna; this has an octagonal basement, to the top of which are ascents by flights of steps supported on arches, and in one face are windows and a doorway, all with semicircular heads. Upon the basement appear to have stood small columns supporting semicircular arches, and forming a gallery about the body of the building like one of those in the Campanile at Pisa. The whole is crowned by a dome, 38 feet diameter, cut from one stone in the form of a segment of a sphere. The voussoirs, in the large arches of the basement, are notched in the Saracenic manner, and a Saracenic ornament surrounds the base of the dome. This work resembles the Mausoleum of Hadrian, from which, perhaps, it has been copied.

In the same, as well as other cities of that part of Italy, are small Tombs or Sarcophagi having semicircular ends, ornamented in various ways; some have the appearance of scallop shells, and others seem to be debased imitations of the ancient Greek fleurons. Such Tombs are to be seen in the Church of St. Apollinare, at Ravenna, which from its resemblance to those of the Greco-Italico style, must be of high antiquity. In the same place are others having their upper surfaces in the form of two curves, rising from the sides and meeting in a longitudinal ridge over the middle; at the extremities of the Sarcophagus the face is sunk and forms a panel with margins about it, the upper one of which has the appearance of a cuspid arch, and may have been one of the first objects from which the idea of that feature has been taken.

CHAPTER II.

Description of the principal Gothic Cathedrals on the Continent of Europe.

Few remains of Roman Architecture in the North of Europe.

Though the Architectural works of the Romans, executed in the North of Europe while they had possession of this part of the World, must have been numerous, yet it is remarkable that nothing remains of them except the pavements and other ruins which have been discovered under ground in various places; and which are insufficient to enable us to form an idea, beyond the vague one of magnificence, respecting the plan or construction of their edifices. So great has been the destruction perpetrated by the Heathen invaders of these Countries upon the monuments of Art left by the Romans, that it is believed every building was destroyed and the Art of construction so completely forgotten, that when the present Monarchies of Europe were established, the Princes were obliged to send to Italy, or to Constantinople, for artists to execute the edifices which they intended to build.

We purpose now to give a short account of the principal Churches erected in the North of Europe from the fall of the Roman power till the complete establishment of the Gothic style of Architecture; beginning with those of Germany, because there are still remaining in that Country portions of buildings which may lay claim to an antiquity superior to that of the existing buildings in any other, on this side of the Alps. Our descriptions are necessarily confined to the Ecclesiastical edifices, because these are the only buildings which have survived the lapse of Time and the destructive caprices of Man; and before we enter into any particulars respecting them, it will be necessary to exhibit the disposition of their parts, and the principal objects which serve the purposes of support and ornament; in order that the reader may be enabled to follow the description to more advantage. In pl. xviii. is given a plan of Litchfield Cathedral, which may serve to show the figure and divisions of the kind of building now to be considered.

General plan of the Northern Gothic Churches.

The Latin cross was the form of plan adopted in the Gothic Churches of Europe, except those of small dimensions, in which the plan was frequently bounded by a simple rectangle; and some of the principal Cathedrals, which had two parallel transepts, both crossing the body of the Church at right angles, and nearly dividing its length into three equal parts. The nave, and sometimes also the transept, was divided into three parts longitudinally by two parallel rows of columns; but occasionally the former was divided in a similar manner into five parts. The columns were at first simple, but afterward, they consisted of several small shafts united in one cluster, from the capitals of which sprang a longitudinal row of arches on each side of the central division of the nave or transept; these were at first semicircular, and subsequently, each consisted of two segments of circles, rising vertically from the columns, and meeting in a point at the top, over the middle of the interval between the columns. The lateral aisles were lighted by windows in the walls; and their ceilings which, in some cases, were on a level with the crowns of the arches before mentioned, were covered exteriorly by an inclined roof, on each side; vertically over the arcades of the nave were raised walls to a certain height, supporting in general a groined vaulting over the central division, and this was covered by a roof which formed two inclined planes meeting in a ridge above. At the intersection of the arms of the cross a central tower was raised upon four arches to a still greater height; this, which occupied the place of the cupola in the Southern Churches, was terminated by one tall pyramid or spire, or by a flat roof with a small pyramid or pinnacle at each angle of the tower. At first the great tower, which in the Italian Churches was at a distance from the building, was attached to the Western extremity, and was also carried considerably above the roof; afterwards, in the Cathedrals, two such towers were frequently raised, one on each side of the nave at the Western extremity, and, in this case, the principal entrance was between them.

In the Cathedrals there was commonly formed above the ceiling of the lateral aisles of the nave and transept, one, or even two tiers of galleries, with open arcades in front vertically over those below, and lighted by windows in the walls. The principal arches of these galleries were commonly divided into two or three apertures, and hence, probably, the galleries obtained the name of *triforia;* we have said that in the primitive Church they were intended for the female part of the congregation; subsequently they served for the stations of persons who came to witness the grand processions which occasionally took place in the Cathedral; and in Conventual Churches they were appropriated to the nuns who assisted at the celebration of divine service; and, thence, they had the name of *nunneries.* Above these galleries were the roofs of the lateral divisions of the Church; the walls over the arcades, which were raised still higher, were perforated by windows, and this was called the *clere* or *clair* story. The ceilings of the interior divisions of the Church were usually constituted by a groined vaulting, often of a complex nature, and ornamented with mouldings, on the ribs formed at the ridges of the groins.

The name of *nave* is generally applied to the Western part of the Church; near the centre is the *choir*, which is separated from the nave by a *screen*, and on the Eastern side of the choir is the *sanctuary*, or place of the altar. The choir, and sometimes all the Eastern part of the Church, was appropriated to the clergy; and hence it had the name of *presbytery*.

Within the side aisles of the nave were sometimes enclosures serving as oratories; and frequently, in the rentrant angles, between the body of the Church and transept, were recesses from the latter, serving as Chapels and dedicated to particular Saints. But beyond the choir, towards the East, and communicating with the nave and transepts by the lateral aisles, was frequently a building constituting a Chapel dedicated to the Virgin, and hence called *Our Lady's Chapel:* the Eastern extremity of this Chapel generally terminated the whole building on that side. This, however, was not always the situation of the Lady Chapel; for, at Canterbury, it is placed in a transept, and at Ely, it forms a distinct building. Immediately within, or in front of the Western entrance, was frequently a porch, which in the primitive Church served as a station for the penitents; subsequently, in Conventual Churches, this was called the *Galilee*, and in it the monks were allowed to see their relatives.

The oldest Churches of the North had their walls ornamented, rather than strengthened, by a sort of buttresses with plain fronts, and projecting but little from the faces of the walls, so that they resembled pilasters without bases or capitals. But in later times, at the angles of the Church, and frequently between the windows along the walls, were placed massive buttresses which, in both situations, generally rose above the tops of the walls themselves, and were terminated either in small pediment heads or in pinnacles. When the side walls over the interior arcades rose very high above the side walls of the aisles, buttresses in the form of arcs of some curve were extended from the top of the vertical buttresses, over the roofs of the aisles, to the top of the former walls; these are what were called *flying buttresses*, and they served to resist the lateral pressure of the vaults in the lofty roof.

The Western extremity of the roof terminated in a pediment or gable, the sloping sides of which, as well as the horizontal summits of the side walls of the building, were sometimes ornamented with battlements. In the Western façade of the building, and in the Northern and Southern façades of the transept, was often a great circular window; but commonly the Western front, between the towers, was occupied by one great window, with vertical sides, and a top in the form of a pointed arch. All the windows, the breadth of which was considerable, were divided into two or more apertures, or *lights*, as they were called, by vertical posts, or *mullions*, the tops of which branched off to the right and left, generally forming several intersections; and, when the height of the window was great, it was divided into two or more parts by horizontal bars, mullions, or transoms. Over the extradosses of the windows were frequently formed rectilinear or curvilinear pediments, the form of the latter coinciding sometimes entirely with that of the curved head of the window, in which case it took the name of a *label*, a *hood*, or a *weather-moulding;* but sometimes the coincidence only took place in the lower part of the head of the window, the upper part of the pediment turning off so as to form a curve of contrary flexure on each side; and these met in a point above the apex of the window.

Frequently there are formed in the walls ornamental apertures, consisting of three or more segments greater than semicircles, disposed about the circumference of a circumscribing circle, and meeting each other in cusps projecting towards the centre; these, from their resemblance to leaves, have, according to the number of the segments which compose them, the names of *trefoils*, *quatrefoils*, &c.

The intersecting ribs of the groined ceilings in the interior, and the branching mullions of the windows, form what was called *tracery-work*. Along the sloping sides of the gables of the building, of the archivolts or pediments of windows, and the ridges of spires and pinnacles, were frequently placed sculptured leaves, at intervals; these were called *crockets*, from their curling forms, and the summits of pediments and pinnacles were frequently terminated by a knot of foliage which was called a *finial*. The tombs and shrines in Churches, and the niches for statues on the exterior and interior faces of the walls, were generally covered with canopies adorned with sculpture of the most elaborate and delicate execution, which received the name of *tabernacle-work*.

Attached to the Cathedral was the Baptistery, a building expressly erected for the purpose, as was the case in Italy. Its plan was frequently polygonal, and its roof was crowned by a tall pyramid or spire rising from the tops of the walls.

On one side of the nave, generally on the South, were situated the cloisters, a quadrangle which, like the interior peristyles in ancient edifices, had its centre open to the sky; surrounding this was a gallery, with an arcade or range of windows towards the centre, and covered above by a groined vaulting either plain or ornamented. It served as a place for exercise, and communicated with the nave of the church by two entrances, for the convenience of the processions. On the exterior sides of the gallery, except on that which joined the Cathedral, were the apartments of the Ecclesiastical Officers; or, if the Church was conventual, the apartments of the monks, the Refectory, and the Common parlour. On one side of the nave was the Consistory Court, and the Chapter-house, where business was transacted; and, near this, was the Library and Treasury, where the Church plate was kept. Besides these buildings there was an Infirmary, an Almonry, and apartments for the entertainment of visitors. The whole, including the gardens, stables, and offices, was surrounded by a high wall, with battlements and towers.

The oldest Northern Churches are of the time of Charlemagne.

If we leave out the doubtful evidence afforded by some very small portions of one or two French Churches, for which a higher antiquity has been claimed, we shall find that the construction of none of the Ecclesiastical structures beyond the limits of Italy can be referred to a period earlier than the time of Charlemagne. From this time is to be dated the reestablishment of something like order in the Governments of the North of Europe; and, by the influence of the Clergy, a great portion of the wealth of the States was then directed to the building of magnificent edifices for Religious purposes. Several of these, erected during the reign of that Monarch, are said to have had great resemblance to the Churches executed in the Eastern Empire; and, like them, to have been proofs of the low state of the Arts in those days.

According to Dr. Moller, part of the Cathedral of Aix la Chapelle, and the portico of the Convent of Lorsch, near Worms, are the only buildings of the time of Charlemagne which are extant in Germany. In France, all the Churches of that period having been subsequently rebuilt, it is become impossible to determine what part, if any, of them remains in its original state.

The portico at Lorsch. The Church attached to the Convent at Lorsch was founded by Pepin, and burned down at the end of the XIth century. It was presently, however, rebuilt, and if this second Church, the ruins of which still remain, resembled the ancient one, it must have consisted of three longitudinal divisions formed by two rows of pillars supporting semicircular arches; the middle division is higher than the other two, and the windows, which are small, have semicircular heads. In front of the Church was a quadrangular peristyle or arcade, at the entrance of which is the portico above mentioned. The plan of this portico is rectangular; its length is 35½ feet and breadth 26 feet; in each of the longer sides are three open semicircular arches formed by voussoirs springing from imposts on the piers. The faces of the piers are ornamented with half-columns of an Order resembling the Composite, and having Attic bases; the height of the column, including the base and capital, is equal to 12.79 feet, and its diameter to 1.176 feet. Over these, is a horizontal band, ornamented with sculptured foliage, and supporting an upper story; in front of which are ten fluted Ionic pilasters, the capitals of every two of which are connected by the two inclining sides of a rectilinear pediment, and above this is a cornice with modillons. This upper story, and the staircases which lead to it, have, however, been erected at a later time.

Cloisters at Aschaffenburg. The Cloisters also of the Abbey Church, at Aschaffenburg, seem to have been erected about the same period. The corridor surrounding the quadranglar area is open towards the interior, and consists of square piers, between every two of which are semicircular arches springing from the half-columns attached to the piers, and resting upon columns in the intervals. These columns are 5 feet high and 6 inches in diameter, with a sort of Attic base, and a capital ornamented with foliage, the height of which is about 18 inches, from the astragal to the top of the abacus. See pl. xv.

St. Castor, at Coblentz. The Church of St. Castor, at Coblentz, part of which appears to have been built in the XIth century, is perhaps one of the latest of the German Churches which were executed with semicircular arcades in the interior; the arches on each side of the nave have this form, and spring from square piers, to each face of which a half-column is attached. A pier thus ornamented may be considered as one of the steps leading to the clustered columns, which sometime afterward became common in Europe.

Cathedral at Worms. During the XIth century, a change seems to have taken place in the style of the German Churches, both with respect to the plan and to the forms of the features, of which change the Cathedral at Worms, executed in 1016, is an example. The plan of this building has the figure of a Latin cross, and the body is divided into three parts longitudinally, by arcades springing from square piers, the faces of which are ornamented with columns. Semicircular arches are the prevailing features on the exterior, but in the interior, the arches are alternately semicircular and cuspid or pointed; the latter being formed of two segments of circles, the radii of which are nearly equal to the span or breadth of the aperture, and their centres in a horizontal line passing through the tops of the piers. This difference in the forms of the arches in the same building, seems to indicate a struggle between the ancient style and one recently invented; and if any dependence can be placed on the date of the erection of this Cathedral, or if the pointed arches have not been introduced at some subsequent period; (and the regularity of their distribution renders it probable that they form part of the original design of the building;) it must be concluded that this is one of the most ancient examples in which that species of arch occurs. Both the central and side aisles of the nave are covered by a groined vaulting. The Church has two chancels, one at the Eastern extremity beyond the transept, terminating in the interior in a semicircle, but in the exterior in a rectilinear face; the other, at the Western extremity, probably of later date than the rest of the Church, terminates in three sides of an octagon. The present entrance to the Church is by a doorway in one of the side walls of the nave.

Church Gelnhau The Churches of Germany erected during the XIth and XIIth centuries present the same mixture of semicircular and pointed arches; but subsequently to that period, the former style seems to have been superseded by the general use of arches of the pointed kind, and, occasionally, there occur apertures the heads of which are formed by the meeting of three segments of circles in the manner of trefoils.

One of the first of the German Churches executed in the new style is that of Gelnhausen, in Swabia, which is supposed to have been built in the beginning of the XIIIth century. Its form is that of a Latin cross, and beyond the transept, the Eastern end, which is flanked by two octagonal towers with plain buttresses at the angles, terminates in three sides of an octagon. In the faces on the exterior of the Eastern extremity are long narrow windows, like those in the Constantinopolitan Churches, but with cuspid heads of the lancet kind; and above them are ornamental recesses of a semicircular form. Over these is a row of small columns, attached to the wall, and supporting arches with trefoil heads; and in the wall, between the columns, are quatrefoil windows inscribed in circles: above the arcade, on each face of the octagon, is a small window divided into two apertures, each of which is terminated above by a trefoil head. Each face is crowned by a rectilinear gable, under the sloping sides of which are *nebulæ*, or semicircular ornaments like small arcades, of the kind exhibited in the Lombard Churches, but without the columns; and the whole octagon is crowned by a lofty, plain, pyramidal roof. The two flanking towers are divided into five parts horizontally by rectangular panels on each face, the upper part of the panel being ornamented with semicircular notches like those above mentioned; each face is crowned by a small pediment, and the tower is terminated by a small pyramidal spire without ornament.

The central tower of the Church is also octagonal, and contains two tiers of windows; some of those in the lower tier have double, others triple apertures, separated by vertical bars, or mullions, and each is formed with a trefoil head; those in the upper tier have double apertures with cuspid heads. The middle aperture, in each of the three light windows of the lower tier, is higher than that on each side; and the heads of all the three are inscribed in one general semicircular top. This tower is also crowned with a plain pyramidal spire. The bases and capitals of the pillars in this Church are well executed. See pl. xv.

Cathe- e, at Op- heim.

The Church of St. Catherine, at Oppenheim, is also in the form of a Latin cross, consisting of a rectangular nave and transept. The chancel at the Eastern end terminates, on the plan, in five sides of an octagon, and in the rentrant angles between the transept and chancel are recesses formed each by three sides of an octagon. Like several other Churches in Germany, there is a second chancel, at the Western extremity, which terminates also in three sides of an octagon, and the entrances are on the North and South faces of the transept. According to a manuscript Chronicle, says Dr. Moller, the nave and Eastern chancel were begun in 1262, and finished in 1317. The Western chancel was consecrated in 1439.

The whole length of the Church, including the two chancels, is 268 feet, of which 92 feet are taken up by the Western chancel, the breadth of which is 46 feet. The length of the nave is 102 feet, its breadth 86 feet, and it is divided into three parts by two rows of pillars, consisting each of several columns clustered together. The length of the transept is 102 feet from North to South, and its breadth 31 feet; and the two side aisles of this Church are occupied by small Chapels, or Oratories.

At the extremities of the nave on the Western side are two towers on square bases, each divided into four stories, and crowned by an octagonal spire; and in the three upper stories are round-headed windows, with single or double apertures separated by a pilaster. The lower windows in the sides of the nave occupy all the spaces between the buttresses; they have no mullions, and are crowned with pointed arch tops. The buttresses have no pinnacles, and their exterior faces are ornamented with panels. The upper windows are crowned by rectilinear pediments, ornamented with crockets, and there are slender pinnacles between them. The doorway in the South transept is terminated by a pointed arch, and there is one lancet-headed window above. The face of the transept is terminated above by a gable, within which are seven small pediments, and at the angles of the transept are buttresses which terminate in pinnacles. The sides of the half-octagon at the East end have lancet-headed arches between the buttresses, and the latter are without pinnacles. A large circular or rose-window is placed in the Western façade; this is one of the most beautiful of its kind, and is formed of twenty small leaves, which are grouped under five large ones. The tower over the centre of the cross is octangular; each face contains a pointed window, and is terminated by a pediment, and between the latter are pinnacles. The centre is covered by a small cupola. The clustered columns of the nave are similar to those in the Church of St. Castor, at Coblentz; they consist of four large and four small half-columns united together, and seem to have been derived from the practice of rounding the angles of a square pier, each face of which had been adorned with an attached half-column.

edral at sburg.

The Cathedral of Strasburg, which, for its high degree of enrichment, holds the first rank among the Gothic Churches of the Continent, was begun in 1277, by Erwin de Steinbach, and brought to its present state in 1439. Its plan is a Latin cross, the Eastern end terminating in a semicircle in the interior, but outwardly in a rectilinear face; and in the rentrant angles between the nave and transept are two small Chapels. The length of the body of the Church is 324 feet, of the transept is 150 feet, and the height of the vault is 98 feet; the nave is divided longitudinally into three parts by two rows of clustered columns.

The Western façade is divided into three parts, vertically, by buttresses, the faces of which are ornamented with canopies and statues; each of the three portals is crowned by a rectilinear pediment, highly ornamented, and the diverging sides of the doorways are filled with statues. The other windows of the façade are of the pointed kind, and they are divided into three or four apertures by slender pillars, which branch at top to form intersecting arches, and the whole façade is crowned by a horizontal cornice. The Cathedral, which has never been completed, has but one spire, crowning the tower at the North-West angle; this is of a pyramidal form, with pointed windows and trellis-work. Its height is 414 feet, which is greater than that of any other Church in Europe.

These examples will be sufficient to give an idea of the styles of the German Gothic Churches: we proceed next to describe some of the Churches of France which were executed within the same period.

The first Churches in France.

The earliest Churches erected in France are supposed to have been those built at Paris, by Clovis and his son Childebert, about the end of the Vth and the beginning of the VIth century: their forms were probably the same as those of the Churches of Italy, and, no doubt, of other parts of Europe at the same period; but all that the advocates for the antiquities of the French edifices can assert to be left of them—and of the assertion who can vouch for the truth?—is the Tower of St. Germain des Près, at Paris, and that of St. Peter, at Chartres. The vault of the Crypt under the Eastern end, and the principal entrance of the present Church of St. Denys, near Paris, are supposed to have been part of the works of Pepin and Charlemagne, by the latter of whom the Church was completed in the year 775.

The Church of St. Germain, which was begun by Childebert, about A. D. 557, is said to have been extremely magnificent. It was cruciform on the plan, and the roof was sustained by marble columns; the pavement was of rich mosaic, the roof externally and internally was covered with gilding, and the walls were painted on a gold ground.

The Church of St. Denys, originally built by Dagobert, resembled, it is said, that of St. Germain, both in its general form, and in the profusion of mosaic work with which it was decorated. This was taken down, and one was constructed by Pepin and Charlemagne, on a greater scale, which was subsequently destroyed by the Normans. The form and ornaments of these buildings sufficiently show that they were copied from the Basilican Churches of Rome, or from the later erected edifices of Constantinople.

Destruction of the Churches by the Normans.

The invasions of France by the Normans considerably impeded the progress of Architecture in that Country; and though several edifices seem to have been raised in those troublesome times, which continued from the VIIIth to the XIth century, yet a greater number was destroyed by the Barbarians. But in the beginning of the XIth century, two of the greatest works of France, *viz.* the Cathedral of Chartres and the Abbey of Clugny, were erected. Both of these edifices have the form of a cross on the plan; the length of the first is 420 feet, and its breadth 108 feet; on each side of the choir the aisles are double, and round the interior of the transept they are single. The Abbey Church of Clugny, which is, perhaps, the most interesting of the ancient Ecclesiastical monuments in France, was erected about the year 1056; and about the same time the Churches of St. Germain des Près and St. Genevieve, which had been destroyed by the Normans, were restored by Robert the Pious. The style of all these buildings is the same as that which generally prevailed in Europe at the same time, *viz.* the Romanesque, or as it was subsequently called, the Norman; and which is sometimes characterised as an imitation of the Lombard-Gothic.

Restoration of the Churches in the XIIth century.

But soon after this time, that is in the beginning of the XIIth century, the cuspid arch appeared in the buildings of France, mixed, as in Germany, with the round Lombard or Norman arches; and, probably, some of the earliest examples of it are contained in the Church of St. Denys and the Monastery of the Knights Templars, the building or restoration of each of which was begun about the year 1137. Towards the end of that century, the Eastern part of the Cathedral of Notre Dame, at Paris, the Choir of the Cathedral at Lyons, and the Collegiate Church of St. Nicholas, at Amiens, were also begun, though they were not finished till long afterward; and from this time the round arch and heavy pillars of the Norman style entirely gave place to the pointed arch and clustered column.

St. Germain des Près.

The Church of St. Germain des Près, after having been thrice burned by the Normans, was rebuilt by the Abbot Morard, in 1014, and part of the work executed under the direction of that Prelate is still standing; the new Refectory was begun in 1236, and the Chapel of the Virgin in 1244. The exterior of the building is not remarkable for any thing but its antiquity; the Western end is terminated by a tower which, it is pretended, is part of the edifice constructed by Childebert, and there are two other towers in the angles formed between the body of the Church and the transepts. The interior is low and mean, and lighted by small semicircular-headed windows. Those columns which have stood since the time of Morard are of an Order resembling the Corinthian, but the capitals of some of the others are composed of birds and griffins. The arches which spring from the columns in the body of the Church are semicircular, but those at the Eastern extremity are of the pointed form; either these were erected at a subsequent period, or, as Mr. Whittington supposes, they were originally made so in order that they might have the same height as the others with a smaller span.

St. Denys.

The Church at St. Denys was restored, after its destruction by the Normans, by the Abbot Suger, who was elected in 1122: and both the Western front and part of the Eastern arcade are ascribed to this Prelate; it must, however, be very doubtful what part was really executed by him, because it is impossible to ascertain what remained after the destruction caused by the fire in 1231. The oldest columns are in the Lombard style, but the pointed arch occurs in all that part of the structure which is supposed to have been executed in the time of Suger. The nave, choir, and transept were built about the middle of the XIIIth century. The spire is lofty and perforated by round-headed windows; the windows of the body of the Church are nearly 40 feet high, and are divided by four vertical mullions terminating in arches, which support three sixfoils or roses delicately sculptured. The walls are supported laterally by perforated or arched buttresses, and the portal is crowned by a semicircular arch.

Notre Dame at Paris.

The Cathedral of Notre Dame, at Paris, is said to have been begun by Childebert, in A. D. 522; but, like most of the Churches in the North of France, it was destroyed by the Normans. The present edifice was founded in 1010, and was, probably, completed about the middle of the XIVth century. The body of the Church is 466 feet long, and 180 feet wide, and of a rectangular form, except that the Eastern end terminates in a semicircle; and the building is remarkable for having no transept, from which we may, perhaps, conclude that the original plan has never been altered. The interior arrangement is extremely simple, its whole length being divided into five aisles by four rows of Lombard columns, and there are rectangular recesses along all the interior of the side walls, and of the Eastern extremity.

In the Western façade are three portals crowned by pointed arches of small elevation above the foot of the curve, and above these is a horizontal row of recesses with trefoil heads containing statues. Over these, in the centre of the façade, is a great circular window, and on each side a double window inscribed in a pointed arch, with a quatrefoil ornament over the mullion. A horizontal row of pointed arches on slender pillars adorns the top of the body of the Church; on the exterior, and over each extremity of the façade, is a tower with a flat roof. The style of the whole is heavy, and in some parts it is excessively ornamented, while other parts are much too plain.

Cathedral at Rheims and Amiens.

In the beginning of the XIIIth century the two most splendid Ecclesiastical edifices of France were erected, *viz.* the Cathedrals at Rheims and at Amiens. The first has the form of a Latin cross, on the plan, the whole length of which from East to West is 492 feet, and breadth between the Northern and Southern faces of the transept is 190 feet. The interior of the body of the Church is divided into a centre and side aisles by two rows of columns. The width of the transept, from East to West, is 98 feet, which is equal to that of the body of the Church, and this is divided into three parts by two rows of columns in a Northern and Southern direction. Beyond the transept, towards the East, are two rectangular Chapels, one on each side, and five recesses, disposed in the circumference of a semicircle, terminate the building at that extremity.

The Western façade has three entrances crowned by very lofty pointed arches, and over each is a pediment ornamented with crockets; the buttresses of the front are carried up between the pediments, and terminate in slender pinnacles, ornamented in a similar way. Between the pinnacles, and over the portal of the centre, is a grand circular window, with radiating mullions, inscribed in a pointed arch. At each extremity of the façade is a square tower, 270 feet high from the pavement, with a low pinnacle at each angle.

Mr. Whittington considers this edifice as the finest piece of Gothic Architecture in the World for its airiness and delicacy; he observes that all the heavy magnificence is below, and the lighter ornaments are towards the summit. The portal is superb, and in good proportion with the rest of the building; and the pinnacles, which are finished with figures, flowers, and crosses, are the most beautiful of their kind.

The same gentleman, speaking of the Cathedral at

Amiens, characterises it by its highly-pointed arches circumscribing equilateral triangles, and its highly-pitched vaulting only ornamented by the diagonal ribs which spring from the columns of the nave. On each side of the choir are double aisles, and in the Eastern extremity is a semicircular colonnade. In the Western front is a magnificent portal covered with sculpture representing Saints, Prophets, and Martyrs; the walls are supported by arched buttresses with ornamental perforations, and between these are two ranges of windows; each window divided by three vertical mullions, surmounted by the same number of roses, and crowned by a pediment ornamented with trefoils. In the Western front, and in each face of the transept, is a beautiful circular window.

ncient hurches in ormandy,

The old Churches of Normandy retain, at present, many features of that style which was introduced from Germany into France and England, *viz.* the semicircular arches, the short and thick pillars with rudely sculptured capitals, and the waving mouldings of the archivolts. In Cotman's *Architectural Antiquities of Normandy*, are many good specimens of the style in which those buildings were executed, and from that interesting Work we have taken the following particulars.

f Lery,

The interior of the Church of Lery, near Pont L'Arche, has a very ancient appearance, and affords evidence that this building is one of the first which was erected in the Country after the conversion of the Normans, even if it is not one of the few of an earlier date which escaped the ravages of that people. The body is divided into a centre and two side aisles; the former is covered by a hemicylindrical vault, and the side walls are supported by semicircular arches springing from columns, which appear about a diameter and a half above the ground; the capitals of these columns have little ornament, and a horizontal string extends along the nave above the crowns of the arches.

Colomby,

The Church of Colomby, near Valogne, which is of later construction, appears to be one of the first examples in which the lancet arch occurs; along the sides are nine such arches with plain buttresses between them. Over the centre is a tower with four pinnacles at the angles and an octagonal spire between them. At one extremity is the doorway with three narrow lancet-headed windows, and at the opposite end is one large window with a cuspid head.

St. ephen, Fecamp,

The circular window is found in the Church of St. Stephen, at Fecamp, but divided into four parts by three vertical mullions; it is placed in the interior of a semicircle which springs from an ornamented pier on each side. In the same Church are arcades, consisting of one large and one small arch, with semicircular heads joined together; the archivolts and jambs are ornamented with a sort of embattled fretwork, and the part where the two archivolts unite is supported by a short column.

umieges,

The Abbey Church of Jumieges is a good example of the mixture of the Norman with the later style. The outer doorway of the porch is crowned by a pointed arch with Norman mouldings, but the inner doorway has a semicircular head. In the Western front are two towers on square bases, in which are semicircular-headed doorways with voussoirs springing from pillars, and above, are two tiers of tall semicircular arches, of which the upper is supported on columns like those on the exterior of the Cathedral at Pisa, and the lower on plain piers. These towers end in pyramidal spires.

ouviers.

Lastly, in the South porch of the Church of Louviers near Rouen, are two pointed arches which meet together and form a pendent cusp in the middle. The windows in the sides have also pointed tops; the roof is hemicylindrical; and the whole Church is richly ornamented with tabernacle-work.

Churches were early built in Poland and Russia.

Christianity is supposed to have been propagated in the North-East parts of Germany, in Poland, and in Russia by Missionaries from Constantinople; and it is, probably, to the influence of some of those Ecclesiastics that we are to ascribe the erection of the Gothic Cathedrals at Tver and Novogorod; this last is said to have been built in the year 988. Churches of considerable magnitude, and of that style which superseded the Roman Architecture, must, therefore, before the end of the Xth century, have been erected from one extremity of Europe to the other.

The Northern style of Gothic Architecture introduced into Italy.

That species of Architecture which subsequently to the erection of the Cathedrals of Pisa, Orvietto, and others of the same date, prevailed in almost every Country beyond the Alps, made its way into Italy, and many Churches were constructed according to that style with certain modifications. Of these the most important is the Cathedral of Milan, which was built in 1336. This building is of white marble, and its plan is in the form of the Latin cross, the transept, however, extending but little beyond the side walls of the Church. The whole length from West to East is 490 feet, and the breadth 295 feet; and at each extremity of the Western façade is a square tower, 43 feet long in each direction. The nave, which is 279 feet long, and 197 feet wide, is divided into a central and four side aisles by four rows of columns, and is lighted by five cupolas; the transept also is divided into a central and two side aisles in the direction of its length, and the Eastern extremity of the Church is terminated by three sides of an octagon.

Cathedral of Milan.

The Western façade is crowned by a great gable or pediment, extending over the nave and side aisles; the apex is 170 feet from the pavement, and the sloping sides are ornamented with tabernacle-work. The towers at the extremities of the façade are 295 feet high, and are each divided horizontally into six parts, which gradually diminish in breadth upward, and the last forms a small pyramidal spire. The faces of the towers are covered with tabernacle-work and statues supported on corbels; and in the third story from the bottom is a window, divided into three parts by mullions, and headed by a cuspid arch. Between the towers the façade is divided into five parts vertically by buttresses, ornamented with statues on corbels, and terminating in lofty pinnacles. The central tower is similar to those on the Western façade, and about 400 feet high, and every tower and pinnacle is terminated by a statue. The roof is covered with blocks of marble so closely connected together that they appear to constitute an entire piece.

The windows and doors of the Western front do not accord with the style of the rest of the building, and have been executed at a late period; the former have semicircular heads inscribed in rectilinear architraves both horizontal and vertical, and are crowned by rectilinear or segmental pediments of which some want the horizontal cornice.

The pointed arch had been introduced into Italy before the period of the erection of this edifice, and examples of it may be seen in the Cathedrals of Orvietto and Sienna, though it did not become a general feature till that time. Many beautiful and curious specimens of the pointed Architecture occur in Italy, particularly

Architecture.

at Verona, Vicenza, and Viterbo; and we may add that the Cathedral of Florence, though erected partly under the influence of the revived Roman style, is connected, by the form of its cupola, with the Gothic edifices of the Country.

Cathedral of St. Lorenzo at Genoa.

The Cathedral of St. Lorenzo, at Genoa, presents a singular mixture of styles; on each side of the nave are Corinthian columns with pointed arches springing from them; over these is a horizontal entablature, and above the latter a semicircular arcade springing from piers and columns alternately. Both the exterior and interior of the building are fancifully adorned with alternate courses of black and white stone in stripes.

Cathedral at Palermo.

The Cathedral at Palermo is ornamented with intersecting pointed arches, and its entablature is crowned by battlements which together form a serpentine line. From the body of the Church rise four towers, in the faces of which are rows of small semicircular arches supported on columns like the ornaments of the Pisan Architecture, and the towers finish with Gothic pediments and pinnacles. In the second story of the porch of the same Cathedral there are three pointed arches supported by single columns: above the arches is a horizontal entablature and a general pediment. The walls are inlaid in the manner of the Saracenic work, and Mr. Forsyth observes that the style of the whole building resembles that of the Moorish-Gothic.

Spanish Churches.

We are but little acquainted with the Architecture of the Churches raised during the Middle Ages in Spain; but that little indicates a style which is compounded of the Saracenic and of that which prevailed in Europe after the introduction of the pointed arch. From the description given by Mr. Swinbourne, it appears that the Cathedral at Seville, which was built near the end of the XIIIth century, is 420 feet long, 273 feet broad, and 126 feet high. The choir is placed in the centre of the Church; all the rest of the building is cut up by narrow aisles, and the ornamental parts are clumsy imitations of models left by the Moors. At one angle stands the *Giralda* or belfry, a tower of brick 50 feet square, and 350 feet high, of which all the part from the ground to the height of 200 feet was built by the Moors about the year 1000, and is adorned with sculpture more simple than that which was generally executed by this people; the rest has been added since. within it is a winding staircase of easy ascent, and wide enough for two horsemen to mount abreast more than half way to the top.

Cathedral at Seville,

at Burgos,

The Cathedral of Burgos, which was built in 1221, is described as being equal to the best specimens in Europe of the kind called Gothic, and as having some resemblance to York Minster. At the Western or principal front are two steeples ending in spires; on the centre of the edifice is a large, square tower adorned with eight pinnacles, and on the Eastern end is an octagonal building crowned by a pyramid. The arches and foliage are executed in the most elaborate and finished manner.

at Batalha, in Portugal.

A splendid example of the Gothic style exists in the Church at Batalha, in Portugal, which was erected, in 1388, under the direction of a native of Ireland. According to the description of the edifice, given by Mr. Murphy, its plan resembles a Latin cross, and the transept is near the Eastern end; the interior is divided by columns into a nave and two side aisles, and the Eastern end terminates in three sides of an octagon. The nave and aisles are equally high, the vaults of both are groined, and the ribs spring from clustering pillars. There are two tiers of windows in the side walls with cuspid heads; those of the lower tier have their radii of curvature equal to two-thirds of the span, and those of the upper tier have them equal to three-fourths. The windows are splayed towards the interior, and the sides are adorned with many small columns, from which, stems proceed and meet at the top of the aperture; each window is divided into three parts by upright mullions; each part ends in a trefoil head; and between the tops of these and the intrados of the arch are six quatrefoils. The windows of the chancel are long and narrow, and terminate in lancet heads. The walls of the body of the Church are crowned by battlements of open-work with pinnacles. The tower is of an octagonal form, and above it is a small spire ornamented with open-work. This building may be considered, says Dr. Milner, as a pleasing variety of the Gothic Architecture, but it is not to be put in competition with many of the contemporary buildings in other parts of Europe, on the general principles of sublimity and beauty.

Having brought the Ecclesiastical Architecture of the Continent down to the time when the pointed style was generally prevalent, we proceed to describe that of England during the same period.

CHAPTER III.

Principal Gothic Edifices in Britain.

Ancient Churches at Canterbury,

As early as the beginning of the IIId century of the Christian Era, a Church is said to have been built at Canterbury by Lucius the first Christian King in Britain; and we have the authority of Bede for saying that when St. Augustine established himself in that city, about the year 600, the Church was dedicated to Christ. In the XXXIIId Chapter of his *Ecclesiastical History*, we are informed that, near the city, King Ethelbert built a Monastery and Church, which he dedicated to St. Peter and St. Paul, and in which the Kings and Bishops of Kent were to be interred.

The latter Church was, probably, built of timber, and it is by some supposed to have been divided longitudinally into three parts lying East and West; for according to Bede's History, (book ii. ch. iii.) St. Augustine and some of the succeeding Bishops are said to have been buried in the Northern portico, which has been supposed to mean the Northern aisle, and two Bishops are stated to have been buried in the body of the Church, because the portico or aisle would contain no more bodies. But Mr. Wilkins, in the *Archæologia*, (vol. xiii. p. 290,) is of opinion that the *porticus* mentioned by Bede, instead of being an aisle, was a portion of the body of the Church cut off at the Western extremity, as has been done in the Church at Melbourne, in Dorsetshire; and he thinks it likely that the British Churches of that Age, were not divided by pillars or arcades. There is nothing, however, to disprove the fact of such a division, and we find that both pillars and arches are mentioned in descriptions of the Anglo-Saxon Churches, by writers of the VIIIth and following centuries.

at York,

About the same period Churches were erected in the Northern parts of the Anglo-Saxon dominions; for, in 627, Edwin, King of Northumberland, was baptized at York, by Paulinus, in a temporary building of timber;

and immediately afterwards a Basilica of stone was erected in the same place. In the following year Paulinus visited Lincoln, where he converted Blecca, the Præfect, and his household, and built a large Church of stone, the walls of which were standing in the time of Bede. (book ii. ch. xiv.—xvi.)

Were- uth,

According to the same venerable writer, Benedict, a noble Saxon, built, in 676, a Church at Weremouth in honour of St. Peter; it is added that he sent to Gaul for artificers who might build it according to the Roman manner, by which is probably meant the style of the Lower Empire. So much expedition was used, that within a year from the time of laying the foundations the roof was put on. And, as the work drew near a conclusion, he sent again to Gaul for artificers to make glass for the windows, the Art being then unknown to the Britons.

Abben- ,

The ancient Church of Abbendon is said, in the *Monast. Ang.*, to have been built at the same time; it is described as a building 120 feet long, with circular recesses both at the Eastern and Western ends.

Scotland.

In the beginning of the VIIIth century, that which was then called the Roman style of building extended into Scotland; for, in 710, Naiton, King of the Picts, sent ambassadors to Ceolfrid, Abbot of Gyrvi, near the mouth of the Tyne, requesting him to send Architects who might build him a Church of stone in that manner; which request, according to Bede, (book v. ch. xxi.) was immediately granted. At an earlier period than this, a stone Church appears to have been erected near Wigton, in Scotland, by Bishop Ninias; this is said by Bede (book iii. ch. iv.) to have been executed in 432, and he observes that the Britons were before that time unaccustomed to building with stone. Perhaps, therefore, stone Churches existed in North Britain before the VIIIth century, but they may have been executed only on a small scale.

thedral at xham.

The Cathedral of Hexham, in Northumberland, was founded by Wilfrid, Bishop of York, about the end of the VIIth century; and its construction is particularly described in the *Tractatus de Statu et Episcopis Hagustaldensis Ecclesiæ*, by Richard, the Prior of the Cathedral, who lived in 1180, and in whose time it existed entire. He says it was furnished with a round tower, perhaps a square tower covered by a cupola; from this, four aisles, or the four arms of a cross, proceeded, and it had deep crypts and oratories with passages under ground. The walls were of great length and height, and were divided into three tiers supported by well-polished columns both square and circular, which, as well as the walls and the arch of the Sanctuary, were of stone, decorated with images in relief and painted of various colours. The body of the Church was surrounded by porticos or aisles, and Chapels of exquisite workmanship, which were divided above and below by partition-walls and winding stairs. Within the staircases and above them were made flights of steps; with galleries and passages leading from them, both for ascending and descending; and so disposed that persons might be there and pass round the Church without being seen by any one in the nave below.

It is probable, as Dr. Milner observes, that the Cathedral of Hexham had some resemblance to that of Sancta Sophia, at Constantinople, which was built about the same time; and it is also probable that the principal Churches of the Continent in that Age were designed and executed nearly in a similar manner; but the Saxon Church at Hexham may have been superior to any of the foreign buildings, for Eddius observes, that no Church equal to it in magnificence was to be met with on this side of the Alps. The same Wilfrid founded a Monastery at Hexham, about 674.

York Cathedral rebuilt.

We are brought next to the rebuilding of York Cathedral in 767. This edifice must have been magnificent for that time, though we have few particulars from which we can obtain an idea of its style; all we know of it is from the Poem of Alcuin, one of the Architects, in which it is described as having all the requisites of a complete edifice, such as pillars, arches, vaulted roofs, porticos, galleries, and altars; but these circumstances are sufficient indications that Architecture must have been cultivated and brought to a considerable degree of perfection in England at that time, which was before the invasions of the Danes occurred. Amidst the troubles produced by those invasions, it was not to be expected that the Arts should receive encouragement, still less that of building; in fact, the fairest edifices which then adorned the Country fell a prey to the ravages of those Barbarians, and the art of construction was lost. But when Alfred came to the Throne a revival took place; this Prince is said to have erected several Ecclesiastical as well as Military edifices, and even to have introduced into the former an improved style. Mr. Bentham supposes that towers and steeples were added to the English Churches in his time, *viz.* about the year 900; however, as no steeples at present exist, of an earlier date than the beginning of the XIIIth century, this circumstance is doubtful.

Ramsay Abbey.

The Abbey, at Ramsay, in Huntingdonshire, was rebuilt in 974; and, in the *Hist. Ramesiensis*, it is described as having two towers raised above the roof; one was at the Western end and the other was supported by four pillars in the middle of the building, which there divided into four parts, connected together by arches, and these extended to other adjoining arches to prevent the former from giving way. This shows, as Mr. Bentham observes, that the plan of the building must have consisted of two rectangles, crossing one another, with side aisles; but the same gentleman's opinion, that this mode of building had not then been long in use, does not appear so well founded, for the description of the Cathedral at Hexham seems to show that this building had also, on the plan, the figure of a cross, and that it was furnished with a tower.

Oxford Cathedral.

It is supposed by some that the Cathedral of Oxford was built in the reign of Ethelred, about the year 1000, but so uncertain are the dates of the early edifices of our own Country, that others place its erection about a century later; Mr. Dallaway thinks it was built in 1112. The only part of the ancient structure which remains, *viz.* the nave of St. Frideswide, is built exactly in the manner of that corrupt Roman style which characterises the oldest remains of edifices in Germany and France, and it has been considered as the best specimen of what is called the Saxon Architecture in England. To one or the other of these periods may, perhaps, be referred the construction of parts of the Cathedrals at St. Alban's and Durham.

Restoration of English Churches about the time of the Conquest.

The long and severe struggle against the Danes, joined, perhaps, to a certain dissoluteness of manner which at that time prevailed among the Anglo-Saxons, is supposed to have been the cause that the Religious edifices of the Country had very much gone to ruin before Edward the Confessor came to the Throne; this

Prince had been educated in Normandy, and, probably, the contrast between the Ecclesiastical structures of that Country and those of England struck him forcibly, and induced him to excite his people to repair their Churches and erect new ones with embellishments similar to those of the Norman edifices. After the Conquest, in 1066, the style of the Norman buildings became very general in England. The most early examples of this style do not remain at the present time in a perfect state, but enough can be seen of their ruins to show its characters. Edward the Confessor built the original Abbey Church, at Westminster; and about the same time was executed the Cathedral of Gloucester, of which a part still remains; and these seem to have served as models for the Ecclesiastical structures subsequently erected. The transept of Winchester Cathedral was erected in 1080, and the tower of Exeter Cathedral in 1112. To these may be added the lower part of St. Peter's in the East, at Oxford, and the Church of St. Sepulchre, at Cambridge; this last was erected in 1130, by the Knights Templars, in imitation of the Church of the Holy Sepulchre, at Jerusalem. It is a circular building, having internally a peristyle of eight heavy pillars, and it served as the archetype of the Temple Church, in London. Many of the Churches belonging to the greater Abbeys were erected at this Era with equal magnificence; but very few of them remain, and those are in ruins.

Cathedral at Durham.

The Cathedral at Durham must be considered as an excellent specimen of the Norman Architecture. It was begun in the time of William Rufus, about 1093, by William de Carilepho, and was, perhaps, finished by the successor of that Prelate. Originally, says Mr. Carter, the side aisles both of the nave and choir were covered with groined work formed by hemicylindrical vaults, and the ribs of the groins were embellished with carving; but both the nave and choir were only covered by the timber-roof. Various additions, however, have since been made, the first of which was the Galilee, or porch before the Western façade, by the Bishop Hugh Pudsey, between 1153 and 1195; this is a low building, with four semicircular-headed windows on each side springing from clustered columns. The plan of the whole Cathedral is rectangular, with two transepts, and it has not the semicircular apsis which was usually formed at the Eastern end of the ancient Churches. The length from the Eastern to the Western façade is 420 feet, and its breadth from the Northern to the Southern face of the Western transept, which is the longest, is 180 feet. The nave is 200 feet long and 100 feet wide; this is divided into three parts by two rows of columns, alternately round and clustering, at 15 feet from the wall on each side. The Western transept is 70 feet wide from East to West, and is divided into two parts, in a Northern and Southern direction, by a row of clustered columns at 15 feet from the Eastern wall.

Four great clustered pillars, each 50 feet high, at the intersection of the nave and Western transept, are connected above by semicircular arches, the crowns of which are on a level with the vault of the nave, and support the great central tower, which is 210 feet high, and the date of the construction of which is not ascertained. The choir is 110 feet long, and is divided into three parts like the nave; beyond the choir is the Eastern transept, which is 144 feet long from North to South, and 40 feet wide from East to West, and this forms the Eastern extremity of the Cathedral.

The centre of the Western façade is crowned by a plain gable; over the entrance is a large window of the cuspid form, divided by six mullions, and having the upper part filled with tracery. This window was formed in 1350; above it is a row of semicircular-headed niches between columns, and in the gable are five lancet-headed arches, whose heights are regulated by the inclining sides of the gable. On each side of this central division of the façade is a square tower, the height of which from the pavement is 140 feet; its face is ornamented with eight tiers of arches resting on small pillars, all with semicircular heads, except those in two of the tiers, and it has a flat roof with battlements. A short curtain, containing four tiers of semicircular-headed arches, in the Pisan style, connects each of these towers with a smaller one, which forms the extremity of the façade; the lower part of this tower is a square, and without ornament; the part above is octagonal, and contains four tiers of semicircular-headed arches; and the tower is crowned by a small pyramid.

Of the three round columns on each side of the nave the diameters are 7½ feet, and the heights, including those of the plinth and capital, are 27 feet; consequently, equal to 3.6 diameters; and the heights of the plinth and capital are each equal to about half a diameter. The plinth is rectangular and quite plain; the abacus is octangular, the curved circumference of the capital below it is divided into eight faces, as if cut by so many planes a little obliquely to the vertical, and a small fillet separates this part from the shaft. One of the three columns is fluted vertically, another is ornamented with zig-zag channels, the general directions of which are horizontal, and the third is channelled obliquely round the column to the right and left, forming a sort of network. The other columns consist of several small ones clustered together, and, perhaps, are of later date.

From the capitals of the round, and from some of the stems of the clustered columns, spring the semicircular arches which extend along each side of the central division of the nave; the other stems of the clustered columns are carried up to the height of 50 feet from the pavement. From the capitals of these, and from angels' heads attached to the walls, immediately over the round columns, and serving as corbels, spring the ribs which ornament the groined vaulting of the nave. The archivolts of the lower arcade of the nave are ornamented with zig-zag mouldings, and on the extrados is a sort of battlement. A horizontal string extends along the nave over the lower arcade; and above this is a tier of semicircular arches equal in span to those below, forming the front of the triforia; the archivolts of these are highly ornamented with zig-zag mouldings, and rest upon small pillars which are placed vertically over those in the lower tier; within each of these arches are two smaller ones, also semicircular, springing from the same imposts, having plain archivolts resting upon small pillars. Above the triforia is a tier of narrow pointed arches within the lateral vaults of the groined ceiling. The roof of the nave is formed by the intersection of ridged vaults, and, except the ribs of the groins, the surface of the vaulting is plain. This part of the building is said to have been finished in 1290.

The arcades of the choir are similar to those of the nave, but the two round columns on each side are channelled with spiral grooves all directed one way, and the ribs of the groined vaulting are more ornamented. The doorways leading from the cloisters to the Cathedral are covered with the utmost profusion of ornament. The ec-

altar-screen and episcopal throne are highly decorated with flying buttresses, niches, and pinnacles, producing a singularly rich and magnificent effect; but it must be remembered that these were executed long after the rest of the fabric. A longitudinal section of part of the nave, and an elevation of one of the doorways in this Cathedral, are given in pl. xvii.

ral at
bury.

The Cathedral Church, at Canterbury, after frequent demolitions by fire, was wholly or partly rebuilt by Lanfranc, in 1085, and enlarged to its present size about the beginning of the XIIth century. The whole length of the building, from West to East, is 514 feet; the nave is 178 feet long and 71 feet broad, and is divided into a centre and two aisles by two rows of clustered columns at the distance of 13 feet from the side walls. At the extremity of the nave is the first or Western transept, the length of which, from North to South, is 124 feet, and breadth 34 feet. Beyond this is the choir, extending from West to East 151 feet, and in breadth 38 feet; on each side of this is an aisle 16 feet broad, and separated from the choir by a row of plain circular and polygonal columns intermixed. The choir is intersected by the Eastern transept, which is 154 feet long from North to South, and 29 feet wide. Beyond the choir is the Trinity Chapel, 104 feet long from West to East, 63 feet wide, and of a semicircular form towards the East; in the interior of this Chapel is an aisle separated from the central part by a curvilinear range of plain columns in couples, at a certain distance from the walls. And, finally, a circular tower, 32 feet diameter, called Becket's Crown, opening into the Trinity Chapel, constitutes the Eastern extremity of the whole building.

At each extremity of the Western façade is a square tower, of which that on the Northern side is 100 feet high, and the other 130 feet; the former was, probably, part of Lanfranc's original structure, but the latter was built about the year 1450. And over the centre of the Western transept is another tower, 235 feet high, which was erected about the year 1500. The two former towers are strengthened on each side of the angles by immense solid buttresses reaching to the top and diminishing upwards, in projection, by steps at intervals; and the tower at the South-Western extremity is crowned by open battlements with an octagonal pinnacle at each angle. The angles of the central tower are strengthened by slender buttresses of equal thickness from top to bottom, and are crowned by pinnacles. On each face of this tower are four large windows in two tiers, of which those in the lower tier have curved pediments of contrary flexure, ornamented with crockets and finials. The exterior of the side walls of the Church are also strengthened by solid, plain buttresses terminating in ornamented pinnacles, and between the buttresses are large cuspid windows subdivided by vertical and horizontal mullions.

The vaults of the nave and aisles are groined and ornamented with tracery; but those of the choir and its aisles are more simple. The capitals of the pillars in the choir and Trinity Chapel have some resemblance to those of the Corinthian Order, and consist of two rows of leaves; from these capitals spring pointed arches, over which are triforia, or galleries, with pairs of arches in front resting on columns; some of these latter arches are semicircular, but the generality of them are pointed, and every two are inscribed within the mouldings of a third which embraces both. The archivolts of the aisles of the choir are ornamented with zig-zag mouldings.

According to the Monk Gervase, the old Church, before the fire which, in 1174, destroyed the choir, was covered with a flat painted ceiling, and there was only one triforium round the choir; the same Chronicler adds that the pillars of the new choir were of the same form and thickness as those of the old choir, but 12 feet longer; (probably their height was then doubled, for they are now about 24 feet long;) that the old capitals were plain, whereas the new ones were delicately carved; and that the vaults of the side aisles were formerly hemicylindrical, but subsequently formed with a ridge at the vertex. The present state of the Eastern end of the Cathedral corresponds nearly with the account given by Gervase, in 1180. He says, "There are large well-proportioned columns crowned with elegant capitals. Upon the abacus rest the bases of slender marble columns which mix their heads with those of other marble columns supporting the arches of the principal triforium, and from their united capitals branch out triple clusters which, at a proper height, form themselves into ribs to sustain the groining." The arches constituting these ribs are formed with an acute angle at the vertex, and those in the upper tier are alternately cuspid and semicircular, but the lower extremities of the latter are rectilinear and vertical up to a certain height above the capitals of the columns from whence they rise.

The present choir was built by two Architects of the name of William; one of these was a Norman, or Italian, the other an Englishman, and the latter is described by Gervase, as *parvus quidem corpore, sed in diversis operibus subtilis valdè et probus.* He is the first English Architect of whom we have any positive account.

The interior of the nave presents an unbroken simplicity, and exhibits the style of the XIVth century without embellishments. Above the lower arcade is a course of oblong panels, instead of the triforium, which is invariably found in all other great Churches of the same Age; and above these is a tier of windows, the form of which corresponds with that of the transverse vaults of the groined ceiling.

The crypt, or substructure, is situated under the choir and all the Eastern part of the building; and, from the ornaments found in the capitals of its pillars, its construction has been referred to the IXth century. In the Trinity Chapel, the angles formed at the vertices of the Gothic arches, by their curved sides, are of different degrees of magnitude; a variety which has evidently been caused by the differences existing in the intercolumniations, the vertices of the arches being all in one horizontal plane.

On the exterior of the building, at the Eastern end, are various kinds of arches, serving as ornaments; some are plain semicircles; others are semicircles, or cusps, intersecting each other; some, again, are of the lancet shape, and others form broad windows, the apertures of which are divided by mullions.

On the Northern side of the nave are the cloisters, a square enclosure 134 feet long in each direction, with groined vaults and arcades of pointed arches surrounding the central area. Between the cloisters and the choir of the Cathedral is the Chapter-house, a rectangular building, 92 feet long and 37 feet broad; and near this are the Treasury, Audit-room, Library, and Baptistery.

Iffley
Church.

We are induced to mention in this place a Church supposed to have been built before the death of Henry II., at Iffley, in Oxfordshire, because it resembles, in some respects, the Churches built about the same period in

Normandy, and because it may be considered as a good specimen of the Parish Churches of England, near the time of the Conquest. (Britton's *Architectural Antiquities*, vol. v.) It is of a rectangular form, 112 feet long and 30 feet wide on the exterior, and has no transept. In the Western front is a semicircular-headed doorway surrounded by zig-zag ornaments and two courses of serpents' heads; and on the exterior of these, a semicircular course of voussoirs sculptured with figures of birds, beasts, angels, and men: over the door there has formerly been a circular window, and, above it, is the gable end of the roof, in which were formerly three semicircular-headed windows, having the archivolts and jambs richly ornamented with three courses of zig-zags. The extrados of the arched tops is ornamented with a course of serpents' heads, similar to those about the doorway, and this member rests at each extremity on a twisted column, in the capital of which are sculptured centaurs, griffins, and the like.

Over the centre is a square tower, having on each face two semicircular-headed windows, the archivolts of which rest on columns.

The faces of the Northern, Southern, and Western walls have at the top and on each side a broad, plain margin projecting a little before them. The inferior edges of the horizonal margins are ornamented with a row of dentels, so that those margins have the appearance of inverted battlements; and about the windows in the tower are similar margins ornamented in the same manner. This practice of recessing the faces of the walls within margins is met with in the Churches of Normandy, and from them it was, no doubt, copied. In Churches of later date, small semicircular notches, or *nebulæ*, are cut in place of the rectangular intervals of the dentels.

Salisbury Cathedral.

The present Cathedral at Salisbury presents the most complete specimen of that kind of Gothic Architecture which immediately followed the introduction of the pointed arch; and, contrary to that which took place in the other Cathedrals of England, (which were erected in parts, at long intervals of time, and some of which are unfinished even at the present day,) this, which was begun in 1220, was completed, if we except the spire, a work of much later date, in about 40 years; so that it is almost without any mixture of the succeeding styles. The plan is in the form of a double cross; the length of the nave is 276 feet, of the choir 140 feet, and of Our Lady's Chapel, at the Eastern extremity, 65 feet; the general breadth is 76 feet, and the height, from the pavement to the top of the vault of the nave, is 84 feet. The length of the principal transept is 210 feet and its breadth 60 feet. The cloisters adjoining it are 160 feet square, and there is an octagonal Chapter-house. The outside walls of the aisles are supported by solid buttresses, and flying buttresses extend from the tops of these to the springing of the vault of the nave. The central tower is 220 feet high, of a square form on the plan, and crowned by a spire, the apex of which is 180 feet above the top of the tower, so that the whole height of the building and spire is 400 feet. The spire itself is 2 feet thick at bottom, and diminishes gradually to 7 inches at the top.

The columns of the nave are 28 feet high, and each consists of one stout cylinder in the centre, with four smaller ones attached to it; two of these are at the extremities of that diameter of the central column which is parallel to the direction of the building, and the other two are at the extremities of a diameter at right angles to this; by which means, as is observed by Mr. Knight, the greatest possible space is allowed for communication and for the passage of light from the side windows. The five columns, thus forming one cluster, have a common base and capital, and from the capitals spring the pointed arches, the radii of the sides of which are equal to three-quarters of the spans or intervals between the columns supporting them; and the sides themselves seem composed of a number of curved reed-mouldings clustered together. Above the arcade of the nave is a small horizontal cornice proceeding through the length of the building, and making a finish for the lower story. Over each side aisle is a suite of low galleries or triforia open towards the nave, but having no windows towards the exterior. A vertical stem rises from the capital of each of the opposite pillars of the nave, crosses the horizontal cornice, and proceeds without interruption to the groined work in the top of the roof. The windows in the walls of the building are lancet-headed; those of the lower tier are placed two together between the buttresses, but those in the clere-story, or upper part of the walls of the nave, are divided into three apertures by columns or mullions.

In the Lady Chapel the central stems of the clustered pillars resemble Roman columns, except that they have no diminution; they have Attic bases coarsely cut, and the capitals are similar to those of the ancient antæ pilasters; the other stems in each cluster are detached from that of the centre, and have distinct bases and capitals. The Western end of the Cathedral is covered with niches and rows of statues; and this is, probably, the earliest example of that practice in England.

In the screens which separate the Northern and Southern ends of the smaller transept from the nave, is a pointed arch springing from the clustered pillars on each side, and rising as high as the tops of the other side arches; and, above this, is an inverted arch descending from the foot of the ribs of the vault at the top of the triforium, on each side, and having its lowest point coincident with the crown of the arch before mentioned; this feature occurs in the Cathedral at Wells, and in several other Cathedrals of this Country.

The Southern face of the transept contains, in the gable, a circular, or, as it is called, a Catharine-wheel window; and below it is a row of narrow windows of the lancet form. The central tower has two windows in each face ornamented with curved pediments and crockets, and it is crowned by battlements, but is without pinnacles. In the gable of the Northern transept is a row of pointed arches placed on small attached columns as ornaments against the face of the wall; and the heights of the arches decrease from the middle one outwards, in order to suit the inclining sides of the roof.

In this Cathedral are some ornaments which resemble those of the Norman Architecture; many of the interior arches are sculptured with a zig-zag, and the same moulding appears round the arches and windows of the West front.

The Baptistery is an octangular building on the Northern side of the Church, with broad and cusp-headed windows, having three circular ornaments within the arch; there are buttresses at the angles terminating in pinnacles; and the whole building is covered with a high pyramidal roof.

York Cathedral.

The Cathedral at York is remarkable for the simplicity of its plan, which is in the form of a Latin cross, the arms of which are all rectangular, and the transept is in the middle of the length of the building. The whole length is 465 feet from East to West, and its breadth from the Northern to the Southern face of the transept is 222 feet; the breadth of the nave is 103 feet, and of the transept 94 feet; and the body of the Church and the transept are divided into a centre and aisles by clustered columns, 20 feet and 18 feet from the walls, respectively. In the intersection of the arms of the cross are four large clustered columns supporting the central tower, which is 182 feet high; and between the two Eastern columns is the screen separating the transept from the choir; the latter is 150 feet long, and beyond it all the Eastern part of the building is occupied by the Chapel of the Virgin. A perspective view of this building from the North-West is given in pl. xvi.

This edifice, like the generality of our Cathedrals, has been executed at different times. The most ancient part is the crypt under the choir, and this is supposed to have been built with the Norman Church in 1171; it consists of a groined work supported on four walls and on six insulated columns, each 5 feet 6 inches high and 1 foot 5 inches diameter, and some of the arches composing it are ornamented with the Norman zig-zag. The capitals, which are octangular, are sculptured, and the bases resemble the Attic kind, except in one instance, where a reversed capital is substituted for a base; from which there is reason to conclude that some part of the crypt has been formed of materials belonging to a more ancient edifice. The Southern wing of the transept was raised between 1216 and 1255, and the Northern wing was begun in 1260; the construction of the Western parts of the fabric probably extended from the beginning of the XIVth to the middle of the XVth century.

The arches of the nave are pointed, and the curved sides are cut in reed-mouldings; above their vertices is a horizontal string extending along the building, and over it comes the upper tier of windows. There are no galleries over the aisles of the nave. The arcades of the transept are sculptured with a double zig-zag, or dog's-tooth ornament on the mouldings, and the clustered columns have small capitals sculptured to represent foliage. Above these arcades are two tiers of triforia, or open galleries. The groined roof of the building is adorned with intersecting ribs of tracery-work, executed in modern times, but, probably, in imitation of the ancient forms.

At the extremities of the Western façade are two square towers with buttresses on each side of the angles, ornamented with trefoil and cinquefoil-headed arches, over which are pediments. The doorways and windows have cusp heads with reed-mouldings; the part of the windows within the arch is either pierced by three open quatrefoils, or is occupied by the branching mullions, and the extrados is crowned with rectilinear or curved pediments, which are ornamented with crockets and finials. The walls of the towers terminate in a range of battlements, and over each angle is a crocketed pinnacle. The side walls of the aisles are supported by plain buttresses terminating in pinnacles, and the walls over the arcades of the nave are strengthened by buttresses more slender than the former. A horizontal line of battlements is placed along the top of the façade and of the side walls of the building; and the inclining sides of the gable are ornamented in the same manner. The great Western window is divided into eight parts by vertical mullions; the arched sides of the head form an acute angle with each other, and the part within the intrados is enriched with open-work in the forms of leaves. See pl. xix. fig. 2.

Lincoln Cathedral.

The original Cathedral, at Lincoln, was built in 1092, by Remigius, the first Bishop appointed to an English See by William the Conqueror, but of this building nothing remains except part of the Western front and towers. The front seems to have been divided into five recesses covered by semicircular arches; over these there seems to have been a tier of small columns bearing intersecting arches, and the façade was terminated above by three gables. The original towers at the Western front were ornamented with three tiers of semicircular arches on each face; these still exist, but, at a later period, the towers were increased to their present height. The building having been injured by an earthquake in 1185, it was subsequently rebuilt, and the work was carried on at various times till the close of the XIVth century.

The plan of this Cathedral is a double cross, like that of Canterbury, but the Eastern as well as the Western front is rectilinear. The whole length is 470 feet from East to West, and the length of the Western, or greatest, transept from North to South is 220 feet. The length of the nave is 240 feet, its breadth 80 feet; and this part of the Church is divided longitudinally into a centre and aisles by two rows of clustered pillars at 15 feet from the walls. The breadth of the Western transept is 63 feet; this is divided into two parts by a row of columns at 23 feet from the Eastern wall, and the space between the columns and that wall is occupied by six chantries founded by different persons. The central tower stands over four large clustered columns in the middle of the Western part of this transept; the screen of the choir is between the two Eastern columns, and the whole length of the choir from this to the altar-screen is 140 feet; on each side of the choir is an aisle 18 feet wide; and beyond the altar-screen is the Presbytery occupying all the rest of the Church. The Eastern transept crosses the body of the Church between the choir and the altar; and it is 22 feet wide, exclusive of four semicircular recesses or Chapels, which occupy all its Eastern side.

The Western front extends North and South beyond the side walls of the building, and is terminated by two octagonal towers which are crowned by small spires. In the centre of the façade are three recesses, of which the middle one is headed by a pointed arch, the vertex of which is above 80 feet from the ground; the two others belonged to the original structure, and are covered by semicircular arches. In each of the three is a portal covered by a flat, elliptical arch with Norman ornaments, and, above them, is a large pointed window of more recent construction. The whole façade, including the flanking towers, is ornamented with tiers of lancet-headed arches on slender pillars, and a horizontal entablature crowns the whole; the execution of these ornaments is referred to the early part of the XIIIth century.

The lower parts of the Western towers are in the Norman style, and are ornamented in the following manner. In that part of each which is above the walls of the Church, are three tiers of recesses with semicircular heads resting on small columns; below these, on the Northern front, is a gable, in which are also three tiers of small semicircular-headed recesses with small columns in the Pisan style, and in two of the tiers the arches intersect each other. Similar courses of ornamental arches are placed in the gable of the Western extremity of the Cathedral, and the upper part of the gable is covered with trellis-work. The upper parts of the Western towers are of the XVth century; in each of the faces are two windows ornamented with crockets, and there is a pinnacle at each angle. The central tower is similar to these, but more enriched; its height is 262 feet.

Above the vaulting of the nave, and within that part of the roof which is between the Western towers, is a stone arch, the chord or span of which is 28 feet, and its versed sine, or rise, but 16 inches: the voussoirs are about 20 inches long, and without any appearance of being tenonted together; this arch is remarkable for being the most slender in the world, in proportion to its span.

The side walls of the aisles are strengthened by buttresses with ornamented pediment heads, and arched buttresses extend over the roof of the aisles from the upper parts of these to the upper parts of the side walls of the nave. The Eastern side of the Western transept is supported by plain buttresses, with flying buttresses over the aisle; and, in this transept, the windows are of the lancet form. In the Northern and Southern faces of the same transept are large circular windows filled with looped tracery. The whole building is covered by a lofty roof forming a ridge over each arm of the double cross.

The pillars of the nave have capitals sculptured with foliage, from which spring the pointed arches; and these consist of arcs of circles, of about seventy-five degrees each, the extrados moulding of which rests upon a head projecting from the wall, above the capital of the pillar. A slender pillar resting upon an ornamented corbel in the wall, above the capital, is carried up to the springing of the ribs which adorn the vault in the nave. A horizontal string proceeds, longitudinally, through the nave, above the crowns of the lower arches, and over this is the arcade of the triforium, or gallery, above the aisle; this consists of lancet-headed arches, in triplicate, resting on small pillars, and crowned by one obtusely-pointed arch embracing every three. Above these is another horizontal string; and, lastly, over this, and within the lateral vaults of the groins, are the clerestory windows, consisting of triple lancet-headed apertures. The dog's-tooth ornament occurs along the mouldings of these arches, and in those of the transept. A longitudinal section of the nave of this Cathedral is given in pl. xviii.

The four great clusters supporting the central tower are each composed of twenty-four attached columns of various diameters; the arches they sustain have a great appearance of lightness from the delicacy of their mouldings, and from their spandrils being decorated with trellis-work.

The Temple Church. The Temple Church, in London, may be mentioned in this place, because it is, probably, one of the first edifices, in England, in which the pointed arch was introduced. It consists of two parts; *viz.* a rectangular nave 82 feet long, and 58 feet wide, and a circular building 58 feet diameter, at the Western end of the former: this is supposed to have been erected by the Knights Templars in 1185, and the rectangular part may have been added in 1240, when the Church is said to have been rebuilt.

Within the circular building are disposed six clustered columns, at intervals upon the circumference of a circle concentric with the walls of the building, and 29 feet diameter; the tops of these are connected by pointed arches of contrary flexure, over which is raised a cylindrical tower 44 feet from the pavement, with semicircular-headed windows. The circular aisle on the exterior of the columns is covered by an equilateral groined vault, and in the walls are single lancet-headed windows. The foot of the circular wall, in the interior, is ornamented with a continuous row of lancet-headed arches on short columns, and the interior of the tower, above the roof of the aisles, is ornamented with a similar row of intersecting semicircular arches.

The walls of the rectangular building are strengthened by plain buttresses, and the whole interval between them is occupied by a triple lancet-headed window, of which the central aperture is much higher than the others, and all three are circumscribed within a broad pointed arch. The interior is divided into a central and two side aisles, all of equal height; *viz.* 37 feet, by two rows of clustered columns supporting equilateral pointed arches; the vaulting is groined, and the three divisions are covered by separate roofs.

Westminster Abbey. A small Church is said, chiefly on the authority of the Monk Sulcardus, to have been built on the site of the present Abbey of Westminster, about the year 604, by Sebert, King of the West Saxons. It was reconstructed on a more magnificent scale by Edward the Confessor, probably about 1050; but all that part of it which extends from the Eastern extremity to the entrance of the nave, was rebuilt in its present state by Henry III., who laid the first stone of the present Abbey in 1220; the central tower was rebuilt in 1245; and, in 1269, the Eastern end, with most of the transept and choir, was completed and dedicated. The nave was carried on slowly afterwards, and it was not till 1498 that the circular windows were formed, and the Western front erected; the towers were not entirely completed till the time of Sir Christopher Wren, who finished them as they now are. The Chapel at the Eastern end, which was built by Henry VII. to contain the tomb of himself and his Queen, was finished about 1512.

The general plan is that of a Latin cross, of which the nave is 234 feet long from West to East, and 90 feet wide; the transept is 225 feet long from North to South, and 100 feet wide from East to West. Beyond the transept towards the East are five Chapels, which occupy an extent, from West to East, of 196 feet. That of Henry VII. is at the Eastern extremity, and terminates in a semicircle, and there are two others on each side between this and the transept. The cloisters are of a rectangular form, 154 feet long from West to East, and 142 feet from North to South; and consist of an arcade enclosing an open court in the angle between the Southern wing of the transept and the side wall of the nave. And at the South-Eastern angle of the same transept is the Chapter-house, an octagonal building 74 feet diameter.

The nave and transept are divided as usual by rows of clustered columns, and the choir is in the central division of the nave, near its intersection with that of the transept.

The Western front is divided into three parts vertically; in the central division is the entrance, which is splayed and vaulted in the pointed form within the thickness of the wall; and above this is a great window divided by six vertical and four horizontal mullions. A gable, in which is a small triangular window, crowns this part of the front; but both the gable and the great Western window are of later date than the rest of the nave. On each side of the central division is a tower 225 feet high, standing on a square base, and divided into four parts or stories, containing windows with pointed-arch-heads, and terminating at top in a crocketed pinnacle at each angle. The faces of the towers are divided vertically into three parts, of which the exterior ones project beyond that in the middle, and are ornamented with rows of panels. These faces are the work of Sir Christopher Wren, and the style in which they are executed is much too simple for the rest of the building. The buttresses on each side of the central division of the façade are adorned with niches and canopies.

Along the Northern side of the nave is a row of graduated buttresses connected with the walls of the aisle and nave by arched ribs; between these buttresses is a tier of tall pointed windows divided into two parts by mullions, and over them is a row of triangular windows with three cinquefoil apertures in each. Above these are the clerestorial windows of the nave, which are similar to those of the lower tier; and the walls both of the nave and aisles are crowned by battlements.

The Northern front of the transept is a rich specimen of the pointed style of Gothic Architecture, and is divided horizontally, between the flanking buttresses, into four stages. In the lower are three entrance doorways, of which the middle one is higher than the others, and each is covered by a pointed arch, the sides of which are formed upon those of an equilateral triangle; over the side-doorways is a row of cinquefoil-headed panelling; and a horizontal row of pierced cinquefoil apertures at the level of the top of the central doorway terminates this division above. In the next division are four deep recesses covered by obtuse, cuspid arches; above them is a tier of small, cuspid arches springing from pillars, and, over this, is a perforated battlement. The third division contains a great circular window, divided into sixteen parts by radiating mullions, and the spandrils of the window are filled with roses and trefoil-headed leaves. The last division is crowned by the gable or pediment of the roof, and contains three pointed arches resting on pillars, and enclosed within the mouldings of one large arch of the same kind. The height of this front from the pavement to the apex of the pediment is 140 feet. The buttresses at the angles of the upper part of the transept are richly ornamented, and terminate in octangular pinnacles; curved ribs extend from these buttresses to those which are attached to the side walls of the transept, and the latter terminate in the same manner.

The Architecture of the exterior of the Eastern Chapels is similar to that of the nave; but Henry the VIIth's Chapel is much more enriched.

The pillars of the nave consist, each, of eight slender shafts surrounding a circular column; in those which are of the more ancient workmanship, that is, of the time of Edward I., the shafts are completely detached, but the bases and capitals are united; the latter are circular, and the pedestals form an entire mass: the more modern columns are surrounded by two fillets dividing them into three parts horizontally, and the small shafts have octagonal capitals and plinths. From the capitals of the columns spring the side arches of the nave, the radii of curvature in which are greater than the intervals of the pillars. The mouldings of the curved sides of the arches are deeply cut, and above the extrados is a concentric rib, or label, as it is called, which springs from a corbel head on each side. Above this arcade is a horizontal string separating it from the arcade of the triforia; this consists of a row of double trefoil-headed arches springing from small columns, and each pair inscribed in a simple pointed arch. From the capitals of the lower range of columns rise slender triple shafts, and from these spring the ribs of the groined work, formed by the intersections of equilateral ridged vaulting over the nave. The crown of this vaulting is 100 feet high from the pavement, and that of the side aisles is 47 feet.

The edifice built by Henry VII. is divided into a nave and two side aisles, and at the semicircular extremity are five small Chapels; it is surrounded at intervals by octagonal buttresses, 64 feet high from the pavement, ornamented with several courses of panels, niches, and tabernacle-work, and crowned by enriched pear-shaped pinnacles. The whole space between every two buttresses is occupied by windows from top to bottom; those along the sides are broken into three faces, and the others into six. The roof of the aisles is 25 feet from the pavement, and consists of a groined vaulting, having the spandrils rounded in a convex form, and ornamented with fanwork panelling; and from the vertices of the groining descend pendent spandrils, or masses of stone of a conical form with the points downward, ornamented in a similar manner. The vaulting of the nave is 63 feet 7 inches from the pavement, and its groins are enriched with fanwork and a triple row of pendents. The octangular buttresses of the nave are 96 feet high, ornamented like those of the aisles, and arched or flying buttresses extend from them to the latter over the roof of the aisles; these are pierced with beautiful quatrefoil and sixfoil apertures inscribed in circles, and the extradosses are ornamented with sculptured lions, dragons, and greyhounds. The walls of the nave, which contain great pointed arch-headed windows, are crowned by a band of panels and a perforated parapet. A plan, transverse section, and elevation of the Eastern extremity of this Chapel, are given in pl. xx. The whole of the exterior has been restored, with great delicacy of execution and strict attention to the original style, within the last few years.

The Chapter-house, at Westminster, which was built by Henry III., is of an octagonal form, and the walls are strengthened by projecting buttresses. The entrance from the cloisters is under two obtusely-pointed arches resting on a pier in the middle, and circumscribed by one large pointed arch which springs from three columns on either side. The inner mouldings of the small arches are sculptured, from the ground to the vertex, with branches and foliage, and over the extrados is a weather moulding springing from corbel heads.

King's College Chapel at Cambridge.

Two splendid Chapels, the one at Cambridge, and the other at Windsor, may terminate this account of the ancient Ecclesiastical edifices of England; since their completion took place in the latest period of Gothic Architecture. King's College Chapel, at Cambridge, was begun by Henry VI. about the year 1443, and is one of the most magnificent examples of scientific construction, as well as of Architectural beauty, in the Kingdom. The plan is a simple rectangle, and at the exterior angles of the fabric are four octagonal towers, with perforated ornaments, terminating in pear-shaped pinnacles crowned with finials. There is no division in the interior, and the vaulting, which was executed in the time of Henry VIII., is of stone, ornamented with fan-tracery. The entrances at the Northern and Southern extremities are covered by low arches, obtusely pointed at the vertex, the ribs of which are sculptured with deep mouldings; and on each side of the aperture is a small pillar, from the capital of which springs an elegant canopy, the sides of which are in the form of curves of contrary flexure, meeting in a point at the vertex; these are ornamented with crockets, and end, at top, in a rich finial. The windows are broad, with low pointed arch heads, and, with the exception of that at the Western end, are filled with painted glass, which produces a soft and pleasing light in the interior of the building.

Chapel at Windsor.

St. George's Chapel, at Windsor, is another example of this highly enriched style of Architecture, and was finished about the tenth year of Henry VIII. Its plan is in the form of a cross, the transept projecting but little beyond the side walls, and ending, at both extremities, in five sides of an octagon. The nave is divided into a centre and two aisles as usual, and the arches are of the low pointed form: bell-shaped spandrils rise from the pillars on each side of the central division, and are covered with fan-tracery up to the vault, the middle part of which is ornamented with curious panelling and pendent spandrils. The walls of the aisles and nave are finished, above, with perforated parapets.

Ecclesiastical buildings in Scotland.

The best remaining specimens of Gothic Churches in Scotland are, the Cathedral of Glasgow, Melrose Abbey, Roslin Chapel, and the Chapel of Holyrood. The first two were, probably, erected in the XIIth century, and the last two in the XVth. The Cathedral of Glasgow consists of a rectangular body 319 feet long, 63 feet broad, and 83 feet high, with one wing only of a transept; about the centre of the building is a square tower supported by four pillars, and, above it, an octangular spire, the height of which from the pavement is 225 feet. At the Western end of the building is another square tower, the pavement of which is supported on groined arches, and has a circular opening in the middle to receive a flight of steps.

Cathedral of Glasgow.

Melrose Abbey.

Melrose Abbey, which is said to have been founded by King David, in 1136, has the figure of a cross on the plan; it is 258 feet long, and 137 feet broad, and was crowned by a tower over the centre. The vaults of the roof are groined, and the ribs intersect each other, so as to produce an elegant tracery on the interior surface; and, besides solid buttresses at the angles of the building, the side walls are strengthened by flying buttresses of light construction. The windows are of the highly-pointed form, and the principal of them are divided by four vertical mullions; the extradosses of the ribs are ornamented with crocketed pediments of contrary flexure meeting in a point at the top, and the walls and buttresses have been adorned with tabernacle-work of a simple and elegant kind. This interesting edifice is now lying in ruins.

Chapels of Roslin and Holyrood.

The Chapels of Roslin and Holyrood are also in ruins; the latter, which was founded about 1440, had its walls strengthened by elegant, flying buttresses, and ornamented with tiers of small, pointed arches resting on slender pillars. The principal windows were divided into two apertures by pillars; those apertures were headed with pointed arches, one arch of a similar form enclosed both, and in the spandril between them were quatrefoil ornaments. Roslin Chapel must have been a beautiful specimen of Gothic Architecture on a small scale; its length is 69 feet, and breadth 34 feet. The roof was supported by arcades springing from two rows of clustered columns, and the vault over the centre division was sculptured with great taste and elegance.

We have already (chap. ii.) mentioned the buildings which usually accompany the Gothic Cathedrals; *viz.* the Baptistery, the Cloisters, &c., but we think it worth while to give here a general description of the Chapter-house, because some of these edifices are remarkable for elegance of design and richness of embellishment.

Chapter-house.

The Chapter-houses seem, originally, to have been of a rectangular form, like those of Durham, Gloucester, and Peterborough, all of which were built in the XIIth century. Subsequently, their plan was polygonal, and of this kind it is probable that the first was the Chapter-house at Lincoln, which was completed in the year 1200; afterwards, were built those of Salisbury, Worcester, York, and Litchfield, which, with many others, were imitations, as is supposed by Mr. Essex, (*Archæologia*, vol. vi. p. 170.) of the circular Churches of the Knights Templars erected at the close of the XIIth century; and these were, as probably, imitations of that erected over the Holy Sepulchre at Jerusalem.

The Chapter-house at Lincoln is a regular decagon, 60 feet diameter in the interior, and 42 feet high, with a clustered pillar in the centre composed of ten fluted columns of Purbeck marble, surrounding a stone pier, and standing on one pedestal. The capitals of these columns are elegantly sculptured, and, from above, spring twenty ribs which meet as many coming from the rentrant angles of the building; the intersections on the ceiling are connected by a similar rib, which forms a decagon about the central column, and the ribs from the angles are supported by clustered columns which rest on highly ornamented brackets. It is covered by a lofty pyramidal roof; each angle is strengthened on the exterior by a buttress terminating in a pinnacle, and ornamented with small pediments and crockets; arched buttresses extend from these to as many plain massive piers at a considerable distance from the walls.

We conclude with an account of the monumental crosses of our ancestors, which are to be considered as connected with the subjects contained in the present Chapter, and, therefore, the description may with propriety be introduced here.

Crosses.

From an early time the practice seems to have been general of erecting Crosses in public places to commemorate remarkable circumstances, and particularly to mark the graves of persons deceased. But those which are deserving of notice as Architectural objects, are a sort of monumental edifices erected in places wherein the body of a deceased Prince has rested for a time, in its passage to the place of interment; and some of these still remain as testimonials of the grief and piety of the surviving relatives. In 1285, Philip III. of France caused several to be erected between St. Denys and Paris, on the occasion of conveying the remains of his father, St. Louis, to interment; but they are all destroyed. In 1296, when Eleanor, the Queen of Edward I., died, her body was brought to London, and at the place wherein it rested each night during the journey, the King caused a building to be erected to her memory; of these, only three now remain; *viz.* those at Geddington, Northampton, and Waltham, which are in an imperfect condition, though still exhibiting great beauty in the design and taste in the execution.

Each building is octangular on the plan, and stands on a platform elevated a few feet above the ground, from which there is an ascent by a flight of steps on each side; the whole is divided into several stages by horizontal mouldings, each part less in breadth than the one below it, and the upper one is a pinnacle surmounted by a cross, from which this kind of monument took its name. These edifices, which from their gradual diminution upwards produce a graceful effect, are adorned with niches and canopies richly sculptured, and containing statues of the Queen; and from them the ornamented tabernacle-work employed about sepulchral chapels, shrines, and the like, is supposed to have had its origin. Crosses afterward became common, and were erected in many markets and other public places about the Country, where they served occasionally as pulpits from whence the Clergy preached to the people assembled about them in the open air.

CHAPTER IV.

Domestic and Palatial Architecture of England during the Middle Ages.

r state of
estic
hitec-
in the
ddle
s.

The domestic Architecture of Europe must have been in a very low state from the first establishment of the Gothic Monarchies on the ruins of the Roman Empire, to the extinction of the Feodal system about the time of Charles V. The residences of the Princes and Prelates during those turbulent times were Castles; that is to say, edifices fortified to resist a siege; the houses of the inferior gentry were mostly of timber, till about the time of Henry VII., when brick came into use in England. In cities, also, the houses of the merchants and traders seem to have been of wood and covered with thatch.

eral de-
tion of
astel-
l edi-

In our *Miscellaneous Division* we have already given some account of CASTLES. They were generally constructed of stone; a ditch surrounded the whole; within this was a wall having towers at intervals, which, besides the purposes of defence, served to lodge some of the officers attached to the service of the proprietor, and occasionally they were capacious enough to serve for the ordinary dwelling of the proprietor himself and his family. In some part of this wall was the gate forming the principal entrance, which was flanked by a tower on each side, and within it was the Chapel and the state-apartments, besides dwellings for servants or retainers, and rooms for stores: in some part of the interior, generally on an eminence, was a second Castle, called the Keep, to which the proprietor retired in case of siege.

There seem to have been but few Castles in England before the Norman Conquest, and that circumstance is supposed to have facilitated the subjugation of the Country; but in the reign of King Stephen a great number were constructed. The style of building in these edifices seems to have been the same as that which prevailed all over Europe during what are called the Middle Ages.

The exterior gateway was covered by a semicircular arch quite plain, because in such a situation any ornament would have been entirely misplaced; but those within the defences, which consequently might without impropriety receive a certain degree of embellishment, were made to correspond in form and ornament with the doorways of Ecclesiastical buildings of the same Age. Within the gateway was a narrow vertical channel cut in the wall on each side, in which the portcullis was drawn up or let down.

The principal apartment of a Castle was the Great Hall, wherein the proprietor entertained his friends and vassals on particular occasions; this room, which was rendered a little ornamental, had one part of the floor (the dais) raised above the rest, and in this part the principal guests were seated. The Chapel was constructed like other Ecclesiastical edifices, and the kitchen was generally a spacious building, but the ordinary rooms seem to have been small and unadorned.

The Keep of Rochester Castle.

The Keep of Rochester Castle, which was a general place of residence for the proprietor, and the walls of which still remain, will give some idea of the interior of such buildings. The plan of the Keep is a square 80 feet long in each direction, with a projection on one side 40 feet long and 20 feet from the wall, serving as a vestibule: the whole height of the Keep is 104 feet, and it is divided into four stories or tiers of apartments. The walls are 14 feet thick, and in them are galleries 5 feet wide, covered by vaulted roofs and surrounding the building on the three upper stories. At each angle of the building is formed a square tower, the faces of which project a little from the general faces of the wall; and in two of them are winding-staircases leading from the floor next above the ground quite to the top of the Keep. The gallery was lighted towards the exterior by loop-holes cut through the wall, and semicircular-headed apertures towards the interior communicated with the apartments. The interior of the building was divided into two equal parts by a screen-wall extending across it from bottom to top, in which were two doorways of communication, one on each side of the centre, except on the third story from the bottom, where the screen was cut away to form four semicircular-headed apertures. The archivolts of these, spring from massive cylindrical pillars, and are ornamented with the Norman zig-zig, and the intrados of each is cut in a serrated form; the interval between every two pillars is occupied by a wall reaching not quite so high as the capitals, and the space between the top of this wall and the soffit of the arch is open. A door of communication is made between two of the columns, and consists of a semicircular arch, the vertex of which is about as high as the top of the wall between the great columns; this arch rests upon two short columns, and the part between the extrados of this arch and the intrados of the great one is also open. In the middle of the great screen, and extending from the top to a well under the bottom, is a hollow cylinder formed in the wall, by which water was raised to the several stories of apartments, where it was received through apertures made in the wall on each floor.

In the interior faces of those two walls of the Keep which are opposite the screen-wall, a chimney is formed on each floor; this is a cylindrical recess terminated above by a semicircular arch resting on two dwarf pillars, and on each side is another pillar supporting a sort of cornice above the crown of the aperture. A funnel left in the wall suffered the smoke to escape from the upper part of the recess to the exterior of the walls of the Keep. The towers at the angles stand 14 feet above what was the ceiling of the upper story, or general roof of the building, and between them is a parapet wall crowned with battlements. The approach to the vestibule was by a flight of steps extending as high as the first floor above the ground, at the top of which was a drawbridge in front of the entrance. The doorway between the vestibule and the body of the Keep was closed by a portcullis, and one of the winding-staircases was in the adjoining tower. The floors of the rooms are entirely destroyed, but the rows of notches in the walls for the lodgements of the great beams are very visible.

The Castle is said to have existed in the year 765, but the present Keep was built by Bishop Gundolph, at the end of the XIth century, of Kentish rag-stone, except the angles and the window-frames, which were of a sort of stone brought from Caen, in Normandy.

Castles of Caernarvon and Conway.

The Castles of Caernarvon and Conway were built by Edward I. to serve as Palaces or Fortresses; and the beauty of the scenery surrounding them must have rendered a residence there as agreeable as was compatible with the restraints which a building enclosed by guarded walls must necessarily have imposed on its occupiers. Conway Castle is in the form of an irregular pentagon, and one side joins the Keep, which is square on the plan: at every angle both of the Castle and its Keep, is a strong round tower, and the approaches are protected by outworks. The Royal apartments were on one side facing the river, and at the foot of the wall is a terrace supported by a part of the rock which here rises abruptly from the shore. The style of this front is stated by Mr. Mitford to resemble a house which Palladio might have built, rather than what we consider as peculiar to a Gothic edifice. From the face of this wall projects an oriel or bowed-window of elegant workmanship, and the interior of the apartments appropriated to the Royal residence is executed in the style of the Ecclesiastical edifices of that day.

Under the Edwards, the English Nobility seem to have partly abandoned the Castles of their ancestors, and to have adopted the Palatial form for their dwelling-houses. The remains of the more ancient structures of this kind are, however, few, and the precise age of any of them is uncertain; and they have suffered so many alterations that it becomes impossible to communicate a satisfactory description of them. We perceive that they contained a number of rooms distributed without regularity, and the general appearance was similar to that of the Castles; though the turrets, battlements, and other features were such as could only serve as ornaments.

From the time of Edward I. to that of Henry VII., observes Mr. Strutt, the common houses were built of wood; there was a porch before the principal entrance, and within was a great hall, with large parlours adjoining: the framework consisted of beams of timber of enormous size. In cities and towns, each story projected over the next below, and the roof was covered with tiles, shingles, slates, or lead. But the perishable nature of the materials has necessarily long since brought them to ruin.

Westminster Hall.

Westminister Hall is a remnant of the most ancient Palatial edifice in England, having been originally, perhaps, part of the Palace of Edward the Confessor; it was probably rebuilt or repaired by William Rufus, who is said by Matthew Paris to have had his first Court in his new Hall at Westminster after his return from Normandy. By the same author he is said to have expressed an intention of building a new Palace; but it does not appear to have been executed till the reign of King Stephen, and then only in part. The Palace erected by this Prince was burnt down in the reign of Henry VIII. The lower parts of the present side walls are remains of the Hall of Rufus; but all above is the work of Richard II., who rebuilt the Hall in 1399.

The plan of the Hall is a rectangular parallelogram, 97 feet 8 inches wide from East to West, and 238 feet 8 inches long. The Northern or principal front is broken vertically into three parts, of which that in the centre is 47 feet wide; in this is the doorway with a great window above, and it is crowned by a high gable pediment, the vertex of which is 92 feet from the pavement; the sides of the pediment are ornamented with crockets, and at the apex is a small tabernacle on a polygonal base, and crowned by a pinnacle. The division on each side of the centre is a square tower, 72 feet high, crowned by battlements. The entrance porch is formed in the thickness of the wall; its sides, which are splayed outward, are ornamented with slender columns, and from those at the angles spring the ribs of an elegant groin-work which covers the vault of the porch. The front of the porch is covered by an obtusely-pointed arch rising from clustered columns; this arch is circumscribed by a rectangular frame, and each spandril is ornamented with a shield formed in a quatrefoil ornament. All the lower part of the façade is ornamented by a tier of niches intended to contain statues, and each is covered by a projecting canopy. In the second story of each tower are also two niches with canopies, and between the niches a low pointed arch divided into four apertures by a vertical and transverse mullion.

The present interior facing of the side walls was executed under the direction of Mr. Kent; this is ornamented with rows of piers, from the capital of each of which springs an arched rib of timber, meeting a horizontal piece of the same material projecting from the top of the wall, and terminating in the figure of an angel also in a horizontal position; from the extremity of this arched rib springs another which meets the corresponding rib from the opposite side of the Hall in a point over the middle. Above the vertex of the timber arch thus formed is a horizontal collar-beam which meets the rafters of the roof, and over its middle point is a king-post reaching to the vertex. Between these ribs and the wall and roof of the building is another rib, which extends in one continuous curve from the capital of each pier to the apex of the arch under the collar-beam; and in the open spandrils of the several ribs are rows of vertical pillars with cusp heads in wood-work over their intervals. The thrust of the roof is counteracted by flying buttresses. Mr. Pugin supposes that the roof was originally supported by rows of columns, for, he observes, it is not likely that the Architects of that day would form one capable of covering so great a span without such support.

The great Northern window of the Hall was built in 1380; it is 30 feet wide and 48 feet high, in the form of a pointed arch springing from the vertical sides of the window at 27 feet 9 inches from the sill; consequently the radius of each curved side is equal to 21 feet 3 inches, or to about two-thirds of the span. The window is divided into three parts by two vertical mullions, and each part into three others by two of smaller size; all the mullions reach to the top of the arch, one great transom crosses them at right angles, and a branch from each principal mullion makes, by uniting with the curved side of the head of the window, a pointed arch over the right and left compartments. The tops of the apertures between the mullions are covered with trefoil cusps.

At the Southern extremity of the Hall is a large window similar to that over the doorway of the Northern front. The whole of the latter has been recently restored, nearly in conformity with the original work executed in the time of Richard II., but the forms of the crockets and finials do not seem to coincide accurately with those exhibited in Hollar's view of this edifice. The range of niches extending from each side of the entrance along the fronts of the towers, together with the decorative panelling overspreading the whole to the height of the cornice, confer an air of superior grandeur on the façade.

ton

In the reign of Henry VIII. the residences of the Nobility had not entirely lost the military character which formerly prevailed in the Country, and the edifice erected, partly by Cardinal Wolsey, at Hampton Court is the best specimen remaining of the style of building in his day. This, which afterwards became a Royal residence, was begun in 1514, and in the time of the above-mentioned Monarch it is said to have had five spacious courts; it now, however, consists of three complete quadrangles only, besides the buildings used as offices. In the centre of the entrance-front is a square tower, flanked by an octagonal turret at each angle higher than the rest of the building; through this tower is a grand gateway formed by an obtusely-pointed arch, over which, both on the front and rear faces, is a rich oriel; the wall is crowned by a battlement of open work, and each of the turrets terminates in an octagonal pinnacle, the faces of which are curves of contrary flexure. On the right and left of the tower the buildings in this front have been partly modernized, but at each extremity is one of the old gables, the sloping sides of which are ornamented with griffins; from these extremities the wings project towards the front at right angles to the body of the building, so that the whole forms three sides of a parallelogram.

The first quadrangle, which is entered by the gateway above-mentioned, consists of dwelling-houses, the walls of which are crowned by embattled parapets; the windows are square, and the doorways covered by plain arches. In the centre of the front, opposite the entrance, is another tower similar to the first but smaller, and flanked also by octagonal turrets crowned with battlements. Through this tower also is an arched passage, over which is an oriel less embellished than the former; this passage leads to the second quadrangle, which is smaller than the first. The left side is occupied by the Grand Hall, which was built by Henry VIII.; this is covered with a lofty roof, its sides are strengthened by buttresses, and in its walls are pointed windows with mullions proceeding straight to the top. On the right-hand side of the Court is a colonnade consisting of coupled Ionic columns, erected by Sir Christopher Wren.

A third gate-tower, in a line with the two former, contains a passage leading to a third quadrangle, which is surrounded by an arcade on piers supporting the fronts of the buildings; the whole of this quadrangle was entirely modernized in the time of William III. The ceiling of the gateway is ornamented with rich fan-tracery, and in the passage is the staircase leading to the state-apartments.

The walls are built of red and dark-coloured bricks, so arranged as to chequer the exterior in diagonal lines, and are crowned by perforated and plain battlements; the windows, doorways, and principal ornaments are of stone. The windows of the ancient building are disposed without regard to symmetry; the frames are rectangular, and, in general, the breadths are greater than the heights; they are divided vertically by one or more mullions, and some of them are again divided horizontally by a transom near the middle of the height; the lights or apertures are terminated above by obtusely-pointed arches within the rectangular frames. An elevation of part of one side of the first quadrangle is given in pl. xx.

The timber-roof of the hall exhibits a fine display of constructive skill; each frame supporting the exterior covering is composed of two systems of beams placed one below the other, and each consists of four inclining timbers, of which the two upper meet in an obtuse angle over the middle of the breadth of the hall, and the two lower rest on the tops of the side walls. The inclining sides of the upper system are connected by two horizontal tie-beams, one at the foot of the upper pair, and the other about the middle of the lower, and the apex of the lower system falls at the centre of this tie-beam. At the foot of the two systems, on each side of the building, is a horizontal timber, projecting from the wall towards the interior as far as about one-quarter of the breadth of the hall; the extremity of this is supported by a curvilinear spur, the foot of which is inserted in the wall below; and, from the same extremity, on each side of the building proceeds a curvilinear rib of the hyperbolic kind to the apex of the lower system, forming together an obtusely-pointed arch. Rigidity is given to the whole frame by vertical timbers between the curved ribs and the exterior system of beams; and below each foot of the hyperbolic ribs is a pendent ornament in wood work. A section of this roof is given in pl. xx.

Most of the Colleges at Oxford are buildings surrounding quadrangular areas, and are executed nearly in the style of the ancient works at Hampton Court.

The style of domestic Architecture which prevailed in England during the reign of Elizabeth, and even of James I., bore considerable resemblance to that which has been just described, though an imitation of the Italian Architecture is supposed to have been introduced into the Country as early as the reign of Henry VII.

We conclude this Chapter with a description of the two most prominent features in the ancient mansions of this Country, *viz.* the Oriels and the Fire-places, of which some interesting specimens are still in existence.

Oriels.

The former are windows projecting beyond the front of the edifice and supported only by the masonry of the wall; the period of their invention is unknown, but their antiquity is considerable, for there is one such, constructed on a face of Conway Castle, which was built by Edward I. They were formed sometimes of three, sometimes of five sides of an octagon; of the latter kind is the beautiful oriel-window in what is called John of Gaunt's Palace, at Lincoln, which was built in 1390. According to the description given by Mr. Pugin, the bracket sustaining the frame of the window is covered with sculpture, and divided into four tiers. In the lowest is represented an angel, the second contains the heads of a king, a queen, and a bearded man; the third is a course of foliage; and in the fourth is represented foliage with six figures, one under each of the abutments or upright pillars of the window. At the bottom of the window, on each side of the octagonal bow, are two quatrefoils in panels; the parts which contained the glass terminate in cuspid cinquefoils, and above each are crockets and a finial. The upright pillars of the window terminate, above, in pinnacles covered with sculpture.

In the Chancellor's house, at Lincoln, is a plain Oriel, consisting of three sides of an octagon, supported by a bracket ornamented with horizontal mouldings, and crowned by battlements. Each of the three lights, or windows, is divided by one vertical and one horizontal mullion, and over it is a rectangular label. This is a kind of weather-moulding forming three sides of a rectangle, of which that above the window is horizontal, and the lower extremities of the vertical branches, which descend on each side of the window, are again broken at right angles to form short wings turning from the window; in the present example these wings are in the lozenge form. A similar Oriel may be seen in the Palace of Hampton Court. In the Age of Elizabeth and James I. the Oriels were divested of nearly all the richness of sculpture which distinguished them at an earlier period, and they sometimes consisted merely of rectangular projections, of which the central one was much broader than the others, and parallel to the wall of the building.

The Oriels seem to have been originally intended to form a retired closet for prayer or meditation, or to afford an extensive prospect from an apartment; but, in the time of the Tudors, they were also accompaniments to the Great Halls of Palaces, and served as recesses to contain a sort of sideboard.

Fire-places.

The Fire-places in the ancient mansions of this Country were very large, and generally enriched with elaborate sculpture; we have mentioned some of a Norman character in describing the Keep of Rochester Castle, but these are far exceeded in magnificence by such as were erected at the time the Gothic Architecture was in its most florid state. Those of Tattershall Castle, in Lincolnshire, which was built in 1440, are described by Mr. Pugin as having the apertures formed in elliptical arches with elegant mouldings; above these are legendary compartments and heraldic insignia. The mantelpieces have battlemented tops, and above them are segmental arches formed in the wall to support its weight. The Fire-places at Hampton Court also are distinguished by a profusion of the richest sculpture. The chimneys of this period assumed a picturesque form, and resembled pillars or turrets; they were square, octangular, or circular on the plan, and placed in couples or groups touching each other at the bases and summits only; the shafts were ornamented with lozenges and mouldings in zig-zag and spiral directions, and sometimes crowned by battlements. See Pugin's *Specimens of Gothic Architecture.*

CHAPTER V.

General Description of the Saxon and Norman-Gothic Architecture.

Absence of Orders in Gothic Architecture.

A grand distinction in the general system of the Gothic Architecture from that of the Greek or Roman, is that while the former possesses certain features peculiar to itself, there is in it a want of the Orders under which buildings differing from each other in style may be classed. In the same edifice are columns of different kinds, and having no constant proportion between their diameter and height; the ornaments also are extremely arbitrary, for in the same column the mouldings of the Doric Order and the leaves of the Corinthian or Composite capitals, with grotesque figures of men or animals, are all confounded together.

Style of the ancient Churches in the North of Europe.

Two very distinguishable styles of the Northern Gothic Architecture may be observed at first sight; the most ancient of which seems to have been in use till the XIIIth century, when it gave place to the other, which, in its turn, prevailed till the XVIth century. The former of these is considered by Dr. Moller as having originated in the South of Europe; and as bearing great resemblance to the Roman style in solidity of construction, in the flat or low pitched roofs, and in the semicircular form of the arches and vaults which had been substituted for the horizontal entablatures of the more ancient buildings. Specimens of this style he considers to be exhibited in the Cathedrals of Aix la Chapelle, Spires, Worms, and Mentz; all of which were executed in the Xth and XIth centuries. These Churches seem to be imitations of the Basilicæ of the Romans, with the addition of the transverse rectangle, and over the intersection of the arms of the cross a louvre or turret open at the sides. The walls were massive and the windows small: the pillars of the nave were short, and supported arches, which, as well as those of the windows, were semicircular. The nave was high, and covered with a groined vaulting, and in the upper part of the building were rows of small pillars attached to the wall for ornament. Above the vaulting was a flat timber-roof covered with lead or gilt tiles, and in the whole exterior of the building a system of horizontal lines predominated. The ornaments were generally of antique origin, and the bases of the columns, of the Attic kind, were correctly formed. The Western front was crowned by a pediment of low elevation, and perforated by a circular aperture which, probably, was the origin of the large rose-window, afterwards so conspicuous in Gothic edifices. The pillars of the interior were beautifully formed, and were probably taken from Roman buildings, but disposed without regard to symmetry, different forms being employed in the same range, and the arches above them being either very small or very large when compared with the size of the supports. The pavements were composed of irregular fragments, and the walls covered with rude paintings. Such are the characteristics of the Churches of Germany and France before the XIIth century.

In the more ancient Churches of Normandy, which are referred, we know not on what foundation, to the time of Charlemagne, the sides and ends present, each, on the exterior, the appearance of one or more great panels between plain piers of small projection, and a general horizontal band joining their upper extremities; these bands are crowned by horizontal cornices, which are sometimes supported by heads like corbels. The inferior edge of the band above-mentioned is frequently ornamented with a row of blocks, like dentels, or of small semicircular notches. The circular extremities of the Churches are frequently covered by very high conical roofs projecting considerably over the walls, and between the piers, if they may be so called, are two or more rows of semicircular arches springing from small columns, and having their archivolts divided in several faciæ. Examples of this style may be seen in many of the Churches in this Province, and particularly in those of St. Paul, at Rouen, and of St. Nicholas, at Caen.

tyle of the axon hurches in ngland.

At a period preceding the Saxon conquest of Britain, the Churches of this Country seem to have been made of willow-rods interwoven; such, at least, is the opinion of Dr. Sayer, and, according to Fuller, the dwelling-houses of the Saxons themselves, and even some of their Churches, he mentions particularly the Church of Glastonbury, were thus constructed. The style of the Cathedral of Hexham, as we have said, was probably borrowed from that of the Constantinopolitan Churches, but the generality of the Saxon Churches were of a more simple character; they consisted, like those before-mentioned, on the Continent, of a rectangular nave with a portico at the Western end; the Eastern end was hemicylindrical, like the place of the tribune in the Basilicæ, and the nave was divided into three parts by two arcades, above which were galleries. The arches were semicircular, and rose immediately from the capitals of the columns. The shafts of these were very massive and generally cylindrical, though columns of a different form seem to have been sometimes used. In each face of the tower of Earl's Barton Church, in Northamptonshire, is an aperture divided into five parts by small columns resembling balusters with simple plinths and abaci, and surrounded in three places by astragals, between every two of which the shaft is formed like a barrel. (See Britton's *Architectural Antiquities*, vol. v.) The walls of the buildings were thick and without buttresses; the principal doorway was crowned by a semicircular arch resting on pillars having sculptured capitals, and the archivolt itself was formed with various mouldings, and sculptured with objects in relief.

The Cathedral at Old Sarum probably corresponded in the plan with the description above given; for, from what can be traced of the foundation, it seems to have had a nave and two side aisles, and the Eastern end was semicircular.

he Anglo-axon Architecture as probably a corruption of e Roman.

The rudeness and imperfection of the sculpture which ornamented the Saxon buildings in England, as well as the similar buildings on the Continent, and its resemblance to that which is found on some of the Roman edifices, are considered as proofs that such sculpture was only a feeble imitation of that which abounds on the Roman edifices; but it must be acknowledged that much of it, particularly the zig-zag ornament and the fretwork, is the invention of the Northern artists themselves. According to Dr. Milner, the Saxons, having a taste for embellishment, copied the ornaments of the Roman Corinthian Order, leaving out the richer parts of the foliage, or substituting the forms of men or animals, which were more easily executed: and he observes, that the Saxon mouldings also have their archetypes in the later buildings of the Romans, from which, no doubt, they were borrowed. And since what has been said of the sculpture is equally applicable to the designs of the edifices themselves, the construction of which is of the same period, it may be inferred that these designs have been taken from the very works which supplied the ornaments. In fact, the construction of the Anglo-Saxon Churches is expressly named by the writers of that day, *Opus Romanum*, and this must sufficiently indicate the source from which the construction was drawn.

Improvement of English Architecture by the Normans.

The Conquest of England by the Normans produced an improvement in the Ecclesiastical buildings of this Country. Previously to this event, the Churches had been suffered to go to ruin, and even the spirit of Religion is said to have been nearly extinct. The piety of Edward the Confessor indeed had induced him to labour for its revival in the minds of his people, and afterwards the obligations of the Conqueror to the Pope rendered it convenient to promote the interests of the Clergy. The result of the efforts of both Monarchs was a general repair of the old and the erection of many new Churches of considerable magnificence in various parts of the Kingdom.

Writers on the Ecclesiastical Architecture of this Country make a distinction, as we have before observed, between the Saxon-Gothic and the Norman-Gothic; but it will be evident, on comparing together the few examples we have of each, that almost the only difference consists in the works executed about the time of the Conquest being on a greater scale than those of the preceding Age, and more highly ornamented.

Style of the Anglo-Norman Churches.

The general plan of the Norman Churches was the same as that before described; the body of the Church was rectangular, its longest side lay in the direction of East and West, and the principal entrance was at the Western end; at or near the other extremity was a transverse rectangle directed from North to South, and over the intersection of the two branches of the cross was a tower, which generally served as a louvre or open lantern. This central tower does not appear to have existed in the more ancient English Churches, except perhaps in that at Hexham. In some of the Norman edifices a square tower was erected at the Western end, and in others there were two such; *viz.* one on each side of the entrance, and extending on the right and left beyond the side walls of the Church, but rising very little above the general roof of the building to which they were attached. The towers were without pinnacles, but were ornamented on the exterior by arcades, in tiers attached to the walls, and consisting of small arches, sometimes separate, at other times intersecting each other. The towers might have been at first intended to contain bells like those of the Italian Churches; but afterward, as is supposed by Mr. Bentham, they might have been built for the sake of the fine effect produced by their height and forms. The wooden rafters of the roofs of Churches were at first exposed to the view from the interior, but they were afterwards concealed in panels, which were painted in mosaic in several colours, as may be seen in the Cathedrals of Peterborough and Ely. The interior of the body of the Church was sometimes quite surrounded by attached columns and arcades, and along the nave and choir were two ranges of cylindrical pillars, one over the other, with semicircular arches springing from the capitals; the upper arcades formed the faces of the triforia over the aisles.

On the outside of the building appeared commonly two, sometimes three, tiers of windows, generally high and narrow; and the walls, as well as those of the towers, were ornamented with tiers of attached pillars and arches. The top of the doorway was sometimes horizontal, above it was a semicircular archivolt projecting from the wall, and between it and the top of the aperture were scriptural figures rudely sculptured in bas-relief.

The buttresses of the Norman Churches were generally rectangular on the plan, of small projection, and uninterrupted in their whole height. In some cases, the buttresses were of cylindrical forms, like columns of

2 z 2

different diameters placed one on another, and the smaller above the larger, such are the buttresses of the tower of St. Peter's Church, at Northampton, at each angle of which are three clustered together.

In the Saxon and Norman Cathedrals, a Crypt, or subterranean Church, was a necessary appendage, and such substructions remain under the Cathedrals of Canterbury, Rochester, Winchester, and Gloucester; all of which are of the early Norman times. The interiors of Crypts are divided by parallel rows of piers, or of dwarfish and massive columns, from the capitals of which spring the arches which form the groined vaulting of the Crypt, and support the pavement of the edifice above.

The greater part of the Cathedrals of England, particularly those of Durham and Carlisle, contain specimens of this Norman, or late Saxon style, which prevailed here about a century and a half; *viz.* from the time of the Conquest, in 1066, to about the year 1200; the nave of the old Cathedral of St. Paul, in London, was of the same kind of Architecture. The basement story of the School and Library, at Westminster, exhibit also some interesting remains, which probably formed part of the Church rebuilt by Edward the Confessor; they appear to have originally composed an apartment 110 feet long and 30 feet wide, covered by plain groins formed by a hemicylindrical vaulting which rests on the piers in the wall and on a middle row of eight short and thick columns with square capitals variously sculptured.

Resemblance of the Saxon and Norman Architecture to the Lombardo-Gothic.

The more ancient Churches of England resemble the Lombard Churches in the plan and distribution of the building, in the general character of the columns, and in the ranges of arches formed for ornament against the faces of the walls; there is some difference, however, in the columns, and those in the Italian buildings approach in form and proportion nearer to the ancient Roman examples; the semicircular archivolts in the walls of the English Churches, as in Norwich Cathedral, and in the Church at Castle Rising, in Norfolk, spring sometimes from the alternate columns, and form intersections with each other, an arrangement which has not been met with in Italy. In the Chapter-house of Wenlock Priory there are as many as three tiers of intersecting archivolts over the columns in the faces of the walls; in this Church also the supporting columns are tripled, and within the intersections small arches spring from the capitals of those next to the wall. Under the sloping sides of the pediment or gable, the face of the wall is recessed, and within the retired part are Saxon columns, the lengths of which have been made various, in order that they may suit the inclination of the sides of the roof; a circumstance which corresponds exactly with a practice before adopted in the Cathedral at Pisa. We may, perhaps, therefore, be allowed to conclude that the English artists, in adopting the Southern style, have preserved the character of the features, but have taken the liberty of multiplying them in order to produce a higher degree of ornament in their edifices.

Forms of Norman Arches.

The arches of Norman and Saxon buildings, as well in the interior arcades as over the doors and windows, and those attached to the faces of the walls, were almost always semicircular, but some variations occur in their forms. The apertures between the columns in Earl's Barton Church are covered by elliptical arches; in the Church of St. Peter, at Barton-upon-Humber, in Lincolnshire, are two apertures separated by a square pier, and each crowned by two rectilinear sloping sides, like those of a pediment, which meet in a point at top; and in the tower of Barneck Church, in the same County, are a door and window terminating at top in the same manner: these circumstances render it probable that this kind of arch, if it may be so called, which, if it had been met with in an Egyptian building, might have been taken for one of the primitive specimens, was not uncommon in the edifices of those days. But, besides these, we may add, that a form, to which the name of the horse-shoe arch has been given, exists in several works executed in this Country in the Norman times. This must not, however, be confounded with the Moorish arch of the same name, the aperture of which is narrower at the foot than at some distance above; the English arches are semicircles, or semiellipses at the top and the sides, and are continued in rectilinear and vertical directions down to the capitals of the piers or columns on which they rest; such are the arches of Romsey Church, in Hampshire. In the doorway of Southweald Church, in Essex, is an archivolt whose extrados is exactly semicircular, while the intrados is of the form above described, though slightly marked. Over the doorway of Little Snoring Church, in Norfolk, is a triple arch, the interior of which is a semiellipse nearly; the second is of the pointed form, and the exterior is elliptical at the top, with vertical sides. (See Britton's *Architectural Antiquities*, vol. v.) The pointed arch is ornamented with the Norman zig-zag, and the whole is supposed by Mr. Britton, with great probability, to be a freak of some builder at a period subsequent to the introduction of the pointed arch in England.

Norman columns.

In the interior arcades of the Norman Churches the columns are cylindrical, or in the form of octangular prisms, and their heights, including those of the bases and capitals, are equal to from four times to seven and a half times their diameters, though cases occur in which the height is as much as eleven diameters. The bases sometimes consist merely of a square or circular plinth, but, in many cases, two or more plinths are placed one on another, and above them are narrow circular mouldings, which are frequently sculptured so as to resemble ropes. The shafts are sometimes plain, but often covered with ornaments in spiral and zig-zag grooves surrounding them; and at other times with rhomboidal or lozenge-formed panels sunk in the shaft. The interior of Durham Cathedral, the South doorway of Iffley Church, Oxfordshire, and the window in the Western end of Castle Rising Church, Norfolk, present elegant specimens of these ornaments; for some of which a prototype might be found in the Treasury of Atreus, in the paintings of Herculaneum, and in the mosaics of the Church of the Nativity, at Bethlehem. Columns of similar forms, with plain shafts, are to be seen in the porches of the old German Churches.

The simplest specimens of the Saxon or Norman capitals are, probably, such as those in the Crypt of Lastingham Church, Yorkshire; (pl. xvii. fig. 3.) these resemble baskets or vases placed on the tops of the cylindrical blocks which serve as columns; the lower parts are of a convex form, and either plain or ornamented with leaves; the upper part is cut so as to form a plain, vertical face under each of the four sides of the abacus, below the angles of which are formed small volutes or scrolls. Often, the abaci and vases are cut in eight vertical faces; and, in the oldest specimens of Norman Architecture, the faces are frequently decorated with rude sculpture representing centaurs, griffins, and other extravagances, as may be seen on the capitals of the columns in Iffley Church.

The intervals of the Norman columns, or the spans of the arches which rest upon them, are equal to about two diameters, and the breadth of the system of mouldings forming the arch varies from about one-half to two thirds of the diameter of the column.

The mouldings about the doors and windows of the Norman Churches consist of reeds and channels with concave or plane faciæ between them, to the latter of which various ornaments are applied; the concave spaces are either left unadorned, or upon their surfaces are placed roses and foliage with figures of birds, beasts, or grotesque heads of men, at intervals, as about the South doorway of Iffley Church; frequently the archivolts are covered with a profusion of zig-zags, and the soffits of the arches are notched to correspond with the forms of these ornaments. When the archivolt is not supported by columns, the mouldings and ornaments of the former are continued down the vertical sides of the aperture to the pavement; and if columns are employed, the ornaments either terminate on the capitals of the columns, or, after being interrupted by them, are continued down the shaft. An arch in Tickencote Church, Lincolnshire, and a doorway in the South aisle of Durham Cathedral, have been chosen to exhibit the manner of ornamenting the arched entrances to Norman buildings. See pl. xvii. figs. 1, 2.

The convex or reed-mouldings, whether rectilinear or curved, are either plain or sculptured in the form of ropes, or rather, so as to present the appearance of a cord wound about a pole; examples of this kind occur in the doorway of Hanborough Church, Oxfordshire, of Wimbolton Church, Norfolk, and of many other Norman buildings. The shafts of the columns themselves, and the astragal mouldings of their capitals, are often ornamented in a similar manner; for which a Roman authority may be urged, as they are represented in the paintings at Herculaneum, and exist in the Palace at Spalatro.

Besides the foliage and animal figures with which the Norman mouldings are enriched, several geometrical forms were frequently employed; these are classed under the heads of billets, hatchings, zig-zags, fretwork, and bosses.

The billet ornament consists of two or more courses of small cubical or cylindrical blocks disposed in the circumferences of concentric circles, if they are placed about the arched head of an aperture, or in parallel lines if along its sides; in the former situation the extremities of the billets, like the joints of voussoirs, tend to the centre of the curve. The extremities of the blocks in any one course are not generally placed in contact, but an interval is left between every two blocks, equal in extent to the length of one block, and the blocks in the next course are opposite the intervals of those in the first course. This disposition may be seen about a doorway in Bingham Priory, Norfolk, and about the windows of Steyning Church, Sussex, and of Castor Tower, in Northamptonshire. Sometimes, however, the ends of square blocks abut against each other in every course, and the courses are so disposed that the general profile of the whole moulding has the form of three sides of a hexagon; each side is broken continually, on account of the lateral edges of the blocks in any one course not being coincident.

The hatched-moulding is very similar to the form of the square billet-moulding, the profile of the whole representing three sides of a hexagon, but in each face is a series of triangular notches resembling such as might be cut by an axe. This kind of ornament is found along the face of a cornice, and on the wall itself, of Castor Tower, in Northamptonshire.

Zig-zag-mouldings.

What is called the chevron work, or zig-zag ornament, is very commonly employed in the archivolts of the Anglo-Norman doorways; it resembles a small reed-moulding broken so as to form a succession of salient and rentrant angles, the broken parts being of equal lengths, and inclined to each other at various angles from a right angle to one of 150 degrees. In some cases the reed is single, as in the doorway of Little Snoring Church, Norfolk; in others, the system consists of four or six parallel reeds on the front; and both of these kinds may be seen about the Northern entrance to Peterborough Cathedral. In some cases the system of reeds is continued from the foot of the arch to the ground along each side of the doorway, as in Iffley Church; and, lastly, two courses of zig-zags are placed beside each other with their salient angles in opposite directions, so that a course of rhomboidal spaces is left between the reeds.

Fretwork

The fretwork ornaments are a species of zig-zag, and were employed in similar circumstances; the most simple is a reed-moulding broken in parts alternately parallel and perpendicular to each other so as to resemble the outline of a battlement, an example of which occurs in Sandwich Church, Kent. In an arch at Ely, the parts form sides of equilateral triangles, the bases of which are alternately situated towards the intrados and extrados of the arch. This moulding, instead of a succession of angles, forms sometimes a waving line or curves of many flexures; in which case it is called a *nebula*, and such an ornament exists in a facia at Bingham Priory. The same name is given to a succession of small semicircular notches which join together at their lower extremities, and extend along the inferior side of a horizontal or curvilinear band; examples of these ornaments may be seen over the doorways of the Churches of Hadiscoe, in Norfolk, and of St. Julian, at Norwich.

Bosses.

The plain faciæ of archivolts and the sides of doors are occasionally ornamented with bosses in the form of small pyramids on rhomboidal bases; they are placed at certain distances from each other, and are usually distinguished by the name of nail-head ornaments, which they in some respects resemble. They are found in the arches of Ely and of Lincoln Cathedrals. Star ornaments may be considered as a variation of the last; they are disposed in one or more parallel or concentric rows, each figure consisting of four rays, like those of a star, in relief. They are found on many of the Norman buildings, and particularly on some of the Churches in Suffolk.

CHAPTER VI.

Opinions concerning the Origin of the Pointed Architecture.

Doubtful origin of the pointed arch

About fifty persons have written on the origin of that species of the Gothic Architecture, the principal feature of which is the pointed arch. The names and opinions of these persons are enumerated by Mr. Britton, in the Vth Volume of the *Architectural Antiquities of Great*

Britain, but among the latter there are only about twelve which may be said to be essentially different from each other. These examples of learned trifling exhibit various objects to which the cuspid arch can be likened, up to the keel of Noah's Ark; and the difficulty is not to form an opinion of the possible origin of the arch, and of the species of building to which it appertains, but to select that which appears the most probable. Each person has brought arguments to disprove the opinion of his predecessors, and his sentiment has been, in its turn, impugned by the next Writer. The impossibility of supporting any one opinion by an appeal to Historical evidence renders it unnecessary to lose time in the effort to determine a question which most persons are now disposed to consider as involved in impenetrable obscurity. But as it may be expected that something should be said on this head, we may be, perhaps, permitted to mention two or three of the most important suggestions.

Referred to the rectilinear pediment;

One party,—reflecting that to form a roof of masonry over any space the extent of which is greater than the length of such stones as could be conveniently obtained, it would be only necessary to take two stones, each greater in length than half the interval of the supports, and to place one extremity of each on the top of the pier, letting the other extremities meet above the middle,—considers this construction, from its resemblance to the pointed arch, as the prototype of that feature; and the passages in the Egyptian pyramids, which are thus roofed, are mentioned as proofs of the antiquity of this species of arch. It may be added that similar coverings to apertures occur in ornaments in many Saxon or Norman buildings, and particularly in the walls of St. Augustine's Church, at Canterbury, where the sides of the covering rest on the tops of small Saxon columns, the erection of which must have preceded the invention of the pointed arch with curved sides. But though this construction may have been the first step to the invention of an arch of masonry in general, or of the pedimented form of a roof, it cannot be considered as likely to have led to a change from the semicircular arch to that formed of two segments, since it must have been known from the earliest Ages; and no reason can be given why the change just mentioned should have taken place at the period assigned to the introduction of the pointed arch into buildings rather than at any preceding period.

to the Egyptian pyramids.

In Mr. Murphy's account of the Convent of Batalha, in Portugal, the pointed arch is derived from the pyramidal form of the Egyptian Tombs. This author supposes that, because the Christians buried their dead in Churches, the towers of the latter were made of a pyramidal form, in imitation of the Egyptian style; and he concludes that since the pointed arch is essential to this form, it must have been derived from it. But it has been replied to this argument that the most ancient Churches have not pointed steeples: and, since the burying of the dead in Churches was but a secondary object, it is not likely that Churches would be made to represent Tombs, nor, consequently, that the pointed arches were derived from the same source.

Supposed invention in the East.

It was an opinion of Sir Christopher Wren, and of several writers subsequent to his time, who, probably, relied too confidently upon his authority in a matter of which he might reasonably be supposed a competent judge, that the pointed style of Gothic Architecture was invented among the Saracens, and that from them it was extended to the North of Europe, either by persons returning home after the first Crusade, or by the Moors, who, having received it from Asia, introduced it into Spain when they made the conquest of that Country. This opinion is founded upon the fact that arches of a pointed form really exist in various parts of the East, and some of them in buildings of great antiquity; such as the Tomb or Chapel of the Virgin, at Jerusalem; the remains of a Church, at Acre; the Tomb of Abdallah; and the Hall of Joseph, at Cairo. In the façade of the first, is a Gothic pointed arch springing from columns, and there are two others on the staircase in the interior; the edifice is supposed to have been erected in the time of Constantine; but this is by no means certain, and even if so, it is very probable that the arches were constructed at a later period than the body of the building. The antiquity of the second ascends to the time of the existence of the Saracenic Empire, and it was undoubtedly built by the Christians while they had possession of this part of Syria; consequently, the pointed arch in it is as likely to have been copied from similar works before that time executed in Europe, as from any thing invented by the Arabians. The last two buildings have been already mentioned, and shown to afford no proof of the Asiatic origin of this feature. It may be added that the form of the pointed arches employed in the Saracenic buildings is different from that adopted in the North of Europe in being very slightly pointed, and in the aperture being narrower at the foot than a little above it: if, therefore, we suppose that the pointed arch originated in the East, it will appear surprising that those who introduced it into France or England should have so far altered its form as to make it spring vertically from the capitals of the columns which support it; and that not one example should occur, in this part of Europe, similar to those which are found in the Moorish buildings of Spain.

Consi- to be a dif the se cular a

It has been observed by Mr. George Sanders that, in some Cathedrals and Churches, where the semicircular extremity on the Eastern side is surrounded by an interior arcade, the columns from which the arches spring are not at the same distance from each other in that arcade as in the nave or choir. Therefore, when it was intended to keep the vertices of all the arches at the same height, if those in the nave or choir were semicircular, it would be necessary to make the others semielliptical; but this kind of curve not being easily traced, the artists would naturally fall into the method of giving to those arches the cuspid form, by making them consist of two segments of circles meeting each other in an angle at the vertex; and thus the pointed arch might originate. That such arches should be employed in this case is very natural; and we see, in the Cathedrals both of France and England, of which that of St. Denys, near Paris, and the Trinity Chapel, in the Cathedral of Canterbury, may be taken as examples, that they really were so; and obviously to obtain an equality of height with those in the adjoining choir or transept. But there is one objection to the opinion that the pointed arch originated from this circumstance; *viz.* that those which are so employed appear to have been erected subsequently to the original invention of the feature; and the method was not universally adopted, for in the Tower of London, where there are wide and narrow arches intermixed, the latter are not pointed, though they are as high as the others.

Sup orig Ge

According to Dr. Moller, the pointed style of Architecture originated in Germany about the end of the

XIIth and beginning of the XIIIth century, probably, from a desire to replace the flat or low-ridged roofs of the former style, by others of considerable elevation, which are better adapted to the climate of that part of Europe from the greater facility with which they suffer the rain and snow to fall from the building. This form of roof, Dr. Moller supposes, would necessarily lead to corresponding alterations in other features of the buildings, in order to produce a harmony in all the parts; hence the walls, the columns, and the towers, were all made more lofty and more slender; the arches assumed a pointed form; and the flat pilaster spreading more outwards was converted into a flying buttress.

osed
of the
section
micir-
arches.

The opinion of Dr. Milner, that the idea of the pointed arch was taken from a view of the intersection of two semicircular arches standing in the same plane, seems extremely reasonable, inasmuch as it makes the former a modification of the other, which its posteriority of date seems to justify; and the change is just what might be supposed to be made by a people acutely anxious to vary the forms and beautify the members of their Ecclesiastical edifices. We find, in the Saxon and Norman-Gothic buildings, that the practice of making arches intersect each other by way of ornament against the walls was common; and as this disposition left a cuspid arch between every two semicircular arches, it is extremely probable that it would occur to some person to perforate the wall under this arch, and thus form a pointed window. The idea being started, the form would be immediately copied for windows, for doorways, and even for arcades. Thus that which was at first, perhaps, only the result of accident, or of a capricious taste, might become the model of an elegant and refined system.

osed
tion of
candi-
n ca-
or
s.

The opinion of Bishop Warburton on the origin of the pointed Gothic Architecture, though extremely fanciful, must not be omitted in an enumeration of the hypotheses proposed to account for the invention of this singular style. That learned divine supposes that the Goths who overthrew the Roman Empire, having been accustomed to perform their Religious rites in natural caverns, or in dark groves under the interweaving branches of trees, when they became Christians, erected for themselves places of worship in a style of Architecture drawn from the forms of those caverns and groves. These they imitated in stone; the doors or arches which led to their places of worship they decorated with a profusion of foliage and tendrils which, with a sort of negligent wildness, spread over the path. This was either intended to represent the entrance to a cavern, about which are scattered shrubs and wild flowers, or the opening into a wood formed by the opposite trees intertwining with each other. The great entrances to some of our Cathedrals exhibit this in a remarkable manner; in the middle rises a pillar resembling the trunk of a tree, which by an expansion of its branches on each side forms a passage through two arches from which the whole avenue of columns with the ramifications spreading towards each other and along the roof, form a perspective, arresting the attention by its grandeur and beauty.

It cannot be denied that this picture is highly interesting; it is pleasing to deduce a complicated system from one simple idea, particularly when that idea is afforded by Nature herself; and, in this respect, Bishop Warburton's hypothesis has an advantage over that which deduces the Grecian and Roman Architecture from an original hut. But if it be objected to the latter hypothesis, that many intermediate steps must occur between the timber-hut and the Greek Temple, much more numerous must be the steps between the natural grove or cavern and the rich Gothic Cathedral with its pointed arches and spires, complete in all their parts. Again, it may be observed, that the Goths and Vandals, who entered Spain in 409, did not then first adopt the Religion of the ancient inhabitants of the Country, for they were already Christians; and, consequently, were not likely to erect buildings in imitation of the groves consecrated to Deities whose worship they had long before abandoned. And even if such had been the case, the style of Architecture which they invented must have remained concealed from the rest of Europe till the XIIth century, when it was adopted by the Germans, French, and English. But this is quite improbable, and there is reason to believe that the earliest examples of this kind of building occur in the North of Europe, and that these were subsequently copied in Italy and Spain.

Supposed
prototype in
the ancient
dwellings
made of
willow.

The ingenious theory lately proposed by Sir James Hall, in his Work on the *Origin of Gothic Architecture*, presents a close analogy with that in which the Grecian buildings are deduced from a timber cottage, and completes the application of the principle to all the different styles of Architecture in use; it therefore deserves to be here mentioned. This theory is founded on the probable practice of a people who, like our Saxon ancestors, formed the walls of their dwellings by interweaving the small branches of trees with the upright posts in the manner of basket-work; and who may be supposed to have constructed their Religious edifices in the same manner, but with greater taste. Sir James thinks they would plant a number of posts, or trunks of trees, in vertical positions, and in two parallel rows, at certain distances from each other, so as to form on the plan a series of squares or rectangular parallelograms, and together constituting one great rectangular avenue. Surrounding each of these they might also plant vertically a certain number, he supposes eight, of long slender branches of a flexible wood, which being bound to the principal posts at bottom and in some part of their length, would cause it to resemble what is called a clustered column, with its base and capital. The upper parts of these branches, being bent till they met over the middle of the interval between the posts to which they are attached, would form the outline of a groined vault with an arcade on each side; and these arches might be either semicircular or pointed, according to the manner in which the branches were bent; lastly, a pole running down the length of the avenue, and joining the vertices of all the arches which cross the avenue, will represent the ridge of the vault. Sir James supposes the sides and top of this framework to be filled up by branches interwoven, leaving intervals for the windows; and thus the walls and roofs of the primitive Churches to have been formed. By other ingenious dispositions of flexible branches he supposes the different kinds of windows which are found in Gothic Ecclesiastical edifices to be represented; and he considers that all these circumstances were copied in the formation of the first Churches which were built of stone, in the North of Europe.

Plausible as this theory must be admitted to be, it can only be considered as an agreeable sally of the imagination; for though a contemplative mind may discover a conformity of the clustering pillars and diverging ribs of vaults to the framework of a wicker house, yet, as is observed by Dr. Moller, it is by no means certain that this conformity is the result of imitation, seeing that it may arise from other causes, and that it wants, what he considers as the characteristics of originality, *viz.* that it be found in some particular Country, and that it arise from causes depending on the manners and institutions of the inhabitants. An insuperable objection to the theory is, that the pointed arch occurs in buildings which have no other characteristic of the Gothic style; and, on the other hand, nearly all the other characters may be found complete in buildings wherein not a single pointed arch is to be found; some of the Churches in Normandy afford examples of what has been just said.

Supposed origin of the narrow lancet-headed windows.

We have already observed that the long and narrow window which is frequently found in the Churches of the East of Europe might have originated in the difficulty of constructing a lintel or arch to support itself in the wall of an edifice which is circular on the plan; and it is likely that the resemblance of such windows to the form of an arrow, might have inspired some builder with the idea of changing the semicircular head which they had at first for one terminating in a point like a lancet or arrow-head. This is a form which we find such windows to have in some of the oldest Churches of Europe; and it is easy to conceive that when they were employed in walls with plane surfaces, two or more of them would be placed side by side, in order to gain more light for the interior of the building; and to make an appropriate finish above them, the mouldings on each side would be continued in curves of similar form to meet in a point above the middle of the window. The space between the exterior arch and the sides of the others would require some ornament, and the perforations in the forms of trefoils, quatrefoils, &c. which are generally employed, accord well with such situations; and the prolongations upward of the mouldings about the lancet-headed curves would naturally lead to the tracery-work, which about the same time became a distinguishing feature of this kind of Architecture.

Forms of Gothic edifices determined by a triangulation.

The triangular form of the vertical section of a Gothic Cathedral has given rise to an opinion that the Architects of those edifices determined the positions of their principal points, on the plan, elevation, and section, by the description of a series of equilateral triangles with the vertices of which those points were in coincidence. The first person who started this idea was Cæsar Cæsarianus, an Italian Architect, who shows, in his edition of Vitruvius, that the principle holds good in the Cathedral of Milan; and Mr. J. S. Hawkins has since endeavoured to show that it is applicable to the Cathedrals of our own Country. The opinion may not be altogether without foundation, for such general methods were, undoubtedly, employed in the works of the Greeks and Romans. Among those people the length of a Temple was made to depend on the number of columns in front, and the length, breadth, and height ultimately depended upon the diameter of the columns; moreover, something like the system of triangles occurs in the rules given by Vitruvius for determining, on the plan, the disposition of the parts of the Greek and Roman Theatres; and there is reason to believe that the Gothic Architects had some established rules, which are now lost, for the construction of their Ecclesiastical buildings. No rules, however, have yet been discovered so general as those of the more ancient Architecture, which were applicable to every edifice of the same kind; an advantage arising from the greater simplicity of its buildings, both in the plan and elevation. In the Gothic Architecture, if the system of triangles is really that by which the artists were guided, a different triangulation seems necessary for every different edifice.

In applying this principle to the transverse section of Salisbury Cathedral, we find that the vertices of the vaults of the aisles are in a horizontal plane passing through that of an equilateral triangle, the base of which is a line on the pavement equal to the breadth of the nave and the two side columns; and the summit of the vault of the nave is at the vertex of an equilateral triangle, the base of which is the interval between the centres of the aisles taken in a horizontal plane passing through the tops of the capitals of the columns on each side of the nave. In York Cathedral, the tops of the vaults of the side aisles are in a horizontal plane passing through the vertex of an equilateral triangle, the base of which is on the pavement, and equal to the distance between the centres of the columns which support the longitudinal arcades; and the top of the vault of the nave is at the vertex of an equilateral triangle, the base of which is on the pavement, and equal to the whole breadth of the nave and aisles, including the thickness of the walls. The vertices of the vaults, both of the nave and aisles, in Lincoln Cathedral, are determined nearly in the same manner as in the last example; and it may be added, that the springings of the vault of the nave are in a horizontal plane passing through the vertex of an equilateral triangle, the base of which is the distance of the centres of the side aisles from each other; and those of the vaults in the aisles are in a plane passing through the vertex of an equilateral triangle, the base of which is equal to twice the breadth of the aisle. But the variations found in our principal Cathedrals leave little chance of discovering any general system for their construction, and it is rather probable that the artists of the Gothic edifices did not bind themselves to any constant rules in the works they executed.

Supposed origin of Freemasonry.

During that period in which the building of Churches was constantly occurring, and every effort was made to execute them in the most perfect manner, persons would be wanted who, having applied themselves exclusively to their erection, had acquired a certain facility in it. Just such a class of men was found in the Freemasons of those times. These were originally, it is supposed, refugees from Greece, Italy, Germany, and France, who were skilled in the Art of Building, and who formed themselves into a fraternity for their general benefit. They are said to have travelled from place to place, and to have engaged themselves to carry on the works which the Architects, that is to say, the Ecclesiastics, had designed. There does not seem, however, to be any foundation for the opinion that they were invested with corporate powers by the Pope, in the XIIth or XIIIth century, as has been supposed; and it is observed by Mr. Britton, that they were not known to exist as a distinct body till the reign of Henry VI., in whose third year, that is, in 1424, an Act of Parliament forbade them to assemble in general Chapters. Persons admitted into the Society were instructed in the mysteries of the Art, and were bound not to divulge its secrets to the uninitiated. Near the building which they had undertaken they formed an encampment of huts, in which they resided, and they were subject to a regular Government of their own. One man, who acted as a Surveyor, was responsible for the conduct of the party employed in the work, and every tenth man was a Warden: and if any Member conducted himself improperly, he was expelled from the

Society. A class, like this, of men jealous of the reputation of their Society, must, by the mutual emulation subsisting among its members, have brought the practice of masonry to considerable perfection; it is not wonderful, therefore, that we find the accuracy of the work performed in those Ages equal to any thing that could be executed by the best workmen of the present day. And we may, perhaps, attribute to the members of that Society the invention of many ornaments, if not of some of the principal features in the buildings of those times.

CHAPTER VII.

Characteristics of the Pointed Architecture in different Ages.

tem- yment of Pointed le in the rth of rope.

About the end of the XIIth and beginning of the XIIIth century, that which is called the *Pointed Style* of Gothic Architecture was introduced into the principal Ecclesiastical buildings of Europe, and gradually superseded the more ancient modes exhibited in the Saxon and Norman buildings. The new style is characterised, in a general way, by its high ridged roofs, its pyramidal towers, and the pointed form of its arches and vaults, all which features give to the buildings of that day an air of lightness and magnificence, forming a powerful contrast to the low and massive works of the preceding Age. Efforts have been made to prove that the acute features, as they are called, are of earlier date in the Continental Churches than in those of England, but the arguments only prove our ignorance of the precise time of their first occurring in the edifices of any Country. In fact, the great intercourse subsisting among the Prelates of the North of Europe, during those Ages in which Church-building was so general, would, naturally, lead to the adoption, in one Country, of any style which had been invented in another. Hence it might be expected that there should be, almost at the same time, an uniformity in the characters of the Churches which it was the chief business of those Prelates to build or adorn.

ress of Pointed t in Ger-

Besides the edifices formerly mentioned, in which the new style of Architecture seems to have been first introduced, Germany has produced many examples which will for Ages remain as proofs of the great talents of her artists in raising magnificent piles for the service of Religion. The Church of the Knights of the Teutonic Order at Marburg, which was begun in 1235, is in this style, and besides being executed in a most skilful manner, is distinguished by great simplicity and elegance. The Cathedral of Cologne, which was begun in 1248; that of Strasburg, in 1274; that of St. Stephen, at Vienna; and the High Church, at Ulm, are also structures in which the same style seems to have been carried to perfection; and some of these possess even greater richness of character than the buildings executed, in England, in the time of the most florid state of Gothic Architecture in this Country. But it seems that, in Germany, the Art declined during the XIVth century; the buildings of that period wanting the regularity of form which constitutes the merit of those which are more ancient. Profusion of heavy and ill-executed sculpture also was resorted to, in order to produce a striking effect, for some time previous to the introduction of the revived Italian style, in the North of Europe.

France,

The Cathedrals of France, the construction or completion of which is referred to the XIIIth and beginning of the XIVth centuries, closely resemble, and equal, if they do not exceed, in richness of decoration, the contemporary Churches of England; and, though, as is observed by Dr. Milner, the most magnificent edifices in the North of France, the Cathedrals of Notre Dame, at Paris and Rouen, and those at Amiens and Beauvais, for example, are by the French themselves attributed to English artists, yet the members of these buildings are distinguished by certain peculiarities which show them to have an independent origin; and the taste which dictated them may, with great probability, be ascribed to natives of the Country.

The wars with the English, and internal commotions, prevented the Architecture of France from making progress, during the two following centuries, corresponding with that which it had made before. And, in the XVIth century, the Gothic Architecture, as well in France as in Germany, was abandoned to make way for the style which had then recently been formed in Italy from the study of the remains of ancient Rome.

and England.

In England, notwithstanding the long period during which the Country was involved in a Civil war, the taste for Ecclesiastical Architecture maintained its ground, and the works executed during the XIIIth, XIVth, and XVth centuries may vie with most of those on the Continent at the same periods. But the cessation of those wars near the end of the XVth century, and the wealth which the nation began then to acquire by commerce, enabled the Sovereign, and the Prelates, to put in execution some of the richest designs which invention could furnish; and just before the revolution in taste which brought on the Italian style, the Gothic Architecture, like the expiring flame of a lamp, shone for a short period with redoubled lustre. It was at this time that the exuberantly ornamented Chapels at Westminster, Windsor, Cambridge, and other parts of England were erected; and these, by the care taken to repair them in their original style, will, probably, for Ages remain among the most perfect monuments of a system of Architecture which seems particularly adapted to buildings consecrated to the Christian Religion.

Changes introduced in the Gothic Architecture together with the pointed arch.

The disposition of the Cathedrals and Churches erected in England, subsequently to the abandonment of the Norman style of Architecture, was the same as before, with respect to the plan; that is, the cruciform style was still retained, with only such modifications as two transverse rectangles instead of one, as in the Cathedral of Salisbury, or two chancels, one at each end of the building, as in some of the German Churches. But the great change that took place in the form of the arch seems to have brought with it a corresponding change in every vertical feature; the exterior of the roofs, the vaults, the towers and windows were made more lofty than before, and even the ornamental objects were made to assume a pyramidal form. The pillars and ribs of arches were reduced in breadth by deeply-cut mouldings and ornamental sculpture, till the greatest degree of lightness consistent with stability was attained. A considerable change took place, also, in the quantity and quality of the sculpture; which then became more abundant and greatly improved.

Uncertainty of the period in which particular style prevailed.

It is impossible to express accurately the peculiarities of style existing at different periods in the Gothic buildings, on account of the great liberties the artists allowed themselves of blending the style of one period with that of another; this is in nothing more evident than in the forms of the arches. It is understood, for example, that in the first Age of the pointed arch; that is, in the XIIIth century, it was of the lancet form, the radius of each curved side being greater than the span of the arch. In the XIVth century, the pointed arch is supposed to have had its vertex lowered, as if the curves were described on the sides of an equilateral triangle, the radius of the curve being equal to the span. After this period the vertex became still lower, the radius being little more than half the span of the arch: finally, a little previous to the suspension of the Gothic style of Architecture, the arch assumed the figure of two hyperbolic branches, of considerable curvature at the springing courses, and nearly rectilinear to a certain distance on each side of the vertex, where the branches met at a very obtuse angle. But, though this seems to have been the general progress of taste with respect to the form of the arch, yet we often find in the more ancient buildings, arches much lower than in those that are less so, and equally great discrepancies may be observed in every other feature; all that is meant, therefore, by assigning a particular period to any one character is, that the generality of the buildings of that period were conformable to it, while the exceptions are numerous. And it is easy to conceive that, in the absence of Historical documents, the indications of antiquity drawn from the forms of the members of a Gothic edifice, are as uncertain as those drawn from the proportions of the parts of a Grecian Temple.

Examples of the first deviations from the Norman style in England.

The Norman style of building began to be modified before the middle of the XIIth century; but, as might be expected, the works erected between the time of the first departure from one method and the complete establishment of another, partook in some measure of the characteristics of both. In fact, the Churches which were built about the time of the first introduction of the pointed arch, contain such a mixture of styles as indicates an entire ignorance or disregard of the principles of good taste.

According to Dr. Milner, the Church of St. Cross, near Winchester, was built in the beginning of the XIIth century, and, if so, it must have been one of the first in which there is a departure from the Norman style of building; but the alterations subsequently made have introduced into it every species of Gothic Architecture. The columns which divide the nave and aisles are massive cylinders or prisms, the heights of which, including the bases and capitals, are equal to about three times their diameter; and from the capitals of these spring cuspid arches which differ little from semicircles. About the middle tier of windows in the choir, are semicircular or flat segmental arches springing from piers and intersecting each other; and, within the intersections, the wall is cut away to form pointed arches crowning the apertures of the windows; while, in the Eastern wall, some of the windows have exactly semicircular heads. The mouldings and ornaments about the windows are of the Norman or Saxon kind.

To the same century are referred the Churches of Barfreston, in Kent, and of Buildwas Abbey, in Shropshire, both of which appear to exhibit the earliest specimens of pointed arches. In the walls of the first are cut lancet-headed recesses, and the arcades in the nave of the other are of the pointed kind, springing from cylindrical pillars, while the upper windows have semicircular heads. Both Churches, also, contain some of the members of a later style which may have been introduced at the repairs made in subsequent periods.

The same mixture of styles prevails in the choir of Canterbury Cathedral, Malmsbury Abbey Church, in Wiltshire; Rumsey Church, in Hampshire; the Temple Church, in London; and many others, which belong to this century. The Cathedral at York is also one of the first grand edifices in which the pointed arch was used, but the part above ground having subsequently undergone many alterations, the original style is hardly perceptible: much of it, however, remains in the crypt, in which place the arches are slightly pointed, and spring from short round pillars, the capitals of which are adorned with animals and foliage. Rumsey Church presents some remarkable peculiarities, which are worthy of being mentioned, though they probably belong to the Norman style. On the Northern side of the chancel, the lower and second tiers of arches are semicircular-headed, but the apertures of the second tier are divided into two equal parts by a single column, upon the capital of which rest the adjacent extremities of the two interior arches, which are also semicircular, and cover the aperture on each side. On the capital of this middle column rests a smaller one, which seems to support the crown of the exterior arch. Above this arcade is an arched passage, formed in the thickness of the wall, and in the direction of its length, with an aperture towards the interior of the Church; the aperture is divided into three parts by short columns, above the capitals of which are rectangular piers, nearly equal in height to half the height of the column, and serving to support the semicircular arches over the intervals of the columns. The employment of a column to support the crown of an arch, occurs, to our knowledge, only in some of the Norman buildings, and it indicates either an absurd taste in ornamental Architecture, or a want of confidence in the stability of that feature.

Examples of lancet-headed arches.

A fine specimen of the style prevailing in the latter end of the XIIth and beginning of the XIIIth centuries, is the face of the Southern transept of Beverley Minster, in Yorkshire, which, fortunately, remains in excellent preservation. In the centre is a doorway, divided into two parts by a single pillar, supporting the adjacent extremities of two lancet-headed arches which cover the apertures; both these arches are included within one of a semicircular form, the mouldings of which spring from an assemblage of clustered columns on each side; above this are two tiers of lancet-headed arches, three in each tier, and at the base of the gable, or pediment, is a circular window with mullions radiating from a rose in the centre, and forming what is called the Catherine-wheel window. In each of the lateral divisions of this face is also a lancet-headed window, over which is a circular panel containing four star-formed perforations. The great pointed window, the tiers of panelling, and the ornamental foliage at the Eastern end are, probably, of later date.

The great Western window of the Church at Wells, is similar to those over the doorway at Beverley, for it is composed of three lancet-shaped divisions separated, however, not by mullions, but by piers of masonry, nearly equal in breadth to the apertures themselves. The present work is said to have been a rebuilding of the original, about the year 1239, and the simplicity of the groining in its nave and transept, shows that it belongs to the first period of the Pointed Style of Architecture.

hitecture.

acteris- of the itec- of the h cen-

From these examples we may conclude, that the Gothic edifices of the XIIth century presented few deviations from the Norman style; the columns may be considered still as consisting, generally, of a single cylindrical shaft; the great arcades, if not semicircular, were formed of two segments differing but little from quadrants, so that the arch had the appearance of being very slighty pointed. The heads of the windows and smaller apertures, on the contrary, were formed of two arcs of circles making a very acute angle at the vertex, the radii of the sides being equal to two and even three times the span of the aperture; and the Norman mouldings and zig-zags were still retained about the arches. The Catherine-wheel window seems to have been introduced; and, in one of the façades at the extremity of the building, three lancet-headed windows were placed at small distances from each other. In the great Cathedrals, where the exterior of the wall is ornamented, the ranges of arches, simply pointed and resting on short pillars, appear to have been employed in the latter part of this century; and it is probable enough that some of the more complex forms of arches were invented during the same period, but their use was not sufficiently general, or the dates of their construction are not sufficiently certain to allow us to consider them as characteristic features of the buildings in that Age.

ous arches h cen-

Salisbury Cathedral, which was almost entirely built in the XIIIth century, is considered as exhibiting the most complete assemblage of the parts belonging to that period; and though individual examples of some of the members often occur in edifices of an earlier time, yet it is from this period that we are to date the general employment of the features, collectively, in Ecclesiastical buildings. In the screen at the Eastern end of the choir of that Cathedral are two clustered columns, consisting each of four shafts united together on a common octagonal plinth, and supporting a pointed arch, the sides of which are formed on those of a rectilinear triangle nearly equilateral. On each side of this, in the same screen, is an acutely-pointed arch, one side of which rests on a column consisting of one stout, cylindrical shaft with four slender ones attached to its surface. A more complex species of clustered column also appears in the nave and transept of this Cathedral; it consists of many slender shafts united in one body like a bundle of rods, to which it has often been compared, and though it may have occasionally occurred before, it became from this time a constant feature in Gothic edifices. The shafts were either plain or divided into two or more parts by small fillets or astragals of stone surrounding the whole pillar, and the capitals, bases, and plinths were commonly octangular.

Columns grouped about a central pillar in the manner just mentioned are usually considered as essentially distinct from those of the Saxon or Norman kind; but this is not a correct opinion, for they occur in several of the old Churches executed according to those styles; for example, in the Churches of St. Etienne and of St. Hildebert, at Gournay, in Normandy, and the Cathedral of Durham in our own Country. It may be remarked that similar groups are found in the Church of St. Catherine at Oppenheim, the construction of which is referred to about the same period as that of Salisbury Cathedral.

In the buildings of this century the arches, which at first had been of the acutely pointed or lancet form, were subsequently made with radii equal to about four-fifths of the span of the arch; the intrados of each branch was generally a continuous curve, but often it was cut into a series of segments of small circles meeting each other and forming rentrant cusps towards the centre of the arch; and these cusps sometimes, as at the entrance of the Chapter-house, at Salisbury, ended in sculptured leaves. The mouldings about the arches of the naves are made to consist of assemblages of slender, curvilinear reeds with concave grooves between them, and above the extrados is a moulding, not resting on the capitals of the columns, but terminating in a sculptured head projecting from the spandril above the capital. Such are the arches of Rumsey Church, in Hants, and of Salisbury Cathedral; the Norman ornaments upon the archivolts were generally abandoned, except the zig-zag, which in some examples was retained; and in the latter part of the century, a series of small crosses, or, as they are called, dog's-tooth ornaments, appears along the mouldings of the arches, as in those of Litchfield Cathedral. This ornament was, however, employed on the Continent at an earlier date, for it occurs in the Abbey Church of the Holy Trinity, at Caen, in Normandy, which having only semicircular arches was, most probably, built before the invention of the pointed style.

The arcades of the triforia are composed of one exterior pointed arch resting on short columns grouped together over those in the lower arcades; within it are two pointed arches, the adjacent extremities of which rest upon a short, clustered column over the apex of the arch below: and within each of these are two smaller pointed arches, the extremities of which rest upon a single column in the middle. The soffit of each of these four small arches is cut by five segments of circles forming rentrant cusps in the manner above mentioned: and in the spandril between each of the two smaller, and also between the two greater arches under the principal one is an aperture formed by ten intersecting segments within the circumference of an exterior circle.

Stone-vaultings and high roofs of the XIIIth century.

In this century, and, perhaps, at a period somewhat earlier, the timbers of the roof, which had been formerly exposed to view from the interior of the building, were concealed by a groined vaulting of stone which was formed several feet below them, so as to leave a void between the extrados of the vault and the outward covering of the roof, a construction to which the name of *chare-roof* was given. The ribs at the edges of the groined vault of the nave were ornamented with mouldings, and, at first, made to spring from the pillars supporting the arcades; but, subsequently, some were made to spring from corbels between the windows in the side walls, or from the capitals of small columns with single or triple shafts resting upon heads which project from the wall between the exterior arches of the triforia. Between the ribs at the angles of the groins, others were formed on the plane face of the wall, and all extended to a sort of spine coinciding with the crown of the longitudinal vault of the nave; the profile of the spine was similar to that of the ribs, and the intersections were marked by knots of foliage or flowers.

The profile of the stone-vaults having, like the arches, an acutely-pointed form, the artists were obliged to give to the external roof that great height which forms one distinguishing feature in the buildings of this and the succeeding Ages. Hitherto the roofs had been low pitched, resembling those of the Greek and Roman edifices, but, from this time, it became common to make the inclinations of the sides to the horizon not less than sixty degrees, so that the gables or pediments have the appearance of equilateral triangles. Wooden spires of a pyramidal form and covered with lead, had, before this century, been common in the Norman Churches; but they began now to be formed of stone, on polygonal bases, and to be highly ornamented. The buttresses, which had hitherto terminated at the top of the side walls, were at this time raised above it; and at the upper extremity was formed either a pinnacle or a sort of pediment. Flying buttresses, consisting of simple arched ribs, were formed above the roofs of the side aisles, in order to resist the lateral pressure of the central roof against the walls over the arcades of the nave.

Windows of the same period.

In the beginning of this century the pointed windows of Churches became broader than before; the aperture was divided into two parts by a vertical mullion, and each division or light was covered by a pointed arch-head of the lancet form, as had previously been the case with the semicircular-headed windows in the Norman Churches. In the spandril between the exterior curve and the heads of the two lights was frequently formed an aperture consisting of three, four, or more segments of circles intersecting each other about a centre, so as to produce rentrant cusps and form a trefoil, quatrefoil, &c. aperture: such are the windows in the side walls of Westminster Abbey, which were probably executed in the time of Henry III.

At the Western extremity of Rumsey Church is a great window divided into three parts, nearly equal to each other by two vertical mullions, the interior faces of which are ornamented with slender columns in clusters, and each aperture is covered by an arch of the lancet form. But in the same century some of the greater windows were crowned by pointed arches nearly equilateral and divided by one principal mullion, ornamented with clustered columns, into two parts with pointed arch-heads similar to that of the whole window; and each of these was subdivided, in a similar way, into two others. The spandril between the secondary and tertiary arches was occupied by a quatrefoil aperture circumscribed by a circle, and that within the principal and between the secondary arches by an octofoil aperture, circumscribed also by a circle: such are the windows of the Chapter-house, at Salisbury. This, probably, preceded the method of dividing the windows by upright mullions, branching off at top and forming a tracery-work by their intersections, a method which, however, occurs in works executed nearly at the same period. In Litchfield Cathedral, and in the Western aisle of the Northern transept of Westminster Abbey are windows formed by describing arcs on the three sides of an equilateral triangle, with the angular points as centres; the interior is occupied either by tracery or by three circles touching each other and the sides of the window. Such windows were sometimes formed in the clere story; but generally the windows in that part of the building are divided by clustered shafts, and the apertures terminate in lancet heads.

The smaller windows of this century seem very generally to have had trefoil heads, but the middle segment in the intrados was formed with a cusp at the vertex. The ornamental ranges of arches on the exterior and interior faces of walls were also of similar forms, and were supported, as before, by small columns.

On the exterior of the building, pediments were, at this time, formed above the extradosses of arches and windows, and terminated at each foot in some figure which projected from the face of the wall; these pediments were sometimes rectilinear, but generally curvilinear, at first concentric with the sides of the arch itself, but about the latter part of the century they became curves of contrary flexure terminating in points and ornamented. The canopies in the walls of Churches, which were before plain, were ornamented in a style corresponding with that of the windows, and were occupied by statues.

Form of pillars in the Cathedrals of the XIVth century.

During the XIVth century the style of Architecture became more light and elegant than before, and may be considered as having attained the state of its greatest purity. The clustered columns now consisted of a greater number of shafts, and formed a mass the plan of which might be circumscribed by a rhombus, so situated that lines joining the opposite angles are respectively parallel and perpendicular to the length of the building. The four principal pillars which support the central tower are much larger than the others, and are carried as high as the top of the triforia; that is from five to seven times the greater diameter of the clustered pillar. At each angle of the cluster are generally three columns united in one, and between every two such united columns are two or more slender ones, all attached to the main body of the pillar. Each column in the cluster has a plinth or, rather, a low pedestal of a polygonal or circular form on the plan, and above this is a torus and fillet; the plinths and mouldings respectively, by uniting, form a general base for the whole cluster. In the same manner, each column in the cluster has its own capital, formed of mouldings, flowers, or foliage, with a circular or polygonal abacus above, and these are united in one general capital for the whole pillar. The columns or stems at the angles are generally uninterrupted from the base to the capital, but those intermediate are broken into three or more equal parts by astragals and fillets. The pillars of the side arches in the nave are about one-third of the height of those under the central tower, and are formed in a similar, though not always in the same manner.

Arches and vaults of the same period.

These arches are of the pointed form and nearly equilateral; each side is formed as if composed of a number of circular mouldings springing from the capitals of the stems which constitute the clustered column. Above the summits of these arches a small horizontal moulding runs quite through the length of the building; over this is the triforium or second arcade, consisting of a series of pointed arches like those before described, and above these is a second horizontal moulding, either plain or ornamented. Between every two arches in the nave, and every pair in the triforium is a slender column, either single or triple, rising from the pavement up to the second horizontal moulding, where it terminates in a small capital, from which spring the ribs in the groined-work of the vault. The height of the lower arcade is generally about five-eighths of the height from the pavement to the rise of the vault, and that of the upper arcade is about equal to the remaining three-eighths. The spandrils between the curves of the arcades and the horizontal mouldings above are generally plain, but sometimes filled with trellis-work, as in Westminster Abbey. In some cases there are two tiers of galleries over the lower arcade, as in the transepts of York Cathedral; but sometimes, as in the nave of the same Cathedral, instead of galleries the whole of the side walls above the lower arcade is occupied by large windows. The most common case, however, is that in which there is one triforium, and above it, within the lateral vaults of the groined-work, a tier of clerestorial windows.

The tracery in the ceiling of the body of the building became, in this century, more intricate than in the former; for the ridges of the lateral vaults not being so high as that of the longitudinal vault, the ribs at the angles of the groins frequently cross each other and also the intermediate ribs, and thus form many compartments, at all the angles of which are knots of flowers or foliage. This kind of tracery is exhibited in the vault of the nave of Winchester Cathedral; and the faces of the vaults between the ribs are sometimes ornamented with trellis-work, as in Lincoln Cathedral.

he towers.

The central tower was a rectangular building terminating with battlements, and containing windows on each side; in some examples the angles of the tower were furnished with pinnacles enriched with sculpture, and in others the tower was crowned by a lofty pyramidal spire. The two towers, which were placed one on each side of the Western front of the nave, were similar to that over the centre of the building; that is, they either terminated in battlements and pinnacles or were surmounted by spires. In some cases we find the angles of the towers plain, in others they are strengthened by buttresses, plain or ornamented, and either rectangular or polygonal on the plan; the pinnacles are usually placed only on the summits of the buttresses, but occasionally one is also placed over the centre of each face of the tower, and all are of a conical or pyramidal form. The towers are usually divided into two or more parts by horizontal mouldings; and between these are either windows, or niches and canopies containing statues, or ranges of arches standing on small pillars, like those in the Pisan edifices; only the arches are either simply cuspid, or consist of a trefoil formed by three arcs of circles blending with each other in a line of contrary flexure. The battlements of the towers or of the general body of the building are sometimes plain, at other times formed of open-work; and the exterior of the walls, gables, and buttresses is ornamented with canopies, ranges of ornamental arcades on slender pillars, and sometimes partly with trellis-work.

indows.

The Western façade of the building was occupied by a window placed over the doorway, sometimes equal in breadth to the whole of the nave and reaching to the top of the vault. This and the other windows were divided by mullions and transoms, the former generally dividing into ramifications near the upper extremity of the window, and by their intersections producing a tracery representing loops and foliage, as in the Cathedrals of York and Carlisle. The rectangular compartments of the windows were filled with painted glass representing Apostles, Saints, or Kings. The arched heads of most of the windows of this time were higher than the equilateral kind; and above the extrados, on the exterior of the building, were pediments in the form of curves of contrary flexure, which, as well as the sloping sides of the gables, pinnacles, and buttresses, were profusely ornamented with crockets and crowned by finials.

Occasionally, the mullions proceeded in rectilinear directions to the head of the window, and the walls and buttresses were ornamented with panels standing immediately over each other, so as to cause a system of vertical lines to appear to predominate on the exterior of the edifice; and hence Mr. Rickman has, with some propriety, applied the denomination of the *Perpendicular Style* to that which prevailed in the latter part of this, and the beginning of the following century.

About the same time the circular window, usually placed at one or both extremities of the transept, was increased in size and divided into compartments by radiating pillars and concentric circles, as in Westminster Abbey, or by a tracery representing loops and foliage arising from the intersections of branching mullions, as in the Cathedrals of Winchester and Litchfield. An elegant circular window of a similar kind, and probably of the same period, remains in each gable of the Church of Buildwas Abbey, in Shropshire.

Besides the buildings we have mentioned, the Conventual Church of St. Augustine, at Bristol, and St. Stephen's Chapel, at Westminster, now the House of Commons, are to be considered as among the best specimens of the Architecture of this Age.

Satirical sculpture.

In works erected during this century, we find the first examples of that sculpture which disgraces many of our noblest buildings. Fools, mountebanks, and satirical representations of Monks are the principal subjects on which this depraved taste was exercised; and sacred edifices, where every circumstance should inspire serious sentiments, were the places chosen to exhibit them. According to Mr. Douce, the figures may have been intended to cast ridicule on certain classes of men, or to express the mummeries practised at the Feast of Fools. The same kind of sculpture was, at a later period, employed on the under sides of the *misereres* or *turning-seats* in some of our Cathedrals.

General characteristics of the Architecture of the XVth century.

From the end of the XIVth to the beginning of the XVIth century another change took place in the style of Architecture. The arches of the arcades, doors, and windows became much lower than before; the upper part of each side was nearly rectilinear, and the two formed a very obtuse angle at the vertex. This, which was called the *Tudor arch*, though generally, was not universally employed, for the equilateral form is also to be seen in buildings of the same Age.

The vaulting in the roof, like the arch which served for its model, became nearly flat about the vertex, the angles of the groins being rounded, the spandrils assumed the form of an inverted bell either entirely or in part, and the upper portion of the surface marked upon the ceiling the whole or a segment of a circle. The spandril itself was covered by numerous small ribs which branched from the capitals of the columns, and gave to its surface the appearance of a fan; and between those spandrils, others, consisting of masses of stone, each weighing more than a ton, in the shape of inverted bells, and ornamented with fanwork, were pendent from the vault. At the intersections of the ribs of the fanwork, armorial shields were sculptured, and the lower extremities of the pendents were ornamented with foliage. The exterior covering of the roof, which before had great elevation, was now again reduced very low in order to correspond with the form of the vaulted ceiling.

The vertical mullions of the windows proceeded from the sill quite to the top of the arched head, and were crossed by transoms frequently ornamented with small battlements. Over the doors and windows was generally a horizontal, rectilinear moulding, which terminated on the vertical sides produced, so that the aperture of the door or window seemed enclosed in a rectangular recess. A horizontal label was placed a little above the top of the recess, and a branch at right angles to it extended a little way down each side, where it terminated either in a lozenge-formed ornament, or in a short branch parallel to the upper part of the moulding.

In the buildings of this Age, the windows occupy so great a portion of the walls that, as Dr. Milner observes, the whole Church has the appearance of a glass-lantern rather than a substantial building.

The vertical buttresses of this Age are of a polygonal form on the plan; they rise considerably above the roof of the aisles, and their faces are highly ornamented with panels, battlements, and elegant projecting canopies; the sides of the flying buttresses also are ornamented with tasteful perforations, and their extradosses with crockets or creeping animals. On the tops of the vertical buttresses are pinnacles, the profile of which is bounded by curves of contrary flexure meeting in a point at the top; the faces of these are ornamented with a sort of network, their ridges with crockets, and their apices with elegant finials; and, in fact, every member of the building received in this century the highest degree of enrichment of which it seems capable. The principal examples of this florid style are Henry the VIIth's Chapel, at Westminster, and King's College Chapel, at Cambridge; and it may be easily imagined that this elaborate workmanship could only be bestowed upon the smaller kind of Ecclesiastical edifices.

of the XVIth century.

At the dissolution of the Monasteries in the XVIth century, the last change took place in Gothic Architecture; the works of Cardinal Wolsey at Oxford and at Hampton Court are examples of the style, which then became common in Ecclesiastical and Palatial buildings, and even in private dwellings.

Instead of that exuberance of ornament which a short time before covered every part of the edifice, the utmost plainness prevailed. This was a necessary consequence of the almost general employment of brick and rubble stone in building, in place of the masonry which permitted a full display of the powers of the chisel. An air of meanness reigns in all the works of this period, because the rude materials of which they are constructed are incompatible with the graces of ornament. The doorways were still crowned by an obtusely-pointed arch, but the windows were rectangular and divided by plain mullions and transoms; small and unadorned arched heads were, however, still retained over the lights or subdivisions of the windows. As if to compensate for the plainness of the exterior, the interior of the Palatial edifices exhibited the highest luxury of sculpture in the marble which surrounded the fire-places and in the wood-work of the apartments.

Timber-roofs, which had before been employed only occasionally for covering great Halls like that at Westminster, became common in the Churches and mansions of this period, and superseded the stone-vaultings of the former Age.

The Architecture of the Churches of France and Germany experienced changes nearly corresponding with that of the Churches in England in the different periods, till the invention of the Tudor style, which seems to be peculiar to ourselves, for no examples of it are to be found in the Churches of the Continent. Previously to that time, whatever may be the differences in the minor parts of Ecclesiastical edifices, their general features either indicate a parallelism in the progress of ideas, or that the artists in one Country adopted almost immediately the variations introduced by those of another.

It is a little remarkable that though the Tudor Architecture was never adopted on the Continent, yet, in the city of Rhodes, the ancient Church and the buildings in the street of the Knights, which cannot be supposed to have been erected at a later period than the end of the XVth century, have windows with obtusely-pointed arches and horizontal labels over them, like those in the nearly contemporary edifices of England: a circumstance which can only be accounted for by considering them to be works executed under the influence of the English Knights, who, before the Reformation of Religion, formed part of the Order then occupying that island.

CHAPTER VIII.

Detailed Description of the component Parts of Gothic Ecclesiastical Edifices.

The general forms of the members which enter into the composition of Gothic edifices have been mentioned in the preceding Chapters, but as it was not convenient then to describe them so much in detail as is necessary in order to afford a sufficient knowledge of their character, we purpose now to do so; and though the great variations found in the different examples, and even in the same building, seem to render hopeless the effort to reduce the Gothic Architecture to general rules, yet a knowledge of the dimensions and proportions adopted in the members of some of the principal edifices, will be of great service in fixing our ideas of the practice of artists in the Middle Ages.

Clustered columns.

Columns with double shafts were employed by the Roman artists in the later period of the Empire, since they occur in some of the Syrian buildings, and possibly there might have been others of a more complex character then existing though since destroyed; but it was not till the XIIth century that the clustered column became general, and assumed the various forms which we are now to describe. At first the central part of the column was circular or elliptical; four slender shafts were applied to the circumference at the extremities of two diameters, which were respectively parallel and perpendicular to the length of the building, and each shaft projected from the central part as much as half or three-quarters of its diameter. Such are the forms of some of the columns of Salisbury Cathedral, and in that building the longest diameter of the cluster is 4.65 feet; the height, including the base and capital, is 25 feet; and the breadth of the aperture of the arch between two columns is 17 feet: consequently the proportion between the diameter of the column and its height is as 1 to 5.4, and the intercolumniation is equal to 3.7 diameters. The heights of the systems of mouldings forming the base and capital are equal to a diameter of one of the attached shafts.

In the nave and choir of York Cathedral, the central part of the cluster is a square each side of which is about 4 feet long; at each angle is a three-quarter column 1.42 feet diameter, and between every two of these, on each side of the square, are two smaller shafts of unequal diameter with small intervals between them. The breadth of the whole cluster diagonally is 8 feet, the height of the shafts at each of those angles from whence the arcades spring is 29 feet, and the breadth of the archway is 19 feet: consequently the proportion between the diameter and height of the column is as

1 to 3.62, and the intercolumniation is equal to 2.37 diameters. The bases of the columns are of the Attic kind standing on octagonal plinths, which are 3.25 feet high, and are divided into two parts by a horizontal moulding; and the capitals are ornamented with foliage. The three shafts at the angle next to the middle of the nave proceed uninterruptedly to the top of the side walls, and support the ribs of the groined vaulting.

The great columns which support the central tower form an irregular rhombus, on the plan, with reentrant angles on two of the sides. In these also, there is one great shaft at each of the four angles, and the intervals between them are occupied by many smaller ones. But the plans of some of the clusters in the transept are nearly circular, and about 4.75 feet diameter; at the extremities of two diameters which cross each other at right angles, is a triple shaft with a vertical fillet or moulding on the face of each; between these is a single shaft with a similar fillet in front; and in each of the intervals is a vertical channel formed in the body of the pillar, and containing a small shaft completely detached from the pillar, except at the base and capital, where it is connected with the general plinth and capital of the cluster.

In Lincoln Cathedral some of the small clustered columns consist of eight shafts disposed about the circumference of a circle; the outline of the plan of each shaft has the appearance of two arcs of circles forming a cusp in front, and the bases, plinths, and capitals are of similar forms. Some of the columns in the nave of this Cathedral resemble those in the nave of York, but the angular shafts are detached from the body of the column, and stand in semicircular channels. There are others in the same line, having eight three-quarter columns about the circumference, with a vertical fillet or bead in front of each, and a semicircular channel or fluting between every two. The shafts at the angles of the cluster are larger than the others, and their heights are equal to from thirty-six to forty times their diameters.

But, in Westminster Abbey Church, the interval between every two of the four secondary shafts is occupied by two smaller ones which are in contact with each other; the diameter of the whole is 5 feet; the height, including the base and capital, is 31 feet; and the intercolumniation is 14 feet; the height of these shafts is divided into three equal parts by fillets, which, on some of the pillars, surround every shaft of the cluster, but, on others, appear only on the four secondary shafts. The capitals are circular or octagonal, and are without sculpture, and the bases stand on high plinths.

At a later period, the clustered columns assumed a still more complicated character: the intervals of every two of the four secondary shafts being occupied rather by vertical mouldings than columns; the plan presenting a succession of salient and reentrant curves, some of them simple, others forming cusps, consisting either of two segments of circles, or two curves of contrary flexure. Such are the columns in the nave of the Cathedral at Wells: their diameter is 5.25 feet; their height 16 feet; and the intercolumniations 11.75 feet. The bases of the shafts resemble those called Attic, and stand upon triple plinths of circular forms, and the capitals are sculptured with elegant foliage. Similar columns appear in Henry VIIth's Chapel, at Westminster, and St. George's Chapel, at Windsor.

The forms of the arches in Gothic Cathedrals cannot be considered as affording sure indications of the Age of their construction. Semicircular arches were generally executed in the Saxon and Norman times, and when they occur, we seldom hesitate to consider them as belonging to one or other of those periods; nevertheless, several examples exist in which from an affectation of the ancient style, or from some other cause, such arches have been executed in later times. Again, the obtusely-pointed, or hyperbolic arch is not known to have been constructed till the time of Henry VII., but in the intermediate Age all the other varieties of the pointed arch seem to have been indifferently used. The high lancet-headed arch is considered as that which immediately succeeded the Norman kind; yet, in buildings of the same antiquity, we also find pointed arches differing but little from semicircles.

Writers on Gothic Architecture are accustomed to divide the pointed arch into several different kinds. Those the sides of which are described with radii greater than the breadth of the aperture, have the name of *lancet-head arches*, and the radii of these are sometimes equal to two or three times that breadth; and those, the radii of which are equal to the breadth, are called *equilateral*. But all those, the radii of which are less than the breadth, are distinguished by the names of *arches of the third point*, *fourth* point, &c.; in the first, the radii are equal to two-thirds; in the second, to three-fourths, of the span or breadth of aperture and so on: it must not, however be understood that in arches really constructed it is possible always to express the proportion of the radii to the span by terms so simple as these, for the artists do not seem to have limited their practice by rules, in this member more than in others.

The arches at the Eastern end of Canterbury Cathedral are of the third point, and this form seems to have been designedly given them from taste, for they are in situations where the high, lancet figure would have been more simple; since, in order to gain the required height, the artists have been obliged to make the curvature of the sides begin at a considerable distance above the capitals of the columns, which gives them in some measure the appearance of the horse-shoe arch. The importance which the Architects of that day attached to the elegant curvature of the arches is evident from the circumstance that those of the acutely-pointed form have, sometimes, each side described from two centres, in order to produce a greater degree of curvature on the hances than would be obtained by one centre. The Tudor arch is invariably of low elevation, the two sides forming a very obtuse angle at the vertex, and each side of these is usually supposed to have been described from two centres. In Henry VIIth's Chapel, at Westminster, the radii of the lower and upper part of the intrados are respectively equal to 0.217 and 0.845 of the span; while in St. George's Chapel, at Windsor, the radii are 0.2 and 1.25 of the span, respectively, and the proportions differ, perhaps, in every example.

Before the doorway of an ancient nunnery, at Rhodes, is an elliptical arch, above which is a projecting mass, like an oriel, consisting of three sides, with cylinders at the angles; the line of the arch is a curve of double curvature, as it projects forward so as to be every where vertically under the faces of the oriel, if it may be so called. In this last are windows, some of which have flat, elliptical, and others pointed heads.

The general profile of a pointed arch is splayed on each side of the intrados moulding, and, in this respect, it corresponds with the plan of the clustered column. No rule can be assigned for the breadth of the archivolt, if it may be so called, but cases occur in which, if we do not include the weather-moulding above the extrados, it is equal to half the breadth of the clustered column from which it springs, for the mouldings about two contiguous arches sometimes meet over the middle of the column; frequently, however, the breadth is less, and in some cases it is greater; in York Cathedral, the extrados-mouldings of two adjacent arches are made to intersect each other and come down upon the capital of the column in front of the interior mouldings. An elevation of one of the arches and pillars in the nave of Litchfield Cathedral is given at pl. xix. fig. 4; and of the arched gateway at King's College Chapel, Cambridge, at fig. 7, in the same plate.

The ornaments on the sides of arches are a series of slender astragal or bead-mouldings, the profiles of which are sometimes semicircular, at other times cuspid, and some have the forms of cymatia, or curves of contrary flexure of various kinds. The semicircular mouldings have, occasionally, a fillet or rectangular moulding on each side, and sometimes they are separated by a rectangular groove, or a circular channel, from each other. The weather, or extrados-mouldings, are in the form of cymatia, with a rectangular fillet on the exterior, and the lower extremity of each branch rests upon a Norman head, sometimes of a grotesque character, or upon an animal. In Beverley Minster it rests on an angel playing on a violin, and the angel stands on a head projecting from the wall over the column between the two arches.

Ranges of arches standing on small columns attached to the exterior and interior faces of walls, which form so conspicuous a feature in the Lombard Architecture, were adopted in the Gothic Churches of the North of Europe, but the arches, instead of being semicircular, correspond in form with those of the Age in which they were executed. In the oldest examples they are simply cuspid in the lancet style, and these are often used with semicircular arches in the same building, as is the case in the tower and gable at the Western end of Lincoln Cathedral. In the interior of the Chapter-house, at Salisbury, is a range of such arches having the intrados cut in cinquefoil shapes by segments of circles which meet and form rentrant cusps, and the upper segment has a point or salient cusp at the vertex. The Abbot's Tower, at Evesham, and the faces of the buttresses in that Church, are covered from top to bottom with tiers of cusp-headed, narrow arches in trefoil and cinquefoil forms. This tower was erected but a short time before the Reformation.

Sir Christopher Wren, though averse from the Gothic Architecture in general, and even censuring its taste severely, allows considerable merit to the pointed arch, on account of its mechanical properties; he observes that it can be raised with little centreing, it requires but light arch stones, and little abutment to resist its lateral thrust on the points of support. But with respect to its strength, Dr. Young, in his investigations concerning the strength of arches generally, published in the *Transactions of the Irish Academy*, has proved that when the radius of curvature is equal to two-thirds of the span, the strength of the pointed is to that of the semicircular arch as 0.826 to 1; and when the radius is equal to three-fourths of the span, the strengths are in the ratio of 0.795 to 1. Dr. Young also shows that the equilateral-pointed arch is the weakest of the kind, and that the strength is increased as the radius is less or greater than the breadth of the aperture.

An opinion of the relative strengths of the different kinds of pointed arches, founded on experiment, might have had some influence in determining the species to be employed in particular circumstances; for wherever great weight was to be supported it was usual, at the time of the first introduction of the pointed arch, to construct one, the branches of which were described from two centres near each other; which, consequently, differed but little from a semicircle; at the same time the arches merely ornamental were of the lancet form, very acute at the vertex; a construction probably chosen from some perception of its beauty.

Arches rising from pillars have always been objected to, but those of the pointed form rising from clustered columns, as in the Gothic Churches, do not seem so improper as those in the Roman and Saxon edifices; because the circular mouldings forming the ribs of the pointed arch appear to be but continuations of those which constitute the pillar, and the latter has the appearance of a bundle of rods which diverge from the capital and meet those of the neighbouring pillar in the vertex of the arch; consequently, the archivolt seems to form part of the pillar, and rather to be an ornament than a support to the wall above.

It may also be observed in favour of the pointed arch that it is easily adapted to any situation; for while the least irregularity in a semicircular arcade would produce an unpleasant effect, the other, possessing less unity of form, conceals many defects, and a series of such arches admits of considerable variations from equality of span without exhibiting an appearance of deformity.

Vaults.

In the ancient crypts, the hemicylindrical vaults, by their intersections, formed diagonal ridges, which were left without ornament, but a plain rib, projecting from the face of the vault, and extending from pier to pier perpendicularly across it, relieved the uniformity of the work. In the Church of St. Cross, in Hampshire, the diagonal ridge is cut off so as to leave a flat face, and this is ornamented with the double zig-zag, but the faces of the perpendicular ribs or cross springers are left plain.

The simple, hemicylindrical groin-vaulting of the Roman and Norman times seems to have been exchanged for that formed by the high-ridged vaulting as soon as the pointed arch had superseded the semicircular one; and the nature of the vaulting depends so much upon that of the simple arch, that there can be no difficulty in admitting that the profile of the former would always be made to correspond with the latter. In Salisbury Cathedral, ribs are formed at the diagonals of the groins and there is one cross springer between every two of these, in a vertical plane perpendicular to the direction of the vault; all these are ornamented with mouldings, and the intersections at the crown are marked by knots of foliage. In Winchester Cathedral the diagonal ribs intersect each other where the vertices of the lateral vaults meet that of the nave, and proceed thence to the longitudinal ridge in the crown of the latter, at which they meet those ribs which are in a plane perpendicular to its length. The upper parts of the divisions between the diagonal and perpendicular ribs are again divided by short ribs, extending to the crown of the vault and connected with the principal ribs by branches. Similar arrangements of ribs are formed on the faces of the lateral vaults, and the intersections of the ribs and branches produce a complicated tracery, almost every angle of which is marked by a knot of foliage. Over the choir of York Cathedral the tracery is still more intricate; the lateral vaults have the same height as the general longitudinal vault of the roof, and the spandril between every two of the former is divided into fourteen triangular compartments, on each side of the building, by three ribs which spring from the column, like those at Winchester, and by others which intersect them in various directions; and every intersection is marked by a flower. The kinds of tracery above described are supposed by Sir Christopher Wren to have been invented by the Freemasons: the ribs were commonly made of free-stone, and the intervals filled with light materials, sometimes with chalk.

The specimens of vaulting executed in the Age of the Tudors, and exhibited in the Chapels at Westminster and Cambridge, have been already described; the fan-work ornament and the pendent spandrils, in which the Gothic Architecture displays its richest character, may be considered as belonging to the last stage of Architectural luxury; artists, perhaps, could go no further in the indulgence of a taste for ornament, and, from that time, they seem to have reverted to a more simple style.

172. The entrances to Gothic Churches, both of the Norman and succeeding styles, are very small if compared with those of the Greek and Roman Temples. In general, the former consists of an aperture terminated by a semicircular or pointed arch resting on piers and preceded by a porch of a trumpet form, being small at the door and increasing in width towards the exterior both at the sides and crown; and, in some cases, the pavement of the Church is lower than the general level of the surrounding ground, so that the entrance resembles that of a Tomb, an idea of which it might have been intended to convey by that descent. In some Cathedrals, as in that of Winchester and Litchfield, a single pillar of small height is placed in the centre of the doorway, and from its capital rise two branches, making with the curve on each side of the doorway two pointed arches, the heads of which are included within that of the porch; each side of the entrance is generally ornamented with a multitude of slender columns, from the capitals of which stems proceed to meet those from the opposite side, at the vertex. The shafts are sometimes plain, but they are often enriched with an endless variety of sculpture, representing foliage and other ornamental objects. In small Churches the sides of the doorway are merely occupied by mouldings, the profiles of which are concave and convex curves.

The upper part of doorways in the Tudor Age was often inscribed in a rectangular recess or panel; a mode which we have stated to have been practised in the Moorish edifices at a period, probably, not much anterior to that of its introduction to this Country.

In almost every case the sides of pointed arches rise perpendicularly to the horizon, but there are some buildings in which those over doorways or windows do not so; such arches, which are very deficient in elegance, are found in Romsey Church and Winchester Cathedral, and they seem like the segments of pointed arches, formed by cutting away some of the lower courses of masonry. The doorway of Magdalen College, Oxford, is crowned by a low pointed arch of the hyperbolic kind, and this is within a rectangular recess, above which is a series of battlements, having small canopied niches containing statues in the faces of the merlons. Above the hances of the arch are armorial bearings, and on each side, from the exterior of the recess, springs a slender rib of a hyperbolic form; the two ribs meet on the middle of the exterior face of the horizontal mouldings over the doorway, and, except at the foot and vertex, they stand quite detached from the rest of the work.

Among the Greeks and Romans, the doorways were made proportional to the size of the building, and extravagantly lofty, but the Gothic Architects, who seem to have felt the impropriety of this practice, generally made them of nearly the same height for all buildings, and that was just sufficient for the passage of persons through them; yet, wishing to give them a suitable proportion to the size of the building itself, they contrived an ingenious way to combine both propriety and proportion by splaying the opening in oblique directions from the inner to the outer face in the thickness of the wall; thus converting it into a porch the sides of which they ornamented with columns, mouldings, statues, or foliage, by which it acquired an air of grandeur and beauty.

Windows. In the Norman Churches the windows were generally small, and consisted of narrow, semicircular-headed apertures, splayed interiorly, and placed singly in the sides, but two or three together at each end of the building, with a small, circular aperture above them in the gable; and, probably, in the smaller Churches, they were without glass. To these succeeded the lancet-headed windows, which were sometimes plain, like those of the Norman kind before mentioned, but at other times they were decorated, inside and out, with marble columns, of which those in the inside, as in Chester Cathedral, were detached from the wall; the proportion between the height and breadth of such windows is very various, but the ratios of 3 to 1 and of 7 to 1 seem to have been the limits.

In buildings of the XIIIth century, the windows were broader in proportion to their height, and were divided into two apertures, days, or lights, by a column, or mullion. The window was splayed on all sides towards the interior, and each aperture was covered by a pointed arch, either plain, or having the intrados cut in trefoils or cinquefoils, and these were either simple or cuspid. Above the apertures, but within the exterior arch, was a quatrefoil inscribed in a circle, or the mullion diverged at top, and formed three compartments ornamented in a similar manner. The window at the Eastern end of Lincoln Cathedral is of this kind, but its tracery is more complex. See pl. xix. fig. 1.

The species of ornament, which consists of circles either plain, or having the interior circumference cut in segments, is exhibited also in the heads of the windows of Churches erected in France during the same period, and it constitutes the first step towards the formation of the more complicated tracery which succeeded when the broad windows were divided into three or more parts by mullions. For then, above the trefoil or cinquefoil heads, which, at the level of the foot of the arch, terminate the vertical divisions, the mullions branched off in curves to the right and left, and formed, by their meetings or intersections, a number of loops, which occupy all the upper part of the windows; the edges of the loops were cut to form salient and rentrant cusps, which give to the loops the appearance of leaves of plants. Where the number of vertical mullions was uneven, as in Worsted Church, and Cawston Church, Norfolk, the central mullion divided into two branches, which meeting the mouldings on the curved sides of the window formed with them two pointed arches, and divided the upper part of the window into three principal compartments, each of which was occupied by the cuspid loops formed by the smaller ramifications. The whole height of such windows exceeded their breadth in various proportions, of which the ratios of 1.5 to 1 and 2.3 to 1 seem to have been nearly the extremes. The style may be considered as belonging to the XIVth century, and the different specimens exhibit a great variety of design. See pl. xix. fig. 2, which exhibits the upper part of the great Western window in York Cathedral

It is uncertain whether the mullions in windows originated from the practice of placing in the middle of an aperture a column for the support of its crown, or from placing two tall and narrow windows near each other, for the purpose of obtaining more light in the interior of the building; in the latter case the part of the wall between the windows, being gradually lessened, might ultimately become merely a vertical bar. The nearest sides of two lancet arches being supported on such a bar, have the appearance of two branches proceeding from the trunk of a tree; and, from this circumstance, it is not improbable that the idea of giving to the tracery in the heads of windows the appearance of foliage might have been taken. Be this as it may, we find that in the Eastern window of the Church at Dorchester, is actually represented a tree, exhibiting the genealogy of the family of Jesse. The central mullion forms the trunk, and, in place of transoms, branches proceed from this to the right and left, and are ornamented with sculptured leaves. There is also a mullion of the same kind on each side of, and parallel to the principal one; each of the three divides into two parts near the top, and these, by intersecting each other, form lancet-headed apertures, the interior edges of which are cuspid. On the mullions are sculptured statues, and a statue of the root of the family lies at the foot of the central trunk. See Britton's *Architectural Antiquities*, vol. v.

But from the middle of the XIVth century the foliate tracery was superseded, and a rectilinear division of windows seems to have prevailed, of which the great pointed window at the Western end of Winchester Cathedral is a striking example. This extends from the top of the doorway to the crown of the vault over the nave, a space equal to three-fourths of the height of the crown of the vault from the pavement, and its breadth is equal to that of the nave. Two principal mullions divide it into three equal parts vertically from top to bottom; and, in the interior, these mullions being continued downward, form the sides of the doorway; each part is subdivided into three others by smaller vertical mullions extending to the curved sides of the head, and these also are continued down to the pavement, except where the doorway interferes. Four horizontal transoms divide all the space, from the bottom of the window to the springing of the arch, into four equal parts, so that the rectangular part of the window is divided into thirty-six compartments, each of which is terminated by a trefoil cuspid head. At the level of the springing of the arch, the two principal mullions divide; one part goes up vertically to the head of the window, the other goes off laterally in a curve to meet the sides of the arch, by which are formed two secondary pointed arches; and all the compartments in the upper part of the window have cuspid heads like those below. According to Mr. Britton, this window was executed in the time of Bishop Wykeham, about the end of the XIVth century.

The windows in the tower of the Church of St. Mary, at Taunton, (see pl. xix. fig. 3.) may be considered as examples of the style of executing them about the middle of the XVth century. Some of these windows have curved tops higher than those of the equilateral kind, but others are more flat, and seem to approach the hyperbolic form, which prevailed about half a century later. Like the window at Winchester, the part below the springing of the arched head is divided into rectangular compartments, each of which is terminated by a cinquefoil, cuspid head; within the upper part, short upright bars rise from the vertices of the cinquefoil heads, and every two are connected at top by others which meet at an angle; from the vertices of these proceed other upright bars which are connected in the same manner, and this arrangement is continued to the top of the window, so that all the space within the arch is occupied by hexagonal compartments, every one of which is subdivided into four similar hexagons.

The species of ornament which consists in an union of polygonal figures, or of circles, is called by Mr. Rickman *Geometrical tracery;* a term sufficiently proper to distinguish it from that kind which is formed by curves of a complex nature.

When the Tudor arch was introduced, the compartments formed by the mullions and transoms were larger than before, but the manner of ornamenting them was nearly the same as in the windows last described. Finally, the breadths of the windows became greater than their heights, and the tops were made horizontal; the breadth was then divided by one or more vertical mullions, and there was sometimes no transom. The rectangular apertures were either not ornamented, or their upper extremities were formed with semicircular or cuspid heads; the latter were sometimes of contrary flexure, and there was a loop cusp on each side, as in some of the windows of Hampton Court Palace.

The weather, or hood-moulding seems to have been an almost universal accompaniment to a Gothic arch, both on the exterior and in the interior of a building, and, except when it became rectilinear or a curve of contrary flexure, its form corresponded with that of the head of the aperture, so that, when the latter became horizontal, the weather-moulding was also rectilinear.

Over a recess in the peristyle of Dioclesian's Palace we find an example of the arch of contrary flexure, which, though it is, probably, more modern than the rest of the building, is likely to have been the first of its kind. The same species of arch, and the rectilinear pediments employed as ornaments above apertures or recesses, are very common in the Ecclesiastical buildings of the Continent; but whether their application in these examples was previous or subsequent to their introduction in this Country does not appear.

A circular aperture is, perhaps, one of the most ancient methods of obtaining light for the upper part of the interior of any building. The Greeks and Romans, who gave rather low roofs to their edifices, had little occasion to make any aperture in the tympanum of their pediments; and, therefore, we do not find it in any of their buildings, except in the interior of the Palace at Spalatro, where, on one side of the peristyle is a circular window of small dimensions; this is, probably, the first of the kind now remaining, and it may have been executed at some period subsequent to the erection of the building. The same kind of aperture was formed in the Christian Churches erected at Rome, and thence the practice may have extended to those of Germany and France. In England, we find it not only in buildings erected subsequently to the Conquest, but also in those of Saxon or Norman origin.

But the taste for improvement increasing, the simple circular aperture was soon, in this Country at least, changed for one formed by three or more segments of circles meeting in rentrant points, and constituting what are called trefoils, quatrefoils, &c.; these were employed not only in the pediments or gables of buildings, but in the wall between the arched heads of doors and long windows, and even in the compartments of windows themselves between the branches of the mullions, as in Lincoln Cathedral.

The resemblance of the circular aperture to the wheel of a carriage probably led to the practice of making it large, and supporting its circumference by bars radiating from a centre; this, which is called the *Catherine-wheel*, is thought to have been first constructed in France, from whence it seems to have been introduced into this Country soon after the Norman style was superseded, and an elegant specimen of it, in its simple state, yet remains in the Southern transept of Beverley Minster. But the increased size of the windows in the next Age of Architecture rendered it necessary to introduce a greater number of bars; and, as these might have been either too far asunder, or too much crowded if they all extended from the centre to the circumference, it was found convenient to divide the window into two by another circle concentric with the first; the radii of the interior circle were continued to the circumference of the exterior one, and within the annulus only, additional bars were inserted in the direction of radii. Such a window as this occurs in the Southern front of York Cathedral; its radii resemble short columns, the tops of which are joined by small arches, and the centre is occupied by an elegant rose.

But the tracery which had been introduced within the arched tops of great windows, was extended to those which were circular, and we find the compartments of the latter afterward, that is, in the XIVth century, made to resemble those of the former; and, according to the form assumed by the ramification of the bars, the aperture had the name of a *rose*, or a *marigold window*. In the Northern and Southern extremities of the transept of Westminster Abbey are immense circular windows, 32 feet diameter, with radiating mullions, each of which, near the exterior, divides into two parts, and the branches form cusps, the vertices of which are on the circumference; between the principal mullions are secondary ones, also in the direction of radii, and forming cusps at their extremities, and within the compartments are quatrefoil perforations. The great circle is inscribed in a square, and within each of the four angles of the latter is a large quatrefoil inscribed in a circle. These windows are of later date than the part of the building in which they are placed, and Mr. Pugin supposes them to have been added in the time of Richard II. In the Western façades of the Cathedrals of Notre Dame at Paris and Rouen are great circular windows, in the centres of which are rich flowers, and between these and the circumferences the aperture is occupied by narrow loops in the directions of the radii. At each extremity of the transept of Lincoln Cathedral is a circular window in which are formed four compartments by two arches of circles, the centres of which are in the circumference of the exterior circle, and the circumferences touch at its centre; in the middle of each of these is a vertical stem from which branches proceed to the right and left, and form loops, the interior edges of which are cut to represent circular and cuspid foliage. The divisions of circular windows sometimes consist of an annulus of quatrefoil perforations inscribed in circles which are disposed about one in the centre; and this itself is composed of circular perforations similarly situated.

Towers and spires.

Some of the oldest towers of Churches in this Country are of a cylindrical form, pierced with small apertures or loop-holes and crowned by battlements. The towers of the Norman Churches were generally square, ending in battlements, and perforated by several tiers of circular-headed windows, or ornamented with arcades of the same kind, disposed also in tiers on the faces of the walls. The tower of Ely Cathedral, which is supposed to have been built in the latter end of the XIIth century, is a decagonal prism divided by eight tiers of windows and arcades, of which the three lower have semicircular heads; the others are formed with pointed or trefoil arches, and the whole is crowned by battlements.

After the pointed arch was introduced, spires were occasionally employed; but generally the roofs of towers were flat, and at the angles were plain or ornamented pinnacles, with buttresses for their support.

As opinions have been various concerning the origin of the pointed arch, so have they been also concerning the origin of the spires which crown the towers of Churches. Dr. Milner supposes that buttresses which were found necessary for the support of walls could not be properly finished but by forming pinnacles at the tops; and these being enlarged became spires: others have deduced them from the Egyptian Obelisks, which they consider as merely ornamental objects: again, others derive them from the Pyramids, which, by all people, have been used to mark the burial places of their distinguishd characters; and they suppose them to have been applied to Churches when the latter were used for the like purpose. In England, the spire is placed above the tower, as if it had been a subsequent addition, and not part of the original idea; and, in fact, the earlier Churches, or those erected during the prevalence of the Norman style, are merely crowned by battlements or plain parapets, and the pinnacles, which are sometimes formed on those buildings, are invariably of a later date than the building itself. One of the earliest spires known was that of the old Cathedral of St. Paul, in London, which was built about the year 1222, of timber, and covered with lead: many such were afterwards constructed, but being often destroyed, they were, finally, built of stone. Of this material, the first executed is that of Salisbury Cathedral, which was erected about 1429, and since repaired by Sir Christopher Wren. From that time hardly any Ecclesiastical edifice was raised without one, and they are in general highly ornamented with sculpture.

While the Pointed Style was in high vogue, the towers and spires were extremely lofty, particularly that which was placed over the intersection of the nave and transept; the top of the spire being, in some cases, as far from the pavement as seven times the height of the roof of the Church. The towers at the Western end were commonly ornamented with arches and windows to correspond with those in the wall of the nave between them, but the central tower had commonly two tiers of windows on each face, with the ornaments about them belonging to the time of their erection; generally a pediment in the form of a curve of contrary flexure, with crockets and finials as usual. The merlons of the battlements were either solid or open, and a pinnacle was placed at each angle. From the centre of the tower rose the spire, generally in the form of an octagonal pyramid, the edges of which were ornamented with bosses or foliage; but the most remarkable circumstance in the spire is its slender profile; that of Salisbury Cathedral is only two feet thick at the base and nine inches at the summit. It is worthy of remark that frequently the choir being less broad than the nave, the four columns supporting the central tower are, in such cases, disposed at the four angles of a trapezoid instead of a square; and the Northern and Southern faces of the tower are consequently not parallel to each other, nor to the side walls of the building.

A curious specimen of a spire is that of the Church at Newcastle on Tyne, which is thus constructed; from each of the four angles of the square tower springs a strong rib of masonry in the form of a quadrant of a circle, and without a spandril; these meet over the centre of the tower, and upon the intersection is raised a square open lantern, crowned by battlements, and having a small pinnacle at each angle; and from the centre of this rises a lofty pyramidal spire ornamented with crockets. At each angle of the great tower is a slender, octagonal turret, with battlements at the height of the vertex of the arch formed by the four ribs, and above each of these is an ornamented pinnacle; and a smaller turret and pinnacle is placed between every two of these on the middle of each face of the tower. The tower is said to have been added to the Church in the reign of Henry VI. This example of a spire supported on the intersection of four open ribs suggested, no doubt, to Sir Christopher Wren the design which he put in practice at the Church of St. Dunstan in the East, in London.

Buttresses. The buttresses attached to the Norman Churches have been already described; we purpose, therefore, in this place to speak of those only which were constructed after the Pointed Architecture became general; from which time they were embellished with decorations corresponding to those on the other parts of the building.

In the first period of that style of building, the buttresses were made of equal breadth and depth, nearly from top to bottom, and they terminated above in high pediments or gables, within which, on the face was, sometimes, a trefoil, cuspid, ornamental arch supported by two small pillars: such are the buttresses at Beverley Minster, in Yorkshire; and in these a rectangular notch is cut along each of the exterior angles of the buttress in a vertical direction, within which is a slender reed column with a small base and capital. At the Eastern end of Lincoln Cathedral are buttresses similar to these, but more ornamented; the edges of the gable tops are decorated with crockets and finials; on the face is a panel formed between the reed columns at the angles, and terminated by a small, pointed arch near the top; and at two places in the height are formed trefoil-arch heads with a small, rectilinear pediment above. Each side of the buttress is ornamented in a manner exactly similar to the face.

In later buildings, they were divided horizontally into several parts, each projecting more than that above it, and the heads of the inferior parts were covered by small inclined planes, or water-tables. In some cases the upper division of the buttress is attached to the face of the wall by short ribs only, and the whole is then crowned by an ornamented pinnacle quite detached from the building. The angular buttresses are not always placed immediately at the quoins of the building, but a little way from them, so that small portions of the walls appear in the rentrant angle formed between their nearest sides. The vertical buttresses of Henry the VIIth's Chapel at Westminster have been described in speaking of the style of Architecture in the XVth century.

What are called flying, or arched buttresses, are generally only ribs of masonry extending from the solid buttresses attached to the walls of the aisles to the upper part of the side walls of the central division of the nave or transept; they are sometimes formed of simple voussoirs without spandrils, and the extrados is usually in the shape of a roof, being covered by two inclined planes which meet in a ridge. But the arched buttresses of Henry the VIIth's Chapel consist, each, of two double ribs one below the other; the inferior rib of each pair is in the form of an arch of a circle, and the superior rib of the lower pair is rectilinear, while that of the upper pair is a curve concave upward; the superior surface of this rib is ornamented with creeping animals, seeming to descend along the rib, and between the two pairs, are perforations in the form of quatrefoils, or loops, inscribed in circles, by which the massive appearance of the buttresses is removed without much diminishing their strength.

Pinnacles. The earliest pinnacles were, probably, only conical terminations at the tops of round towers, and when afterwards polygonal towers were erected, the pinnacles above them necessarily became pyramids. Along the ridges of these, were reed mouldings, and they were frequently adorned with small crockets, as is the case with some of those on Salisbury Cathedral, and occasionally the upper extremity terminated in a finial. The pinnacle was generally mounted on a small prism, in each face of which was an aperture or a recess terminated by a small arch, either semicircular or pointed, and then a rectilinear pediment crowning each arch; smaller pinnacles were sometimes disposed about the base of the principal one, and these were enriched in a similar way.

From the end of the XIIth century pinnacles were almost always placed on the tops of buttresses, and those of Lincoln Cathedral, (pl. xix. fig. 9.) may serve as specimens of the manner of ornamenting them. Each face of the buttress is crowned by a pediment or gable, the height of which is equal to about twice its breadth; the figure of a beast projects forward horizontally from each of the lower extremities of the gable and the sides, which are ornamented with crockets, terminated in a finial. Between the sides of the gables, rises an octagonal turret with a reed column at each angle and a lofty gable over each face; the whole height of the turret, from the bases of the gables below to the summits of those above, is equal to about three times its diameter, and the latter gables are ornamented with finials only. Lastly, between the sides of these, rises an octagonal pyramid to such a height that the distance of its apex from the bases of the lower gables is five times the diameter of the turret; the ridges are ornamented with small scrolls, and the pyramid is crowned by an elegant finial.

In edifices, the towers of which are very much enriched, the figure of a bird, animal, or a man frequently projects horizontally to a considerable distance from each angle of the tower, and supports a square pillar or small clustered column terminating in an ornamented pinnacle; the whole pillar is detached from the turret or great pinnacle in front of which it is placed, except near the upper extremity, where it is connected with it by a bar or piece of open-work. This kind of ornament is exemplified in the tower of St. Mary Magadalen's Church at Taunton.

The form of the pinnacles employed in the Tudor Age, has been described in speaking of the general style of Architecture practised in the XVth century. Pl. xix. fig. 6, is an elevation of a pinnacle on one of the buttresses of Henry the VIIth's Chapel at Westminster.

Niches seem to have been a late addition to Gothic Churches, and were made, on the exterior, to contain statues, or in the interior to contain tombs or piscinas. The simplest and earliest constructed were rectangular on the plan, but with the progress of luxury, they became hexagonal and even octagonal, and were adorned with every variety of sculpture. On the exterior of the building they were placed indifferently in the towers, buttresses, and walls; and, often, they were disposed in horizontal ranges along the Western front, above and on each side of the doorway.

In front of the recess containing a piscina, in Salisbury Cathedral, are three columns, with circular bases and capitals, which support two pointed arches, the intradosses of which are cut to form trefoil heads, and the exterior of the recess is surrounded by a circular moulding disposed on the four sides of a rectangle described on the face of the wall; this is one of the most simple forms. In later times, the upper part of the face of the recess was a pointed arch, the sides of which were cut to form rentrant cusps, the latter ornamented with foliage, the curves with mouldings, and the lower extremities resting on single or clustered columns of small height. Frequently, this kind of façade was crowned by a pediment with sides either rectilinear or in the form of curves of contrary flexure, and decorated with the usual ornaments; and on each side of the recess was a buttress or pillar terminating in an ornamented pinnacle.

In the more enriched works, when the recess is of a polygonal form, the interior sides are ornamented with rows of panelling having trefoil or other curvilinear heads; at the upper part of the niche is a canopy projecting before it in the form of three sides of a prism, the lower extremity of each face is cut in a trefoil or quatrefoil arch, above which is a pediment ornamented with crockets and a finial; and between these arches, that is at the angles of the prism, is a small pinnacle ornamented as before, and rising as high as the level of the ornaments above the arches, but terminating at the lower extremities of the same arches, so that they seem suspended in the air, and resemble the tops of buttresses or piers of which the lower parts have been removed. Sometimes the whole of the upper extremity of the canopy is ornamented with fleurons, and on the sides which are attached to the walls are columns, single or clustered, or slender piers ornamented in the same style as the canopy and interior of the recess.

Shrines or sacella were commonly tombs placed in recesses of the walls in the interior of Cathedrals, and originally they consisted of plain sarcophagi or coffins, with little other sculpture than the recumbent figure placed upon them; afterwards, the recess was formed with an arched front ornamented with foliage, and at a still later period it was enriched with elegant canopies executed with open sculpture or filigree work. Finally, the shrine became a splendid Chapel like that of Henry the VIIth at Westminster.

Bishop Bridport's monument in Salisbury Cathedral, is a rectangular space in the body of the Church. In front are two pointed arches of the equilateral kind with concave and convex mouldings; each of the two outer branches rests upon two small pillars a little detached from each other, with circular bases and capitals which unite together, and the two adjacent branches rest upon three similar pillars. Each aperture is divided into two, by a single pillar of the same kind as the others; these apertures are crowned by smaller, pointed arches nearly equilateral, and having the intradosses cut in trefoils with cuspid heads, and the whole of the spandril between these and the exterior arches is perforated in the form of a quatrefoil enclosed in a circle. Over the extrados of each principal arch is a rectilinear pediment with crockets and finial; and its lower extremities rest on fanciful figures projecting from the wall. At each extremity of the front is a column, with a circular base and capital, as high as the tops of the principal arches, and above the capital is a base surrounded and surmounted by foliage; a small column, similarly crowned, stands over the centre columns, on the face of the tomb, above the meeting of the adjacent faces of the pediments. On the face of the wall between, and on each side of the pediments, are figures of Angels and human beings in the act of adoration.

In Westminster Abbey, the Tomb of the Countess Aveline, who died in 1275, is one of the earliest specimens of sepulchral monuments in the Gothic style. It consists of a sarcophagus surmounted by a pyramidal canopy; the front is divided into six parts by graduated buttresses enriched with crockets and finials; in each compartment is a small figure standing within a trefoil-headed recess, under an angular pediment which is ornamented like the buttresses, and within the angle over each recess is a circle enclosing a quatrefoil. The surmounting canopy is supported on each side by a pier-buttress, sculptured with panelled arches and large crockets of oak leaves. In the recessed part or tympanum of the pediment is a compartment formed by curvilinear mouldings, within which are traces of an historical painting; the under part of the pediment is formed into a gracefully-pointed arch springing from a small column at each angle, and having its architrave studded with roses, and within this is a kind of trefoil arch rising from the outer capitals of the clustered shafts which sustain the archivolt. The front spandrils are sculptured in mezzo relievo with a vine branch and acanthus. (Britton's *Architectural Antiquities*, vol. v.)

Observations on Gothic Architecture.

In the Grecian Architecture it seems to have been an object of importance to preserve the horizontal lines of the buildings unbroken, in order to convey with facility to the mind a perception of their lengths, while a truly vertical line scarcely appears. In the Gothic Architecture, on the contrary, we find an effort constantly made to exhibit a system of vertical lines; this is evident, not only on the exterior of the building, where they are strongly marked by numerous lofty buttresses extending from the ground to the summits of the walls and towers, but also in the interior, where slender shafts rise from the clustered columns in the lower arcades, pass between the arches of the triforia and proceed to the springing of the vault, thus indicating at a glance the whole height of the edifice. The system of horizontal lines is, however, not neglected in the Gothic buildings, and the ranges of arcades and windows serve, perhaps, sufficiently to indicate the extent of the edifice in that direction; these features being wanting to the Grecian Temples, the system of horizontal mouldings along the building was, in them, essentially necessary.

The fillets placed at intervals across the shafts of the Gothic columns are not so great either in height or projection as to interfere much with the continuity of their vertical lines, and they just serve to obviate the effect arising from the disproportion of the height of the shaft to its diameter, by giving to the whole the appearance of several columns placed one on another.

In the Grecian Temple, all the powers of the artist were expended on the exterior, and a spectator on entering such a building would certainly be disappointed to find that so much magnificence led to a cell enclosed by four naked walls. Within the Gothic Cathedral, on the contrary, every variety of feature and ornament seems to have been exhausted; the ranges of columns, arches, and vaults produce, when seen in perspective, an appearance which the mind dwells on with surprise and pleasure; and which, jointly with the richness of the decoration, seems to render the building worthy of the Deity to whose service it is consecrated.

In the Middle Ages the Ecclesiastics engrossed nearly all the wealth, and it may be added, almost all the talent of Europe. With such means, and a disposition to increase their power over the minds of men by every circumstance which could inspire reverence, and the ambition of excelling each other in the splendour of their establishments, it is easy to conceive that the energies of their minds would be directed to the building and adorning of their Cathedral or Conventual Churches with the highest possible degree of magnificence. We are not, however, to consider any of the great Cathedrals of Europe as the work of one person, or even of one Age; the practice seems to have been for some Prelate to give the design, and to execute only as much as was in his power; this part was consecrated and employed for Divine Service, and it was left for succeeding Prelates to carry on the work till it should be completed. This accounts for the variety of style observable in different parts of the same edifice; a variety independent of that produced by the repair of such parts as became dilapidated by time or accident; and also for the circumstance that many of our old Churches are, even now, in an unfinished state; the Reformation and the Dissolution of Monasteries having broken that chain of operations, which had been going on for Ages, before the design was completed.

CHAPTER IX.

Ancient Indian Architecture.

Nature of the Architectural works in India.

The Architecture of India is worthy of the serious attention of Europeans, both from its style and execution, and we devote the present Chapter to a description of the principal monuments of the Art in that Country, which, according to the accounts of travellers, abounds with stupendous excavations and magnificent buildings for Religious purposes, displaying a profuse expenditure of wealth and labour.

From the excavated rocks which have been discovered in that Country, resembling in form, though not in embellishment, those of Egypt and Persia, and, like them, seeming to be destined for Tombs or Temples, there has arisen an opinion that they have claims to an antiquity at least equal to that of the Egyptian works. These claims, however, are unsupported by any Historical evidence like that which we possess in favour of the Architecture of Egypt. We are utterly ignorant of the time of the formation of any one of the excavations, and there are many circumstances which justify an opinion that none of them are much more ancient than the period of the conquest of the Country by the Mohammedans, which took place during and after the XIth century. The Temples raised from the ground are, with great probability, referred to a still later period; and it is from these circumstances that we think it proper to introduce the account of Indian Architecture in this part of the Work.

Of the excavations, the most magnificent are those at Adjuntah or Nizamabad, and Elora in the Khandesh; and those in the Islands of Elephanta and Salsette near Bombay.

Caves at Adjuntah.

The caves at Adjuntah, which were visited by Lieutenant Alexander in 1824, are described by that gentleman nearly in the following manner. They are disposed in series rising gradually above each other, at the termination of a glen remarkable for picturesque beauty, and are excavated in horizontal strata of greywacke with imbedded portions of quartz; the lower cave is about 40 or 50 feet above the rivulet Nullah, on the Northern face of a ridge of hills; those of the centre are about 150 feet from the stream; and the most remote is in the vicinity of a bluff rock of 200 feet elevation. These stupendous remains of antiquity and Art are mostly formed with low roofs, supported by massive pillars having cushioned or globular capitals which have received but little ornament from the chisel. In many of the caves are paintings in fresco representing the dresses, habits of life, pursuits, and general features of the Jains, the crisp-haired Aborigines of India, who, according to tradition, were driven from thence after the introduction of Brahmanism.

The principal cave, forming the grand Temple, is at about 150 feet from the bed of the Nullah. On the face of the hill, jungle and brushwood surround the entrance, which is very striking, having in the centre an arch of the horse-shoe form, with a colossal Jainter 10 or 12 feet high on either side. In the interior is a well-lighted hall, about 25 feet high, the roof of which is of a form nearly semicircular without ribs of any sort, and supported by hexagonal pillars which, as well as the entablature, are unornamented. Opposite to the entrance, and about 30 feet from it, is what has been supposed to be a circular Temple, but which Mr. Alexander considers as a rostrum merely, from which the Priests of Boodh recited prayers in public; it is a hemisphere of solid stone, resting on a pedestal something larger than itself, and surmounted by a square block, resembling the capital of a pillar. Some of these excavations, he supposes, were converted by the Portuguese into places of worship; and adjoining the large cave are several cells furnished with stone bed-places, and seeming to have been the abodes of devotees.

The other caves, which are all flat-roofed, are in good preservation, and one of them consists of two tiers of excavated rock, in one of which are fluted pilasters.

chitecture.

The paintings in many of the caves represent battles and hunting scenes, in which the elephants and horses are well executed; and there is what seems a representation of a zodiac, not, however, resembling that at Tentyris in Egypt.

Elora,

The caves of ELORA have been fully described in our *Miscellaneous Division*. A front view of *Indra-sab'hà* is given in pl. xxi.

According to information given to Sir C. W. Malet, the works at Elora were executed about A. D. 900, by Elloo, the Rajah of Ellichpour, who at that time is said to have built the town; but it is evident that no dependence can be placed upon an account which is unsupported by any inscription or other Historical document. The late Dr. Heber, Bishop of Calcutta, remarks that the excavations are not mentioned, even incidentally, in any Sanscrit manuscript, and that the Images they contain are the same that are now worshipped in every part of India; and his Lordship concludes that they have been formed in a time of Peace, under a Hindoo Prince; therefore, either before the first Afghan Conquest, which took place in the XIIth century, or subsequently, during the recovered independence of that part of Khandesh and the Dekan.

Carli,

Excavations similar to those at Elora exist at Carli on the neighbouring coast; the roof of one of the latter, like that of Biskurma, is in the form of a Gothic vault; but the ribs, instead of being of stone, are formed of teak-wood, and are attached to the rock by wooden pins.

Ele-nta,

At Elephanta is a grand Temple excavated in the rock, 120 feet square on the plan and 18 feet high, and having a flat roof supported by four rows of columns. The columns are about 9 feet high, formed like balusters, and covered with vertical channels; they are supported on pedestals, the height of which is about two-thirds of that of the columns. Above each capital is a block, on which rests a horizontal architrave of stone extending along the tops of the columns in each row. Along the sides of the cavern are forty or fifty colossal statues, from 12 to 15 feet high, attached to the rock; some with pyramidal helmets, and others with crowns; some with four hands and others with six. At the Western end of the cavern is a dark recess 20 feet square, which is entered by four doors, and there are two gigantic figures at each door; this recess is without ornament, but there is an altar in the centre.

naran.

Excavations similar to those at Elora and Elephanta have also been made at Canarah, in the Island of Salsette, near Bombay. The front of these is formed by cutting away one side of the rock as before, and there are four stories of galleries, containing in all three hundred apartments. Before the entrance to the principal Temple, is a portico with columns; the length of the interior of the Temple is 84 feet, and its breadth 46 feet; its roof is vaulted, and the height is 40 feet from the ground to the top of the arch. The vault is supported by thirty-five octagonal pillars, each five feet in diameter, and their bases and capitals are formed of elephants, horses, and tigers. Round the walls are two rows of cavities for lamps; at the further end is an altar 27 feet high and 20 feet in diameter, and over it is a dome-vault cut out of the rock. The excavations are filled with Idols, and the walls are covered with sculpture representing men, women, elephants, horses, and lions.

Having described the principal Temples formed in India by excavating rocks, we are next to mention some of those which have been constructed of masonry; and in these we shall find proofs that the Art of Building, as well as of Sculpture, has long been cultivated with success in that part of Asia.

Part III.

Temple at Chillambaram,

At Chillambaram, on the coast of the Carnatic, is a cluster of pagodas within a rectangular space, 1332 feet long and 936 feet wide, enclosed by a wall 30 feet high and 7 feet thick; on each of the four sides of the wall is an entrance which is covered by a richly adorned pyramid. This general enclosure includes four particular ones, of which that in the centre contains a piscina, or basin for purification, surrounded by a colonnade and by steps to descend to the water; the second, which is on the Southern side, forms a cloister, in the midst of which are three contiguous Temples, called *Chabei*, which are lighted only by their doors, or by lamps: the third, which is on the West, forms also a cloister, and in the midst is an open portico supported by one hundred columns, bearing a roof formed of great stones, like those in the roofs of Egyptian buildings: the fourth, which joins the last, is a square court containing a Temple, and a piscina called the Stream of Eternal Joy. In front of this Temple is a portico of thirty-six columns disposed in four parallel rows: the breadth of the central interval is double that of the others, and in the midst of it is a platform, on which is placed a statue of the Bull Nundee. The Temple itself is filled with sculpture, but it receives no light except from lamps, which are carefully kept burning.

On the Eastern side of the central enclosure is a magnificent Temple raised on an elevated platform 224 feet long and 64 feet wide, and in front is a portico consisting of a thousand columns of blue granite; at the extremity of this portico is a square vestibule with four portals, the middle one of which leads to the Sanctuary, called *Nerta Chabei*, or the Temple of Joy and Eternity, at the extremity of which is the altar. The Temple is covered with sculpture, representing all the Divinities of India. At each side of the door of the *Nerta Chabei* is a highly-ornamented pilaster, (see pl. xxi.) but the greatest curiosity in the Temple is an immense chain of granite cut from the rock; it is attached to the pilasters, and is supported at four other points in the face of the rock so as to hang between them in festoons; each link is about three feet long, and the length of the whole chain is 146 feet. Similar stone chains are frequent in other parts of India.

The pyramids, which are placed over the entrances of the exterior enclosure, are formed on rectangular bases, and consist of several floors; a passage is made through them on the level of the ground, and on one side of this are the steps which lead to the floors above. One of these pyramids, represented in pl. xxi., is 160 feet high,* and composed of a stone basement having two open galleries, one above another, with pilasters in front, standing upon and supporting sculptured mouldings. Above these are seven floors, each of which is ornamented with bas-reliefs made of baked earth on a ground of white cement, and with little niches in the form of shells elegantly formed to receive lamps. Coussin, *Du Génie de l'Architecture.*

at Juggernaut,

At Juggernaut, on the coast of Orissa, about 300 miles from Calcutta, are three great Temples or Pagodas, each surrounded by a wall composed of great stones deposited without cement. At the entrance of the prin-

---

* In our *Miscellaneous Division, ad v.* CHILLAMBARAM, we have given Lord Valentia's admeasurement, 122 feet, which is, probably, the more correct of the two.

cipal Temple is a pyramid 344 feet high, covered with sculpture. The Temple itself is built of immense blocks of granite, and the foundations are laid in the natural rock.

at Seringham.

One of the largest of these Temples at present known is situated at Seringham, a small Island near Trichinopoly, on the coast of Coromandel; it is contained within seven square enclosures, 350 feet distant from each other; the outer walls on each side of the square being one mile long, 25 feet high, and 4 feet thick. On each front there is a gate, and that on the Southern side is adorned with pillars, several of which consist of single stones 33 feet long and 5 feet in diameter.

Ruins at Bamiyan.

In a branch of the Caucasian mountains, between Bahlac and Cabul, are the remains of the ancient city of Bamiyan, consisting chiefly of apartments and recesses cut out of the rock, and adorned with niches and carved work; some of them, on account of their great dimensions, are supposed to have been Temples. On the summit of a conical hill are the remains of a Palace of the ancient Kings of this part of the Country, and round it are the ruins of several buildings executed in masonry. This city was destroyed by Genghiz Khan; therefore, the excavations must have been made before his time, and, probably, while the city was in the hands of the Tartarian Princes of Persia. *Asiatic Researches*, vol. vi.

Comparison of the Indian and Egyptian Architecture.

On reviewing the examples which have been described, we shall find that the resemblance of the ancient Indian Architecture to that of Egypt, with which it has been frequently compared, consists only in a few general circumstances. In both Countries, Temples have been excavated in mountains of stone, and the designs do not seem to have been subject to any system of proportions: the Indian columns are rectangular, polygonal, or circular, some are large at bottom and diminish upwards, while others are slender at bottom and thick above, in which respects they have certainly some similarity to the columns of Egypt. But if we descend to the particular forms, we shall find such differences in the works of the two people as to render the fact of the derivation of one style from the other extremely doubtful. In Egypt, the greatest solidity and simplicity prevailed; while, in India, as much lightness was given to the supports as is consistent with the mass they have to bear; and the exteriors of the edifices are adorned with elaborate sculptures in relief. The statues of Egypt and India are equally colossal, but the differences between them in respect of figure, position, and costume, will not permit us to consider them as emanating from a common source; and though the frequent introduction of the lotus-leaf into Indian Sculpture may appear to afford an argument in favour of that opinion, because that plant is one of the ornaments most generally exhibited in Egyptian works; yet much stress ought not, perhaps, to be laid on this circumstance, since the lotus abounds equally in Egypt and India, and might have been chosen by the artists of both nations as an appropriate subject for the chisel.

It has been observed by a late author that we find examples of the use of arches in India, and even constructions indicating that the feature originated in that Country; by arches, here, no doubt, are meant those horizontal courses of masonry overhanging each other and meeting at the top over the middle of the interval of the piers; but while we are ignorant of the date of the erection of any such arch in India, it will be unnecessary to suppose that the Egyptians or Greeks, who employed similar constructions, were indebted to the Indians for the first idea of them, since their simplicity is such that they could hardly fail to present themselves to the mind of a builder in any nation, even in the infancy of the Art.

In his observations on the general opinion of the great antiquity of the Indian Architecture, the Bishop of Calcutta remarks that there is a complex impression made on us by the sight of edifices so distant from our own Country, and so unlike what we have seen there, which makes us think them more ancient than they really are. The firmest masonry of India is sorely tried by the alternate influence of a pulverizing sun, and a continued three months' rain. The wild fig-tree, which it is a sin for a Hindoo to root out, sows its seeds and fixes its roots in the joints of arches; in a few years it increases the antique appearance, and brings on certain destruction. At Benares, the principal Temple appears so venerable that one might suppose it to have stood unaltered since the time of the Treta Yug; yet it is certain that it was built since the reign of Aurung Zebe, who was contemporary with Charles II. in England.

PART IV.

MODERN ARCHITECTURE.

CHAPTER I.

Revival of Roman Architecture in Italy.

iability
'aste in
hitec-
l.

It has been the fate of every invention of the human mind which depends on Taste, to be cherished at first as a novelty, to be pursued for a time ardently to the exclusion of all other modes, to be cultivated till it has acquired all the embellishment of which it seems capable, and then, to be abandoned for some new form. This, in its turn, passes through the different stages of refinement, and, finally, gives place either to a third mode, or to some modification of those which preceded it. Such has been the case with the Greek Architecture, which having been overloaded with ornament by the Romans, gave way to the more simple style employed by the Saxons or Normans: from this arose the Florid Gothic, which, when it admitted no further enrichment, ceased to be the prevailing Taste of the Age, and gave way once more to the chaster styles of Greece and Rome.

se of the
al of
ot Ar-
cture in

The capture of Constantinople by Mohammed II., induced the artists and men of learning who had hitherto been patronized in the Court of the successors of Constantine, to seek employment among the Nations in the West of Europe; and hence the Language and Literature of ancient Greece were introduced and became objects of study in that part of the World. The comparative freedom then enjoyed in the cities of Italy, which by commerce had acquired wealth and importance, elevating a great portion of mankind above the state of vassalage and ignorance, in which they had hitherto been held, gave them a relish for Science, Literature, and Art. A natural desire to possess private dwellings constructed with elegance, might operate powerfully to introduce an inquiry into the principles of Architecture; and as, during the prevalence of the Gothic systems of building, edifices for Civil and domestic purposes had been much neglected, all the energies of the artists being exhausted upon Ecclesiastical and Military structures, men might begin to look to the remaining buildings of ancient Rome, and to the writings of Vitruvius, for rules to guide them in their constructions. This would naturally give rise to an imitation of the Roman style in their Civil and Ecclesiastical edifices. Greece being at that time in the possession of the Turks, the Italian Artists may have had few opportunities of contemplating the splendid examples of Art then existing in good preservation in that Country; and, even if these had been more accessible, their deficiency in Taste would not have permitted them to execute any thing comparable to the productions of that School of Architecture.

Gothic Architecture fell into disrepute.

That which ceases to be the favourite mode soon becomes despised, and, accordingly, in the Works of most of the writers who treated of Architecture after the revival of the Roman style, we find expressions of contempt unsparingly lavished on that which for five centuries had been cultivated with so much ardour. The Italian writers stigmatize the Tedescan style as barbarous. In England, Sir Henry Wotton, speaking of the pointed arch, which is one of its distinguishing characteristics, says, that "from its weakness and want of beauty it ought to be abandoned to its inventors, the Goths and Lombards, with the other relics of a barbarous Age." And in Sir Christopher Wren's *Parentalia*, the Gothic Architecture is described as consisting of "an unreasonable thickness of walls, with clumsy buttresses and towers, and sharp-pointed arches; doors and other apertures without proportion; nonsensical insertion of various marbles impertinently placed; turrets and pinnacles thickly set with monkeys and chimeras:" it is added that "abundance of busy work and other incongruities dissipate and break the angles of the sight, and so confound it that one cannot consider with any steadiness where to begin or end; taking off from that noble air of grandeur, that bold and graceful manner, which the Ancients had so well and judiciously established."

Style of the ancient houses in Venice.

A peculiar disposition and style prevailed in the houses of the Nobility of Venice from an early period. In the lower part a grand and simple substruction rises from the water, and above this the façades are of various styles of Architecture, some resembling the Saracenic, others the works of a later Age. A hall extended from front to rear, quite through the building; on all the principal floors, and on each side of the hall, were the dwelling apartments. In the oldest buildings the centre of the façade was occupied by one or more tiers of balconies ornamented with small pillars and arches in various ways. The latter were either semicircular or pointed, and frequently were formed by curves of contrary flexure; sometimes in the same building were rows of intersecting semicircular and pointed arches, and within the intersections were trefoil ornaments. On the right and left of the centre of the façade were two windows on each floor, with a wide pier between them, and these windows always looked over a canal.

Ducal Palace.

The façade of the Palace of the Doge, which is one of the edifices built in the Saracenic manner, is composed of three stories: the lower one is an arcade consisting of eighteen simply pointed arches, springing from thick and dwarfish columns; above this is an open gallery, in front of which are thirty-six small pointed arches of contrary flexure, having the intrados cut in a trefoil shape, and there is an open quatrefoil inscribed in a circle in the spandrils. The height of these two tiers of arches is equal to about half the whole height of the building, and in the centre of the upper arcade is a large balcony having in front one pointed arch supported on columns with tabernacle-work above and pinnacles at the sides. Over this arch is an Attic, ornamented with sculpture and crowned by a statue. The whole façade to the right and left of the balcony is formed of masonry jointed diagonally, which gives it an appearance of trellis-work; and in this part, are six large windows with pointed heads. The cornice of the whole building is horizontal, and terminated by a battlement of open-work. Several buildings of a similar character exist at Venice; their style seems to be compounded of the Lombard, Moorish, and Tedescan-Gothic.

The Cathedral of St. Mary, at Florence.

The spirit which dictated the style of the Cathedrals at Pisa, Orvietta, and other places in Italy, continued to influence the artists of that Country till they returned to the Classic Architecture of the Ancients; and, considering those works as modified copies of the more ancient Basilican Churches, we conclude that the Roman Architecture, though once in a state of degradation, has been employed in that Country without interruption to the present time. But the Roman Architecture, travelling Northward, acquired, as we have observed, the Gothic character, and this subsequently was partially adopted in Italy. The building which seems to connect the Gothic style with the revived Roman, is the Cathedral of St. Mary, at Florence, which, in 1298, was begun by Arnulfo di Cambio da Colle, an Architect of that city; and though it, in some respects, resembles the older edifices, yet it bears marks of a genius rising above the prejudices of its Age and Nation.

The plan is that of a Latin cross, the whole length of which is 520 feet, and that of the transept 313 feet. The nave of the Church is divided longitudinally into three parts by magnificent arcades, supported on piers ornamented with Corinthian pilasters. At the extremity of the nave, are the communications between that part of the building and the transept; these are terminated above by three arches, of which the span of the central one is 58 feet. The interior of the body of the Church, at its intersection with the transept, is of an octagonal form, and its length and breadth between the opposite faces of the octagon are 140 feet. The wings of the transept and the extremity of the Church opposite to the nave are recesses in the form of half octagons on the plan, and the breadths between the opposite faces are each 58 feet; they are all open towards the interior of the Church; and each is covered by a semicupola springing from the walls of the octagon and ending in a point over the centre of a circle which would circumscribe the octagon if complete. The horizontal cornice from which the cupolas spring is 97 feet high above the pavement, and the vertex of each cupola is 43 feet above the level of the cornice.

Above the level of the vertices of these cupolas is built a wall of an octagonal form, 16 feet thick and 43 feet high, resting upon four massive piers and the tops of four intermediate arches about the central part of the Church; and in each of the eight faces of this wall is formed a circular window to give light to the interior. This wall is terminated by a horizontal cornice, and from it springs the grand dome, which is composed of eight faces rising from the sides of the tambour, and joined together in salient ridges, which if produced would meet in a point over the centre of the body of the Church. The span of the dome between the opposite faces of the octagon is 140 feet, and its vertical section presents a figure formed by two segments of circles meeting each other in a cusp at the vertex like a Gothic arch. The faces of the dome terminate at 280 feet above the pavement of the Church, or 116 feet above the cornice from which they spring; and at this elevation is constructed an octagonal lantern. 45 feet high, and 24 feet diameter between the opposite sides. Above the lantern is an octangular pyramid, or pergamena, surmounted by a ball and cross.

The dome is composed of two shells or vaults one within the other, and having an interval of about 5 feet between them; the thickness of the interior vault at bottom is 5 feet 6 inches, and at top 2 feet 1 inch; that of the exterior vault at bottom is 4 feet 3 inches, and at top little more than 1 foot. The radius of curvature of the interior surface of the inner vault is 120 feet, and the exterior surface of the other is described from nearly the same centre. Eight buttresses fortify the angles of the vault; and the voussoirs in the circumference of its base are connected by a chain of iron to prevent them from being thrust outwards by the lateral pressure of the courses above.

The arches in the interior of the Cathedral are of the pointed form, and the radius of each segment is equal to about two-thirds of the span of the aperture. On the capitals of the pilasters in the nave are pedestals which support another tier of Corinthian pilasters; and from blocks above the capitals of these proceed the cross-springers and ribs of the groined vaulting of the nave. Round the whole interior and exterior of the Church, on a level with the tops of the side arches of the nave, are galleries supported by brackets and protected by an elegant pierced parapet. The windows of the lower tier in the Church terminate above in pointed arches, and are divided by a slender column into two apertures with trefoil heads; on the exterior, each window is crowned by a small, rectilinear pediment, with a slender pinnacle at each extremity; and in the walls of the nave, above the aisles, is a row of circular perforations on each side of the Church.

The whole exterior of the edifice is ornamented with attached pilasters or piers, projecting but a little way from the wall; and their faces, as well as that of the wall between them, are covered with inlaid marbles of different colours, which destroy the grand effect the building would otherwise produce. The tops of the pilasters, about the exterior of the transept and Eastern end of the Church, are connected by semicircular arches. These render the style of the building something like that of the Italian Churches of the Xth and XIth centuries; while the pointed windows and trefoil ornaments identify it with the Gothic style of the North of Europe, and the pilasters in the interior indicate a connection with the Architecture of ancient Rome.

The Taste and judgment displayed in the construction won, for this building, the praise of one of the greatest masters of the Art, Michael Angelo himself; who considered it as the first modern edifice of its kind, and one which prepared the way for a return to the methods of the Ancients. The body of the Cathedral was erected under the direction of Arnolfo, and the dome was designed by the same artist; but the opposition he experienced from his contemporaries prevented him from executing it; and it was reserved for Brunelleschi, at a later period, to carry on that which his illustrious predecessor had begun. Arnulfo died in the year 1300, and the building remained as he left it during one hundred and twenty years; Brunelleschi superintended the work from the year 1420 till his death, in 1440; and during those twenty years the dome was carried up to the base of the lantern, by a particular contrivance which rendered a general centreing of carpentry unnecessary. No similar work, before constructed, was equal to this dome in size or magnificence; and if its span is measured diagonally between two of the opposite angles, it is greater even than that of St. Peter's at Rome. The lantern was not completed till 1456, and the Western façade of the building remains still in an unfinished state; a lamentable proof of the poverty or indifference of the citizens of Florence.

The choir is an octangular enclosure having its centre immediately under that of the dome. It is surrounded by a stylobata supporting a screen of Ionic columns and pilasters, with an entablature and balustrade above; and the whole height of the enclosure is 19 feet 6 inches. There are four entrances to the choir, at right angles to each other, and each is crowned by a semicircular archivolt without spandrils. This choir was built according to the designs of Brunelleschi, with some few modifications.

At the South-Western angle of the building stands the *Campanile*, a prismatic tower 268 feet high to the top of the parapet, and on a square plan, each side of which is 47 feet 9 inches long. It consists of five stories with groined ceilings; a flight of steps inside leads quite to the top, and the exterior is ornamented with pilasters in the same style as the Cathedral itself. The three lower stories are lighted by narrow rectangular windows; in the faces of the fourth story are two tiers of windows, each tier consisting of two lancet-headed apertures, divided, by a slender twisted pillar or mullion, into two parts, with trefoil heads. In each face of the upper story is a broad window with one general head in the form of a pointed arch; the window is divided by slender twisted pillars into three apertures, with trefoil heads formed within the intersections of semicircular arches, which spring from the pillars and from the sides of the window. Above the fifth stage, and surrounding the building, is a gallery supported by brackets and protected by a parapet. The tower was begun by Giotto, in 1334, and carried on by Taddeo Gaddi; it was to have been crowned by a pyramid or spire 95 feet high, but this was never executed.

After building the Cathedral of St. Mary, or, as it is generally called, the *Duomo*, at Florence, Brunelleschi built several Churches in the same city, in which he abandoned the pointed arch but preserved the general features of the Lombard edifices. The plan still had the form of a Latin cross, and, as in the Gothic Churches, the length and height of his buildings were considerable in proportion to their breadths. In the nave of the Church of San Lorenzo, he has placed Corinthian columns with isolated entablatures, and double semicircular archivolts springing from above them. The centre is crowned by a dome, the lower part of which has the form of a spherical zone; and, instead of a lantern, there is placed above this, a hemisphere of smaller dimensions. The Church of San Spirito is similar to that last mentioned; but at the intersection of the nave and transept are four great piers ornamented with pilasters, which carry a regular unbroken entablature over the arcades of the aisles. In this building are still retained some Gothic mouldings, but those in the entablatures resemble nearly the antique. Lastly, the Capella dei Pazzi, by the same Artist, indicates a still nearer approach to the Roman style: its plan is rectangular, and it has six columns in front; about the interior are pilasters supporting entablatures, and above is a hemispherical dome.

In the long period which elapsed between the fall of the Roman Empire and the time of Alberti or Brunelleschi, nothing is known of the domestic Architecture of the Italians; and we can only suppose that it arose from the forms of the ancient castellated edifices of the Country. We are, therefore, obliged to commence our account of it with a description of the Florentine Palaces, of which the oldest remaining were executed about the latter of the above-mentioned periods.

These ancient mansions consist generally of a range of buildings disposed on the four sides of a *cortile* or quadrangular area which they enclose. At the angles are square towers crowned by battlements and machicolations; and, as well as the buildings between them, divided into stories, with a bold horizontal cornice to each. In the lower story of the principal façade, are from one to three grand entrance gateways covered by semicircular arches; and the windows in each story are commonly of similar forms. A Palace for the Spada family, which was built in or before the time of Brunelleschi, seems to be the oldest example existing of those mansions which, in Italy, succeeded the fortified Palaces, and the first in which the Orders are employed; the badness of the proportions in those Orders shows how little, before this time, the antique examples had been studied.

Palazzo Pitti.

The Palace Pitti, at Florence, was designed, and the lower part of it was executed, by Brunelleschi, consequently it may serve as a specimen of the disposition and style of the mansions of Italy at the end of the XIVth and beginning of the XVth century. The plan of the central part is a long parallelogram; at each extremity of this is a wing projecting forward at right angles to the front, and behind the centre is a small *cortile*. The elevation of the front approaches the pyramidal form; being divided into three stories of equal height, of which the second story is less extended than the lower and the third less than the second; a fourth story was to have been added, and this also was to have been shorter than the story below it, but it has never been executed. Each of the three stories is rusticated, that is the joints of the masonry are marked by grooves; each also is crowned by a cornice supporting a gallery, in front of which is a balustrade of small Ionic columns; the windows are semicircular-headed, and the joints of the voussoirs are also marked by grooves; but in the lower story there is only a window under each alternate window of the story above. Each of the faces next to the court contains three Orders of Architecture one above another; of these the lower is Tuscan and the shafts of its columns are covered with horizontal flutings. The second Order is Ionic, with square blocks at intervals along the shafts; between the columns are semicircular-headed recesses containing windows surrounded by architraves, and having pilasters on the jambs. On the exterior of the architrave, under each window, is a projecting table supported by corbels, placed not under the pilasters, which would seem to be the most natural place, but under the vertical architraves. The windows are crowned by pediments. The upper Order, which is probably of later date than the rest, consists of Corinthian columns, having also blocks at intervals upon the shafts. Between the columns are recesses with horizontal lintels formed by voussoirs; within each of these is a semicircular-headed recess and a window crowned by a circular pediment. The whole building is of a colossal character, and like the rest of the Italian mansions of that day, looks rather like a Prison than a Palace.

Works of Alberti.

Leon Battista Alberti, who was for some time the contemporary of Brunelleschi, flourished in Italy during the first half of the XVth century, and executed several works in a style which approximates to that of the pure Roman; his best edifices are the Church of San Francesco, at Rimini, and that of Santa Maria Annunziata, at Florence. The latter is a circular building, 76 feet in diameter, and 63 feet high, with nine hemicylindrical alcoves, and crowned by a dome 38 feet high, rising from a tambour supported on a circular range of arches in the interior. On each side of the arches is a Corinthian pilaster with its entablature, above which are termini, and between these are square windows with pediments above. The Corinthian Order in this Church possesses a character of great purity, and the artist appears to have adopted the proportions of the antique more accurately than his predecessor.

St. Maria Annunziata.

Cathedral at Rimini.

The front of the Cathedral at Rimini was also executed by Alberti. This is adorned with four half-columns attached to the wall, and an entablature broken over each; in the centre is a grand doorway with a semicircular head, the archivolt of which springs from imposts projecting before the wall, but unsupported by columns or pilasters. Within the great doorway is a smaller one having a pediment above, which rises to the level of the foot of the arch over the other; and on each side is a semicircular-headed recess. According to a medal by Malatesta, there was to have been a segmental pediment extending over the whole façade, and the Church was to have been crowned by a dome, but neither of these intentions have been executed.

Attached to one side of the Cathedral is a *loggia* or covered arcade, which was built by the same artist: it consists of seven semicircular arches surrounded by archivolts, which rise from imposts on a range of piers 5 feet 10 inches wide, and 16 feet 2 inches high; and these stand on a podium 9 feet 7 inches high. The spans of the arches are 11 feet 7 inches; the spandrils between them are ornamented with wreaths, and the whole is crowned by a cornice, the mouldings of which resemble those of the Greek or Roman buildings.

Alberti is the first Architect who has written on his profession since the time of Vitruvius, at least he is the first whose Works have been preserved to our times. In X Books he treats of the origin of Architecture, which he supposes to have taken place in Asia; he explains the method of forming the foundations, and of building walls and arches in masonry; he gives general directions for designing Palaces, Basilicas, and other public and private edifices, and shows the manner of ornamenting their different members: he also treats of four Orders of Architecture, *viz.* the Doric, Ionic, Corinthian, and what he calls the Tuscan, which is that we usually designate the Composite Order. He makes the proportions of the parts of columns and their entablatures nearly the same as those assigned by Vitruvius; he forms the shaft cylindrical as far as three-sevenths of its height, from which place it diminishes up to the capital, and he gives a simple base to the columns of the Doric Order.

The artists of the Lombard School had made their arcades rise immediately from the capitals of columns; but Alberti observes that the ancient masters placed above the capital a projecting cornice on which the archivolt was made to rest; and this method was, by the example of Brunelleschi and himself, brought again into general use. Alberti moreover, very justly, prefers square piers to columns for the support of arches and vaults. The Rucellai Palace, executed at Florence by this artist, is one of the first in which pilasters are placed in front of each story; and this afterward became a general feature in the buildings of Italy.

Orga

About the same time, the Architect, Orgagno, built a loggia adjoining the old Ducal Palace at Florence, the length of which is about 109 feet, and its depth 37 feet. The front consists of four octagonal piers with a pilaster on each face, supported by a podium; from the tops of the pilasters spring plain, semicircular arches, and the ceiling is formed by a groined vaulting, the ridges of which are ornamented by ribs rising from slender shafts in the rentrant angles formed between the pilasters. The *loggia* is crowned by a projecting machicolated parapet supported on brackets; the face of the parapet is pierced with quatrefoil apertures, and between the brackets a series of trefoil, cuspid arches is formed in front. This fabric presents a striking and graceful appearance, and its proportions are good, but its effect is rather injured by too great a height above the crowns of the arches.

Succession of Italian Architects from Brunelleschi to Scamozzi.

From the time of Brunelleschi till the commencement of the XVIIth century, there followed each other, in Italy, several celebrated Architects; who having studied the remains of the works of their ancestors, with which the Country abounds, formed the style which, by subsequent improvements, is become that which now prevails in every part of Europe.

Alberti survived Brunelleschi about thirty years, and both of these artists were employed in various Ecclesiastical buildings at Florence, Mantua, or Rome. Bramante d'Urbino and Raphaele d'Urbino were contemporaries, and the immediate successors of Alberti; these built or gave designs for several Palaces for the Italian Nobility; and the former has the glory of having begun the building of St. Peter's Church, at Rome. Peruzzi followed, who, besides sundry other works, made alterations in the original design for that edifice. San Michaeli built several Palaces and Churches within a few years after the time of the last-mentioned Architect; and about the same time lived Michael Angelo Buonarotti, the most celebrated Architect and Painter of his day, and under whose direction a considerable part of St. Peter's Church was carried on. After these may be mentioned the names of Sansovino and Julio Romano; of Serlio, who wrote VII Books on Architecture, and was the first to measure and describe correctly the ancient edifices of Italy; and of San Gallo and Barozzi, commonly called Vignola, who were either contemporaries or immediate successors of each other. Next in order of time comes Palladio, who distinguished himself particularly, not only by his designs and buildings, but by the Work which he has left on Architecture, and which is indispensable to every one who would acquaint himself not only with the principles of the Italian but also with those of the Roman Art. We may, in the last place, mention Scamozzi, who died

itec-
re.

in 1616, and Bertotti, who took the same name, and published a collection of Palladio's designs, which is deservedly held in estimation.

The Greco-Italico style, which had been improved by Brunelleschi and Alberti, was, by Bramante and his immediate successors, made to approach still nearer to the style of ancient Rome; this modification acquired a certain degree of perfection in the latter part of the XVth and during the XVIth century; and from the merit which it displays at a time when Architecture in other parts of Europe was at a very low ebb, rather than from any peculiarities it exhibits, it has obtained among artists the distinction of the *Cinque-cento style*, from the number of hundreds in the dates of most of the works. Palladio subsequently improved it by a more strict adherence to the principles of the ancient Roman Architecture; and by the merit of the works he has executed, in a style which he made his own, he has rendered the Architecture of Italy that of all the rest of Europe.

CHAPTER II.

The Architecture of Italy during the XVth and XVIth Centuries.

ante.
zo
ld.

The Palazzo Giraud, at Rome, was executed by Bramante about the middle of the XVth century, and may be classed with those which are designated as being of the *cinque-cento* style. It consists of a range of buildings disposed about a quadrangle, 249 feet long, and 190 feet wide, and the entrance is by a vestibule in the middle of one of the shorter sides. This, which is 47 feet long and 34 feet wide, is divided into three parts longitudinally by two rows of columns, and it leads into a square court, 89 feet long in each direction; the latter is surrounded by an interior arcade, about 20 feet wide, which is covered by a groined vaulting, and the faces of the piers next to the court are ornamented with half-columns. At the extremity of the court, opposite the entrance, is a passage, 26 feet long and 15 feet wide, the sides of which are adorned with pilasters and niches. This leads to the rear vestibule, which is 53 feet long in the direction of the short side of the building, and 21 feet wide, and the extremities of its length are terminated by hemicylindrical niches.

The front elevation exhibits three stories, all of which are rusticated; in the lower part of the ground-story the joints of the masonry are marked by horizontal and vertical grooves, and in the upper part by horizontal grooves only; in the centre is a semicircular-headed doorway with a horizontal cornice above, and on each side are three square windows. In the lower part of the second story is a plain podium, and above this, the joints of the masonry are marked by horizontal and vertical grooves; a row of seven semicircular-headed windows is contained in this story, with horizontal cornices above them; the archivolts rest on pilasters, and the spandrils are ornamented with sculpture representing vases and stems of plants. Between the windows, are coupled pilasters of an Order resembling the Corinthian, with Attic bases on high plinths, under which the podium is broken and projects so as to give it the appearance of a line of pedestals connected by walls; and above the pilasters is a simple entablature. In the third story there are coupled Corinthian pilasters, with Tuscan bases over those in the second story; these also stand on high plinths placed above the projections of the podium; and between the pairs of pilasters, are two tiers of windows, the lower rectangular, and the upper having semicircular heads. These pilasters are crowned by the entablature of the building, the frize of which is occupied by blocks for the support of the cornice. The roof is formed with sloping sides, and is covered by hollow tiles. The proportions of the pilasters are good, but they would now be considered as having hardly sufficient relief from the wall.

Cancellaria, at Rome.

The front of the Cancellaria, at Rome, also executed by Bramante, is in the same style, with some few differences. The lower story contains merely a row of plain semicircular-headed windows; the windows of the second story are placed low, and above each is a small circular recess with a flower in its centre; those of the upper story are of a rectangular form with cornices above, and are cut through the podium; over these are small windows with semicircular heads inscribed in plain rectangles. The two upper stories are ornamented with pilasters of the Corinthian Order, disposed in pairs, but those in each pair are at a greater distance from each other than coupled columns or pilasters usually are. At each angle of the building a small projection of the façade takes place, so that it has the appearance of being flanked by towers; and in the breadth of the projection are contained four pilasters having the same dimensions and intervals as those on the other part of the façade.

Bramante constructed several other buildings, also, among which is the Church of San Pietro in Montorio, a circular edifice, considered as one of the first specimens of the regular Architecture of that day. This celebrated Architect died in the year 1514.

Palazzo Strozzi.

In 1454, that is during the life of Bramante, the Strozzi Palace, at Florence, was built by Benedetto da Majano and Pollajuolo, in a style which resembles that of Bramante, but partaking in some degree of the character of the old Lombard Architecture. The façade is rusticated from top to bottom, by vertical and horizontal grooves; it is divided into three stories, separated from each other by frizes, ornamented with dentels; and the whole is crowned by a plain frize, and a bold cornice, in which are both dentels and modillons. In the centre of the lower story is a semicircular-headed doorway, and on each side are three rectangular windows; the windows of the upper story are semicircular-headed, with voussoirs, the joints of which are marked by grooves; each window has half-columns attached to its sides, and a column in the middle, all of a kind resembling those in the Norman edifices. The two apertures of each window are crowned by semicircular heads, which are circumscribed by the outer semicircle; and the spandril between the three curves is occupied by a patera.

Peruzzi.
Palazzo Farnese.

The small Farnese Palace, at Rome, is a splendid example of the talents of Peruzzi, who was contemporary with Bramante, and survived him twelve years. The plan is rectangular; and, attached to the wall of the ground-floor is a range of Doric pilasters, which surround the building except where they are interrupted in front by a superb *loggia* or portico, composed of five arches, the spans of which are equal to the interval between every two pilasters. A similar range of Doric pilasters, between the windows, surrounds the building on the story above the ground-floor, and these are remarkable for being more massive than those in the lower range. Between the two stories are a *mezzanine* or an intermediate story with small windows in front, and the frize which surrounds the upper story is ornamented with festoons supported by Genii and candelabra. The portico above-mentioned gives variety to the edifice without destroying the unity of the composition; and the profiles of the mouldings are remarkably elegant.

Palazzo Massimi.

The Massimi Palace, at Rome, is the last and best work of this Architect. It is on an irregular plan, and in a confined situation, which prevents the upper part of the building from being conveniently seen by a spectator in the street; and on this account the artist has judiciously given it less ornament than the part below. The façade is rusticated, and divided into four stories; in the lowest is a superb *loggia*, the plan of which is in the form of a segment of a circle, convex towards the street; its ceiling is highly ornamented, and there is a hemicylindrical recess at each end; in front are two pairs of coupled columns, besides a coupled column and pilaster at each extremity. The columns are of the Doric Order, elegantly proportioned, and crowned by an entablature without triglyphs or mutules; they have Attic bases, and the profiles of the ovolos in the capitals, instead of being quadrants, are flat segments of circles. From the *loggia* is an entrance through a vaulted corridor into the *cortile*. In the lower part of the second story is a plain podium, over which are seven rectangular windows with horizontal cornices above; the windows in the two upper stories are square and without ornament, and the building is crowned by a horizontal cornice supported by modillons.

The details of this edifice are correctly antique, and every part indicates a refinement of taste far beyond that displayed in any other work of the Age. The interiors of the apartments are highly finished; some of the ornaments resemble those on the Greek Temples, and others are like those represented in the paintings at Herculaneum and in the Baths of Titus. In one apartment is a fire-place, ornamented with fluted pilasters on each side, accompanied by cossoles of equal height with the pilasters; above these is an entablature with swelled frize, and over it a sort of sarcophagus ornament.

Palazzo Medici or Riccardi.

The last of the Florentine edifices of the kind we are now describing is the Riccardi Palace, which was executed by Cosmo the Great, and nearly resembles the Strozzi Palace, built probably a hundred years before it. Its façade is divided into three stories, of which the lowest consists of blocks in irregular courses, some projecting before others, and in it is a circular-headed doorway. The second story is rusticated, but faced with wrought stone, and in it are seventeen windows almost close together, with semicircular heads; each window is divided into two lights by a column, and these have also semicircular heads. A high, plain face presents itself above the windows of this story, and at the top is a dentel band. Above this is the third story, of plain stone-work, with seventeen windows similar to those in the story below; and the whole is crowned by a bold and beautiful cornice resembling those of the ancient Roman Architecture.

Venetian edifices of the XVth and XVIth centuries.

In the buildings at Venice is exhibited an adherence to the Lombard style of Architecture after it had been every where else abandoned. The Palazzo Camerlinghi seems to have been one of the latest works of that School. It is divided into three stories, with a double semicircular-headed window in the centre of each, and on either side of it a single window of the same kind; the arched heads of the windows rest on panelled pilasters, and the extremities of the building are ornamented with pilasters of a similar kind. To the same class may be referred the façade of the School of St. Mark, which was built by Martin Lombardi, but at what time is uncertain. This is divided into two stories, ornamented with Corinthian pilasters carrying an entablature which is broken over each; between these, on the second tier, are semicircular-headed windows, crowned by segmental or triangular pediments: in the lower story is a semicircular-headed arch supported by two columns; and on each side of the arch between the pilasters of this story are panels filled with sculpture in bas-relief, representing Architectural subjects in perspective. The whole front is crowned by semicircular pediments of different heights, and surmounted by scrolls and statues.

The Church of San Salvador also partakes in some measure of the Lombard character. This is in the form of a Latin cross, and has three cupolas in its length; in the interior the lower Order is ornamented with panelled Corinthian pilasters supporting an entablature; above which is a *mezzanine* story with semicircular arches in front; and from between them, spring pendentives which are crowned by the domes.

Sansovino.

But the edifices of Venice at length partook of that change in the general Architecture of Italy which arose from the study of the antique examples, and the works of Sansovino contributed materially to the establishment of the new style in that city. The Procuratie vecchie, which constitutes one side of the Grand Piazza of St. Mark, is an edifice probably of the XVth century, and forms a good specimen of the style of that Age. Its façade is divided into three tiers of arcades of semicircular forms, and those of the lowest range are supported on piers; the two upper tiers rest on columns, and each arch is only half as broad as one of those in the lower tier, so that two of them stand over one of the latter; between the tiers are plain podia, and the building is crowned by an entablature with a high frize in which are circular apertures. In the small Piazza adjoining the former, is the Libreria vecchia, a work of Sansovino; the façade of this building consists of two tiers of arcades, the lower ornamented with columns of the Doric, and the upper with columns of the Ionic Order; each range of columns supports a heavy, unbroken entablature with a balustrade; the Ionic columns stand on pedestals; and in order to diminish the massiveness of the upper entablature it is perforated by small apertures, between which are festoons of flowers supported by Cupids. In the grand Piazza, and at right angles to the Libreria vecchia, is the Procuratie nuove, in the façade of which are three Orders, of which the two lower are continuations of those in the other building, and were executed by the same artist; but the upper one, which is of the Corinthian Order, was afterward added by Scamozzi. Sansovino was born nearly at the same time as Peruzzi, but he survived the latter 34 years, having attained the advanced age of 81 years; he died in 1570.

San Michaeli.

San Michaeli, though born five years after Sansovino, died eleven years before him. He distinguished himself by various works with which he adorned Verona, and of his mansions the best is, probably, the Palazzo Pompei; in the façade of this building there are two stories, of which the lower is rusticated, and contains a doorway and windows with semicircular heads, over which is a balustrade; the upper story contains also windows of a similar form, but the piers between them are ornamented with eight attached, three-quarter columns of the Doric Order, which support a bold and continuous entablature.

The frontispiece of the Piazza dei Signori, at Verona, another of his works, consists of a semicircular arch springing from imposts; on each side are two fluted Ionic half-columns with Corinthian bases. The entablature is broken over the two extreme columns, and the part over the arch and the adjacent columns is crowned by a pediment. The same artist built the Castello St. Andrea, on an island at Venice, to form a sort of water-gate to the fortifications. It consists of three arches, having half-columns attached to the piers, and at each extremity is a column and pilaster coupled, of which the latter forms the quoin of the building. The columns as well as the piers are rusticated, and the former support a well-proportioned Doric entablature with triglyphs in its frize. A curtain, which is connected with the arcade, is crowned by a parapet, and has casemates on a level with the water, which comes up to the gate.

lazzo di by Julio mano.

The Palazzo di T, so named from its shape, at Mantua, may be considered a fair specimen of the works of Julio Romano, who lived during the first half of the XVIth century. Its façade is divided into two stories, of which the lower is merely a rusticated basement with semicircular-headed arches. In the centre of the upper or principal story, is a portico containing four groups, each consisting of four columns, two in front and two in depth; these support imposts from which spring three semicircular arches, and above these, is a general pediment to the portico. In each wing of the building are three rectangular recesses, of which the one nearest the portico on each side contains four columns, the next on each side three; and the last on each side two; the interval of the centre columns in the recesses nearest the portico is covered by a semicircular arch, and above these is a general horizontal entablature to the whole building.

The grouped columns give to this edifice a singularity to appearance, which is increased by an instance of depraved taste in making some parts of the Doric entablature lower than the others; in consequence of which it appears as if part of the edifice had sunk, and thus the perception of stability, so essential to architectonic beauty and fitness, is wanting.

bedral Iantua.

The interior of the Cathedral of Mantua was also executed by this Architect. It is divided into seven aisles, separated from each other by columns; the central and the two outer divisions are covered by flat roofs, and the others by hemicylindrical vaults. The central division is separated from that next to it on each side by a range of fluted Corinthian columns, supporting an entablature; above this, is a tier of pilasters, carrying also an entablature, which, as well as the former, is unbroken, and the whole is crowned by an elegant dome.

ael do narotti.

As specimens of the Taste of Michael Angelo Buonarotti in Architecture may be mentioned, first, the Church of Santa Maria degli Angeli, which he formed in the principal hall of the Baths of Dioclesian, at Rome, and which is remarkable for its grandeur and simplicity. The entrance is in the centre of one of the long sides, through the ancient circular vestibule; and both those sides, which were originally open, are filled up and adorned with Composite columns, extending from the pavement to the springing of the groined vaulting; some of these are antiques, and the others have been formed in imitation of them. The Capella dei Depositi, at Florence, is a work of the same artist; this is a square building with a hemispherical dome supported on pendentives.

Campidoglio.

The present Campidoglio, at Rome, the site of the ancient Capitol, is occupied by buildings for which M. Angelo gave the general plan, and some of which are supposed to have been executed under his direction. The buildings are disposed on three sides of a trapezoid about a platform, to which there is an ascent by an inclined plane, about 177 feet long, 26 feet wide at the foot, and 37 feet wide at the top; on each side of the ascent is a balustrade, and at the top are two pedestals supporting statues of Castor and Pollux; on the right and left of these is a balustrade, with pedestals at intervals along it, containing statues and trophies. The platform is 250 feet long, 134 feet wide at the end next to the inclined plane, and 182 feet wide at the opposite end, and is elevated about 40 feet above the level of the neighbouring streets. In the centre, is an equestrian statue of Marcus Aurelius in antique bronze. On each side of the platform is a grand Museum, and in front is the Palace of the Senator of Rome. The last-named building, which there is great reason to believe to be the work of M. Angelo, is of a rectangular form, and its façade is decorated with a majestic Order of attached Corinthian pilasters rising from a lofty basement, and supporting an entablature which is crowned by a balustrade. This façade is remarkable for its purity and simplicity, and appears to advantage when contrasted with those of the neighbouring buildings, which are also ornamented with Corinthian pilasters and half-columns, but mounted on pedestals. The height of the Order above the basement is divided into two stories; the ascent to the lower is by steps on the right and left hand, which meet in the centre where the doorway is situated; and below this is a fountain. Between the central building and the left-hand Museum, is an ascent by a flight of steps, about 100 feet long and 48 feet 6 inches broad, to an arcade forming the side entrance to the Church of Ara Cœli. On the right hand a similar flight leads to private dwellings on the site of the Tarpeian rock. On the right and left hand of the Senator's Palace is a descent by a flight of steps leading to the great Forum, and the former flight is supposed to coincide with the ancient *Clivus Capitolinus*.

Palazzo Farnese, by San Gallo and Vignola.

The great Farnese Palace, at Rome, which was built by San Gallo and Vignola, both of whom lived during the XVIth century, is a rectangular building 236 feet long, 170 feet wide, and 177 feet high from the ground to the top of the cornice; and its general plan resembles that of the Palazzo Giraud before mentioned. The principal façade is one of the most majestic in the world, presenting to the eye one unbroken mass, which is crowned by a noble frize and cornice; it consists of three stories, which are separated by horizontal bands filled with sculptured foliage. The windows of the lowest story are rectangular, with simple architraves, and surmounted by horizontal cornices supported by corbels; those in the second story are also rectangular, but those in the upper story have semicircular heads, and the windows in both these tiers are crowned by pediments, the entablatures of which are supported by columns. The doorway has a semicircular head with voussoirs; the angles of the building and the wall between the doorway and nearest windows are rusticated.

The faces of the building within the *cortile* contain three Orders of columns, the lowest Doric and the second Ionic; both of these support entablatures, and between the columns are semicircular arches springing from imposts on the piers; the upper Order is Corinthian, and in the intervals of its columns are rectangular windows. Between the second and upper stories are *mezzanine*, with small square windows towards the court.

The Cathedral of St. Peter.

We conclude our account of the Italian edifices of this Age with a description of the Cathedral of St. Peter, at Rome, which may fairly be considered as the most magnificent building in the World, and the noblest monument of the science of the Italian Architects. This edifice was built on the site of the Church which had been dedicated by Constantine to the same Apostle; it was begun during the Pontificate of Julius I.; was carried on by contributions from all Europe; was the subject of anxious solicitude to twelve succeeding Popes; occupied the talents of as many Architects during more than one hundred years; and it now remains the boast of the Christian World.

The interior has the form of a Latin cross, the whole length of which, from East to West, is 735 feet, and its breadth 510 feet. The interior breadth of each arm of the cross is 75 feet, except of that which forms the nave, which is 90 feet. At the intersection of the arms are the four great piers on which the dome is supported. Four aisles, each 50 feet broad, at right angles to each other, and intersecting the four arms of the cross also at right angles, separate those piers from the exterior walls of the Church.

The piers support four semicircular arches, the crowns of which are at the height of 200 feet from the pavement, and on them is built a cylindrical wall, 70 feet high, and 150 feet in diameter internally; this is perforated by windows with rectilinear or circular pediment heads both on the interior and exterior; between which are coupled Corinthian columns carrying an entablature broken over each pair of columns. The top of the wall rises 20 feet above the entablature of the columns, and from it springs the great dome; this is double, consisting of two shells, of which that on the exterior is of a spheroidal form, 170 feet in diameter externally, and 100 feet high from its foot to the level of the base of the lantern. The interior dome is also spheroidal, but flatter than the other, its internal diameter being 140 feet, and its height 77 feet; and these domes are connected by sixteen ribs of masonry formed in vertical planes. The lantern is 40 feet high, and above it is a small spire terminating in a ball and cross. Three tiers of windows are formed about the circumference of the outer dome, and the extrados of the other is worked in steps for the convenience of ascent. The height of the building from the pavement to the top of the lantern is 440 feet.

Along the whole of the Western extremity of the Church is a porch 50 feet wide, separated from the nave by a wall in which are five doorways, opposite to as many others in the façade. The nave is divided into three parts or aisles by massive piers ornamented with pilasters, and supporting arches in the direction of the length of the building. A Chapel is formed on each side of the nave, where the latter joins the transept; they are rectangular on the plan, and covered by spheroidal domes similar to the principal one. These domes stand upon octagonal walls ornamented with pilasters; their height from the pavement to the base of the lantern is 250 feet, and their interior diameter 50 feet.

The Western extremity of the Church presents a façade adorned with half-columns and pilasters; its whole length is 425 feet, and its height 125 feet from the pavement to the top of the entablature of the columns; within this height are included two stories, and above the entablature is another story 50 feet high, which is crowned by a balustrade. Over the four central columns is a pediment and the entablature on each side is broken vertically into three parts. Between those columns is the principal entrance which has a horizontal head; on each side of it is a small one with a semicircular head, and further to the right and left are two other grand entrances similar to that in the centre. At the extremities of the porch are two square wings projecting beyond the side walls of the building and crowned by its general entablature, and in each side of these wings is a magnificent doorway with a semicircular head.

Before this façade of the Church, is a trapezoidal area 400 feet long, and having its greatest breadth equal to that of the whole front; this is bounded on each side by a corridor, from the Western extremity of which proceeds a semicircular colonnade, and these two colonnades form part of the periphery of an oval area, 650 feet long from North to South, and 500 feet wide from East to West.

Under the centre of the dome is a magnificent *baldachino*, or canopy, of a square form, executed in bronze, and 120 feet high, covering the Grand altar. The upper part is supported by four columns of the Composite Order resting on marble pedestals; the columns are formed so as to appear twisted, and are channelled in spiral grooves as far from the bases as one-third of their height; the remainder of the shaft is ornamented with laurel leaves and figures of boys, and above the canopy are four great figures of angels standing over the columns.

According to the original design of Bramante, the plan of the whole Cathedral was to be in the form of a Latin cross, and as such he commenced the building, in 1506; after his death, Jocondo, Julian San Gallo, and Raphael were employed in increasing the magnitude of the piers which were to support the dome: subsequently it was proposed by Peruzzi, Antonio San Gallo, and Michael Angelo, to change the form of the plan for that of a Greek cross, and under the direction of the two former, the body of the Church was completed, and the dome commenced; the latter was chiefly employed in embellishing the dome with paintings. Sundry additions were made by Ligorio and Vignola, and, in 1590, the dome was completed by Fontana. Twenty years afterwards the nave and Western façade were built by Carlo Moderna; and the building, which may now be said to have been finished, again assumed the form of a Latin cross. The colonnades were built by Bernini, in 1721, that is, about a hundred years afterward.

Defects the desi and exe tion of building

The passion for dividing large masses into an infinite number of small parts, and an inattention to the principles of sound Taste which require, in a work intended to inspire sublime emotions, that with its magnitude it should possess a certain simplicity of form, are both remarkably exhibited in this splendid edifice. The exterior and interior surfaces of the walls have so many vertical divisions, and are so covered by columns and pilasters, as to form innumerable angles which distract the attention of the spectator, and impede the conception of the general plan of the building.

The haste with which some parts of the walls were erected prevented the Architects from taking sufficient pains to secure their stability; from want of attention to the foundation, and from the unequal settling of the masonry, several considerable fractures soon made their appearance; the repair of which has long exercised the ingenuity of the Italian artists; and to prevent the dome from giving way by its lateral thrust towards the exterior, Van Vitelli, in 1743, caused it to be surrounded by four hoops or chains of iron imbedded in the masonry.

The impression made on the mind of a spectator on entering St. Peter's Church is, that its apparent magnitude is less than its dimensions seem to indicate; the cause of which deception, according to Montucla, is the small number of principal parts into which the Church is divided, and the great magnitude of the ornaments, particularly the figures, which serve as appendages to those parts. And the same Writer observes, in his *Philosophical Recreations*, that if the number of aisles in the nave had been greater than three, and the arches supported on groups of columns, instead of piers, the edifice would have appeared much larger. The effect which should be produced by a dome of such magnitude is here also considerably diminished; in the interior, because it is not seen till the spectator has passed the nave, which causes it to appear a subordinate part of the building; and on the exterior, by the great projection of the body of the Church, which prevents the spectator from getting a good view of it.

racteris-
of the
ian Ar-
ecture
he XVth
XVIth
turies.

The Architecture of Italy during the XIVth and early part of the XVth century is chiefly exhibited in the Palatial buildings which adorn its cities. At first, plain and massive, like fortresses, they subsequently acquired a great degree of lightness and elegance. The mansion of an Italian Nobleman consisted of a suite of buildings surrounding an open *cortile*, a disposition rendered necessary by the impossibility of extending the whole building in a line where, as in cities, frontage is scarce. The edifice was divided into three or more stories, and occasionally into two; the façade of the lower story was generally a rusticated wall pierced by arches or by windows with horizontal or semicircular heads; the piers were sometimes strengthened or adorned with three-quarter columns attached to their fronts, and having their shafts apparently interrupted, at intervals, by cubical blocks of masonry representing, in an unwrought state, parts of the mass of stone from whence the column is supposed to have been formed. Sometimes the upper stories are also rusticated and decorated with columns similar to those below; but occasionally the Ionic and Corinthian Orders are employed over a rustic basement without columns; in which case those above present by their delicacy an unnatural contrast with the style of the lower part of the façade. Horizontal entablatures, often loaded with heavy ornaments, divide the stories, and crown the whole edifice; the height of the architrave of the upper Order seems to have been made proportional to that of the Order itself; but the frize and cornice proportional to the whole building considered as an Order; and this was, perhaps, intended to enable the artist to give that great projection and consequent boldness to the cornices which are so much admired in the Italian edifices. In the same Age we find a frequent employment of the *mezzanine* stories, or suites of apartments of low elevation between two principal stories; a disposition which afterward became very common in Italy, and extended thence to other parts of Europe, where it is still practised; and though the good effect of the tier of small windows in a façade has been questioned, it must be admitted that in some cases it adds greatly to the beauty of the elevation; such apartments have, moreover, the merit of great convenience in the interior of a building.

The rustication of the masonry conveys an idea of great strength, with a degree of rudeness not inappropriate to the substructure of a building; but in the works of this Age it is carried too far, inasmuch as we frequently find the joints of the most slender piers and of the columns, even those of the delicate Ionic Order, marked in the same way, which not only weakens the shafts, but takes away the beauty arising from the view of their smooth surfaces.

In the public edifices, the style of Italian Architecture during the XVIth century seems to have been borrowed from that of the works executed during the later period of the Roman Empire, particularly, it bears some resemblance to the ornamental parts of the edifices at Spalatro and Balbec. The Porta di Venezia, at Padua, may serve as an example. This is a semicircular gate with coupled columns on each side resembling those of the Corinthian Order, with Attic bases; each pair stands on a common pedestal, and these are supported on consoles. At a distance from these and on each side of the arch is another pair of coupled columns, and the interval between each pair is occupied by a semicircular niche with a pilaster on each side. From the wall behind the columns projects a pilaster, the breadth of which is equal to that of the two columns; in the face of this pilaster, is a broad panel; and at the top, the angles of the pilaster are ornamented with foliage like that in the capitals of the columns.

In the façades of the Churches erected in this Age are generally two porticos or tiers of columns one above another; and the upper tier is crowned by a pediment: the lower portico is extended on each side beyond that above, on account of the side aisles, the roofs of which are not so high as that of the central division of the nave, and each flank of the upper portico is sometimes supported by a great scroll or volute, in a plane parallel to the face of the building; this must have been intended to serve as a buttress, but it forms an absurd member when applied to a work executed in masonry. A capricious taste is often exhibited in Churches of this period mingled with that which characterises the best works of a later day. In the Capella Pelegrini, at Verona, which is a cylindrical building covered by a hemispherical dome, are columns disfigured by spiral flutings, yet the interior of the cupola and the Order which carries it are two of the most beautiful things of their kind in existence. The upper portico of the Church of Santa Maria in via lata, at Rome, consists of four Composite columns supporting a pediment, the horizontal entablature of which is interrupted over the two middle columns, and a semicircular arch is formed cutting the tympanum of the pediment; yet the columns of both the lower and upper portico are well proportioned, and a high podium between the Orders gives to the façade a fine effect. The Church del' Carignano, at Genoa, exhibits an example of a well-arranged plan, while the proportions of the Order employed on the exterior are bad. The plan has the figure of a vast Greek cross with the principal dome over the intersection; in each rentrant space, between the arms, is another cross, connecting those arms, so as to permit a vista quite through; and the centre of each of these crosses forms a Chapel which is covered by a small dome. The ancient houses of the Genoese Nobility had their fronts ornamented with parallel stripes of black and white marble, alternately disposed; but most of these have disappeared, and the more modern Palaces are faced with stucco, which is frequently painted in fresco: some of the Churches of Genoa, however, retain the different-coloured stripes, and prove how much this strange kind of embellishment must have been once esteemed in that part of Italy.

Italian Altars.

All the riches of Art have been displayed in the Altars of the Italian Churches; according to Milizia, each is a mountain of columns supporting only pediments of fantastical forms, which serve but to harbour dust and spiders' webs; every sort of precious marble is employed and covered with gilding, but the Architecture and the ornaments are equally devoid of taste. This reproach is applicable even to those Altars which are disposed in recesses in the interior of the Church; when placed under the dome or in the choir they are further attended with the disadvantage of interrupting the view and diminishing the apparent length of the edifice, and this is particularly the case with the High Altar in St. Peter's Church, which we have already described. But though these observations apply to the generality of the Italian Altars, it must be admitted that there are some which possess a certain degree of elegance and classical taste, and among them may be named those which Palladio has disposed along the sides of the Church of the Redeemer, at Venice.

Tombs.

The monumental edifices of Italy which have been executed since the revival of Roman Architecture are deserving of notice in this place. At Bologna is a curious one consisting of nine columns raised on a square plan and carrying a floor, on each side of which are pillars supporting three Gothic arches, and the whole is crowned by a pyramidal spire: at each of the four angles of the wall is a Roman oreille, and within the space enclosed by the arches was the sarcophagus. In the *Monumenti della Toscana* are given delineations and descriptions of Tombs, chiefly found in Rome, Venice, and Tuscany, which appear to be works executed in the XVIth century: they consist of a sarcophagus on which is a recumbent statue of the deceased, and about this are columns or pilasters supporting an ornamented entablature, above which is a semicircular or semielliptical panel surrounded by a scroll and containing a sculptured representation of the infant Jesus in the arms of his mother. The tomb of the Scaligeri, erected in the XVIIth century, at Verona, is probably an imitation of some of those which were executed in the preceding Age: it consists of a hexagonal floor supported by piers without arches and carrying the sarcophagus; above this is a rich, open canopy of a hexagonal form, with pointed arches supported on twisted columns, and the whole is crowned by a frustum of a pyramid supporting an equestrian statue, and ornamented with tabernacles at the angles. Round the base, is a low hexagonal wall with tabernacles at the angles, supported by square piers.

Fountains.

The Fountains of Rome exhibit some grand designs representing the façades of mansions or Triumphal Arches, and the water, gushing through apertures in the buildings, is received in a reservoir at the foot. The façade of the Fountain of Trevi consists of a centre and two wings ornamented with Corinthian columns bearing an entablature and an Attic above; the whole stands upon a plain basement, in front of which is a mass of rock-work, and over this the water pours from under a statue of Neptune in a recess formed in the centre of the façade; the reservoir below is of white marble, and there is a descent to the water by a flight of steps of the same material. Upon the rock-work are figures indifferently sculptured, and the rude forms of the materials at the foot of the building does not accord with the delicacy of the Corinthian Order above. The Fountains dell' aqua Felice and dell' aqua Paolo, built or restored by Dominico and Giovanne Fontana, have each, in front, three semicircular-headed arches between Ionic columns which support an entablature and two Attics crowned by a segmental pediment; the first of these is situated on the Viminal hill, and is supplied by the Aqua Claudia, the other crowns the Janiculum. Both elevations are meagre and ill adapted to their destinations. The Castel dell' aqua Julia, near Rome, is a more appropriate edifice; the front is ornamented with pilasters, bearing an entablature, and between them are three hemicylindrical recesses; the two extreme are occupied by trophies, and the third contains a statue on a pedestal; above the entablature is an Attic with an inscription, and the whole stands on a lofty plain basement, in which are numerous small apertures for the passage of the water to the reservoir in front.

The five Orders of Architecture modified by Vignola.

Vignola, in his *Treatise on Architecture*, has modified the Roman Orders, and given them a considerable degree of lightness. His Tuscan column is 7.5 diameters high, including the base and capital, both of which resemble those in the Vitruvian example; the diminution of the shaft is one-sixth of the lower diameter, or the difference of the semidiameters is $\frac{1}{78}$ of the length of the shaft. The height of the architrave is 0.417 diameter, of the frize is 0.583 diameter, and of the cornice is 0.667 diameter, consequently, the height of the whole entablature is equal to $\frac{1}{4.5}$ of the height of the column. The projection of the corona from the axis of the column is equal to one diameter.

He makes the height of his Doric column equal to eight diameters, including the base and capital, each of which he makes equal to half a diameter. The base, in some examples, consists of a plinth and torus, and in others is of the Attic kind; the capital consists of an abacus and an ovolo, the profile of which is in the form of a quadrant of a circle; this member is either plain or sculptured, and below it are fillets and a hypotrachelion, which is separated from the shaft by an astragal. The diminution of the shaft is equal to one-sixth of the lower diameter, and, consequently, the difference of the semidiameters is $\frac{1}{84}$ of the length of the shaft. The height of the architrave is made equal to half a diameter, and the frize and cornice each equal to three-quarters of a diameter; consequently, the whole entablature is one-quarter of the height of the column. The centres of his triglyphs correspond with the axes of the columns; the metopes are square and ornamented with ox-heads or trophies. His cornices have great projection, but in this member, the examples he has given differ from each other; under the corona of some are high mutules with horizontal soffits, and guttæ below; others are without mutules, but have a row of dentels under the corona. In the ancient Greek or Roman examples we find the Doric columns are without bases; but from the time of the revival of the Roman style Architects seem to have considered a base as necessary for this Order as for the others; and they have compared a column without one to a man without feet.

Vignola's Ionic column is made nine diameters high, of which the base and capital are each equal to half a diameter, considering the height of the capital to extend

tec-
e.

from the bottom of the volutes to the top of the abacus. The base is similar to that given by Vitruvius; the volutes in the capital are small and their faces are in a plane parallel to that of the entablature; which was also the case with those given by Alberti and Serlio. The diminution of the shaft is one-sixth of the lower diameter, hence the difference of the semidiameters is $\frac{1}{96}$ of the length of the shaft. The height of the architrave is equal to 0.625 diameter, and is divided horizontally into three faciæ, of which the lower one is vertically over the upper part of the face of the shaft; and the others project before it. The height of the frize is 0.75 diameter, and this member is highly ornamented with sculpture. That of the cornice is 0.875 diameter, and in the face is a row of dentels. The whole height of the entablature is equal to one-quarter of that of the column. The effect of this Order is grand, but several parts are liable to objection; the base appears incapable of supporting the weight of the column, the volutes are too small, and the corona is deficient in height.

We have said that in order to avoid the bad effect arising from the dissimilarity of the Ionic capital on its face and flank the Ancients had formed diagonal volutes on the columns at the angles of their buildings; but soon after the revival of Roman Architecture, the want of symmetry which was evident in those capitals was remedied by forming two volutes on each of the four faces in planes concave towards the exterior, and cutting each face of the abacus in the form of a rentrant arc of a circle so as to leave a projection above the two diagonal volutes which meet at each angle; this construction was applied not only to the capitals of the extreme columns, but to all those in a portico or peristyle. Such capitals having a festoon, sculptured to represent foliage, suspended between the catheti of the two volutes on each face, are employed in the Church of St. Peter, and in the Vatican Palace; and are supposed to have been an improvement by Michael Angelo on the volutes of the Temple of Concord. Another form of the Ionic capital was also said to have been invented by the last-mentioned artist; its volute had the appearance of a conical or bell-formed shell, the side of which was turned inward in spiral curves; but this seems never to have been esteemed.

The proportions of the Corinthian column given by Vignola, are nearly the same as those of the columns of Jupiter Stator; the sculpture of his capital is very elegant, except that the tops of the leaves in the second row project rather too much; the same thing may be said of the corona in the entablature, for the lacunaria in the soffit, between the modillons, have the form of parallelograms instead of squares, which is that usually given to them.

Vignola has given two designs for the Composite Order, which chiefly differ in the entablature; one of them resembles that in the Roman edifices; and is ornamented with mouldings of a sufficient boldness to be distinctly seen at a considerable height above the eye. In the other design, the height of the entablature is little more than one-sixth of the height of the column; the architrave is divided into two faciæ without a moulding to separate them, and is crowned by a large ovolo; the frize is ornamented with sculpture, and on each face, at the angle of the building, is a corbel seeming to support the cornice above; over each corbel is a projection like a modillon in the form of a scroll, and supporting a moulding under the corona.

The ornamental doorways of Vignola form a good medium between the ancient and modern style. The aperture is rectangular, and has its height equal to about twice its breadth; the surrounding architrave is divided into three faciæ, which are broken, above, by the horizontal part projecting to the right and left beyond the vertical sides. Above the architrave is a plain frize, and a cornice supported by elegant consoles, the breadth of which at top is greater than at bottom, and they descend to the level of the top of the aperture. In the cornice are both dentels and modillons.

The details above given will convey some idea of the advanced state of Architecture in Italy in the latter part of the XVth and beginning of the XVIth century; and we shall perceive from them that many of the features of Palladio's style had been anticipated by the artists whose names we have already mentioned.

CHAPTER III.

Italian Architecture modified by Palladio.

Palladio improves the style of Italian houses.

Palladio was born in 1518, and therefore must have been for several years contemporary with Peruzzi, San Michaele, and Vignola; and as he lived to the age of sixty-two, he must have practised during a considerable part of the XVIth century. For the number of works he executed, either wholly or in part, and the still greater number of designs he gave, he is to be considered as having done more than almost any other Architect for the advancement of his profession and the embellishment of his Country. It happened, however, with Palladio, as it has happened with some fortunate professor in every other Art and every Science, that much had been previously done by the labours of his predecessors to prepare the way for him, and when he entered the profession there was only wanting a comprehensive mind to combine the materials already existing, into one system. This is what Palladio did; but mankind, in bestowing the meed of praise which was really merited by the author of so many excellent productions, has nearly overlooked what was due to those who had furnished the means by which that excellence was attained. The basis of the practice of Palladio is to be found in the works of the artists of his Country, who lived during the XIVth and XVth centuries; but, instead of imitating the gloomy Palaces of the ancient Nobles of Italy, he introduced a light Architecture, more congenial with the state of society in his time, and capable of being applied, with small modifications, to every other climate The admiration excited by this new style almost immediately caused the heavy mode of building at that time practised, as well without as within the limits of Italy, to be abandoned for that which, in spite of its faults, and they are many, possessed numerous graces. In fact, within a short time from Palladio's death, the Architecture of Italy was adopted in every Country of Europe.

We proceed, in the first place, to give a few specimens of the works of this master; we shall afterward endeavour to exhibit their general characteristics and make a few observations on his style.

The Church of the Redeemer at Venice.

The Church of the Redeemer, built by Palladio, at Venice, is considered by Bertotti Scamozzi as a model of regular and elegant Architecture, though rather beautiful than magnificent. The interior has some resemblance to a Latin cross, but on each side of the nave are three Chapels together, occupying its whole length, which make the breadth of this part of the Church equal to the length of the transept. The length of the interior of the nave is double its breadth; the extremities of the transept and the head of the cross are semicircular, and the centre of the cross is covered by a dome; this is supported by four arches, surmounted by a cylindrical wall, the upper part of which serves as a base for the dome: the choir is situated within the head of the cross and is surrounded by isolated columns. Along each side of the nave, are half-columns coupled and attached to the piers between the Chapels; these Chapels are open towards the interior of the Church; and the apertures are crowned by semicircular arches, springing from entablatures on the capitals of Corinthian pilasters, which are of smaller dimensions than the columns of the nave; between the columns in each pair is a niche and statue. The heights of the apertures are a little more than twice their breadth; and above the entablature of the grand columns in the wall of the nave on each side is a row of three semicircular windows, each divided into three parts by two vertical bars.

The façade is elevated upon a stereobata, to the top of which is an ascent by steps extending all the breadth of the central division of the nave. On this, stands a portico consisting of two three-quarter columns and two pilasters, all of the Composite Order, with a pediment above them. The two wings of the façade are ornamented with Corinthian pilasters; this Order is continued along the sides, and its height is little more than two-thirds of that of the Order in the portico. The doorway has a semicircular head, and is decorated with two half-columns, of the same Order and dimensions as the pilasters of the aisles; and the columns support an entablature with a pediment under that of the portico. The roofs of the aisles are formed in an inclined plane on each side of the Church, and present on the façade the appearance of a great pediment cut in two by the Order of the portico. The height of the Church is 248 feet, its width 94 feet, and the height from the pavement to the top of the vault of the nave is 69½ feet. The base of the dome is elevated upon a cylindrical wall 23 feet high above the ceiling of the nave, and the crown of the dome, exclusive of the lantern, is 27 feet higher.

Bertotti Scamozzi observes that the solidity of this building is ensured by the thickness of its walls, and the resistance against the thrust of the dome is derived from counterforts which rest upon the walls separating the Chapels from each other. The half-pediments and plain, conical pinnacles detract, however, considerably from its merit as a piece of Architecture, though the interior disposition and embellishment may claim our admiration.

Church at Masera.

The Church at Masera, another of Palladio's Ecclesiastical buildings, is circular on the plan, and on one side of it is a recess covered by an elliptical vault; an entablature, supported by fluted Corinthian columns, surrounds the edifice, and between the columns are niches crowned by pediments. In the portico are six Corinthian columns, between the capitals of which are festoons of stone-work hanging in the air; a caprice similar to that which has been executed in some of the Temples of India: the entablature of the columns is crowned by a pediment. The Church of San Francesco della Vigna, at Venice, is considered also as one of Palladio's most esteemed works.

Count d
Porti's
house at
Vicenza.

One of the best specimens of Palladio's town-houses is that which he designed for Count Giuseppe di Porti, at Vicenza, the plan of which is a rectangular parallelogram, 250 feet long and 111 feet wide, the extremities of which fall in two public streets. It consists of two equal buildings separated from each other by a *cortile* or peristyle; an imitation, as Palladio himself asserts, of the Greek houses: only one of these buildings, however, has been executed, and that differs in some respects from the design he has given. In the façade are three stories, of which the lowest is rusticated and contains a semicircular-headed doorway and six windows; on the exterior of the middle or principal story are eight half-columns of the Ionic Order projecting from the wall, with an entablature broken over each; and between the columns are windows terminating in triangular and segmental pediments alternately; the attic or upper story contains eight square windows, and between them are short pilasters, before which statues are placed. Within the entrance is a square vestibule ornamented with four Doric columns without bases; these support an entablature, above which is a groined vaulting covering the vestibule. A vaulted passage leads from this to the cortile, which is surrounded by twenty columns of the Composite Order at the distance of 11 feet 6 inches from the walls; these columns are 41 feet high and nealy 4 feet in diameter; behind them are *parastatæ* or pilasters of smaller height serving to support an open gallery surrounding the *cortile*, by which the communication between the middle stories of the two buildings is made. See pl. xxii.

Rotunda at
Vicenza.

The most elegant of the villas built by Palladio is that called the Rotunda, situated on the gentle slope of a hill near Vicenza. Its general plan is a square, and, according to B. Scamozzi, this figure was given to it that the inhabitants might command the beautiful prospects afforded by the surrounding Country; each side of the square is 69 feet 4 inches long, and on the middle of each face is a portico of six Ionic columns supporting a pediment. In the centre of the square is a circular saloon 34 feet diameter; at the four angles of the square are the four principal apartments, which are of a rectangular form with vaulted ceilings, and between them are small rooms with doors of communication opening into the vestibules between the porticos and the saloon; the staircases are placed at four points on the exterior of the circumference of the latter. The building stands on a basement 10 feet 3 inches high, and containing the kitchens, the dining and servants' rooms; and the walls of the saloon are carried up vertically to the height of 32 feet, above which they terminate in a hemispherical dome. At the height of 22 feet 9 inches from the pavement is a gallery surrounding the interior of the apartment and protected by a balustrade. The bed-chambers surround the upper part of the saloon.

The edifice is encircled at the level of the entablature of the portico by a frize, the exterior surface of which has a small convexity; this kind of frize is always, and sometimes with justice, condemned, but in a building which, like the present, has little exterior enrichment, its effect is not displeasing; the same thing cannot be said of the tablets over the central intercolumniations of the porticos, which were, probably, intended for inscriptions, and of two elliptical windows formed in the tympanum of each pediment. It is probable, however, that these last have been executed since the time of Palladio.

The Vi
Pojana.

As another specimen of Palladio's villas we have chosen that which he designed for Count Boniface Pojana, in a village of the same name, at twenty miles from Vicenza.

The principal story of this building is elevated 5 feet from the level of the ground; it consists of a portico, a vestibule, six chambers, two closets or cabinets, and two staircases leading to the bed-rooms above. In the ground-floor under the principal story are the kitchens and cellars, both of which have vaulted roofs. The façade is broken vertically into five parts disposed symmetrically, two on each side of that in the centre, (which is crowned by a pediment;) and receding from it the portico consists of four rectangular piers supporting two concentric semicircular arches, all in the same plane as the central division of the façade. The want of the horizontal cornice to the pediment is a great defect, but B. Scamozzi supposes it was left out, because the arch of the portico would have approached it too nearly. In the design, a corridor, the roof of which is supported in front by Doric columns, proceeds from the wings of the building to the right and left, and returns on each side at right angles towards the front, so as to enclose an area before the house. See pl. xxii. The two extreme wings of this building have never been executed.

Of the public buildings designed by Palladio for Civil purposes, the Basilica and the Olympic Theatre, both at Vicenza, are the most important, and a description of them may be properly introduced in this place. The Basilica, or Palace of Justice, is supposed by Vincent Scamozzi to have been originally constructed during the reign of Theodoric, King of the Goths; be this as it may, it had become so ruinous by the effect of time and several conflagrations, that Palladio was employed to restore it. According to his own account, in the XXth Chapter of the IIId Book of his Architecture, the porticos or arcades were designed by him, and he considers the building as one of the finest works that had been executed since the time of the Romans.

The plan of the building is a rectangular parallelogram, 170 feet long and 67 feet wide within the walls; the whole consists of two stories surmounted by a high roof of timber, which is covered with plates of copper, and the profile of which is similar in form to a Gothic arch. The lower story, in the interior, is divided longitudinally into three aisles, of equal breadth, by twelve square piers which support its groined vaulting.

Round the exterior of the body of the building are two tiers of arcades, forming corridors 18 feet wide and open towards the exterior; the ceiling of the lower is 25 feet 9 inches from the pavement; that of the upper is 27 feet 6 inches above the former; and the walls of the building are still 17 feet 3 inches higher; therefore, the whole height of the walls is about 70 feet 6 inches from the pavement, and this is independent of the vaulted roof, which is 34 feet higher. On one side of the Basilica the ground is many feet lower than on the other, and here the building is supported by a basement, which adds much by its solidity to the effect of the arcades above.

The exterior of the lower arcade is ornamented with half-columns of the Doric Order attached to the piers, and supporting an entablature which is broken over each column; the intervals of these columns are occupied by four others of smaller dimensions, also of the Doric Order, and placed in pairs perpendicularly to the face of the building; those faces of the piers which are opposite the smaller columns are ornamented with pilasters which, with the columns, support an entablature; this is discontinued at the interval between every pair of columns, and its place is occupied by a semicircular arch, to which the entablature serves as an impost; and the extrados of each arch rises to the inferior surface of the entablature of the principal columns. The upper arcade is exactly similar to the lower, but the columns are of the Ionic Order, and are supported on pedestals; the small columns of both arcades are without bases and have circular plinths. The windows in the upper part of the body of the building are crowned by pointed arches, and these belonged to the original edifice. Above the second arcade, and also on the top of the walls of the Basilica, are elegant balustrades and statues.

The Olympic Theatre.

In the very year of his death Palladio gave the design and laid the foundations of the Olympic Theatre at Vicenza, which was afterwards finished by his son. The rows of seats are of a semielliptical form; their whole extent parallel to the proscenium is 109 feet 4 inches; the horizontal depth from the proscenium to the back of the seats is 42 feet 4 inches; and the proscenium is 80 feet long and 21 feet 4 inches deep. Along the circumference of the upper seat is an elegant row of Corinthian columns 12 feet 6 inches high, above the entablature of which is a balustrade with statues. The façade of the scena, which was designed by Vincent Scamozzi, is composed of two tiers of columns of the Corinthian Order mounted on pedestals; the lower columns are detached from the wall and have pilasters behind them, and the upper Order is composed of half-columns attached. Between the columns, are elegant niches with rectilinear and circular pediments, supported by fluted Corinthian pilasters, and above the upper Order is an Attic ornamented with broad pilasters, between which are sculptures representing the labours of Hercules. In the scena, are three large open doorways leading through five passages, three of which diverge from the central doorway to the interior of the scena. The sides of these passages are ornamented with perspective representations in relief of Temples, Palaces, Basilicas, &c., executed in wood, and producing a surprising effect. The whole of the internal distribution seems to have been made according to the practice of the Romans, as nearly as the limits of the ground would permit.

Design for a bridge.

Palladio has given several designs for bridges, among which is a very elegant one, supposed by Temanza to have been intended for the Rialto, at Venice: if this is the case, the design of Palladio was not adopted, and, instead of it, was chosen one given by Antonio da Ponta. On the bridge are indicated one grand central street and two lateral ones, and on each side of all three, a row of shops; the whole construction is supported by three semicircular arches resting on rusticated piers. The ascent to the roadway is by three flights of steps at each extremity of the bridge, one parallel to its length and two at right angles to it; consequently, the bridge could only have been intended for foot-passengers, and, probably, to serve as a sort of Exchange for the meetings of the merchants. At each extremity, and over the central arch of the bridge, is a portico, consisting of Corinthian columns with square pilasters at the angles, and having above it a pediment-roof.

Characteristics of Palladio's style.

Like his contemporaries and immediate predecessors, Palladio was chiefly employed in designing and erecting houses for the Italian Nobility, and his designs for that kind of building are those which have been of the most importance in forming the taste of succeeding Architects. His ground-stories are generally composed of arcades serving as basements for the upper stories which are ornamented with columns, and in these basements were the offices or apartments used as shops; the principal story, or, as it is called, the *piano nobile*, is above these, and the Attics were reserved for store-rooms. He gave small extent to his façades, in order that the length might be nearly equal to the height; and, frequently, in the midst of the façade he made an anterior vestibule with three arches or rectangular apertures in front.

In the distribution of the interior of his buildings, he conformed to the taste and customs of his Age. It is said that at that time the Nobles required vestibules and peristyles, and apartments of great capacity to serve as Libraries and Galleries of Painting and Sculpture; and in these respects, Palladio's dispositions are considered as excelling those of his contemporaries. His arcades consist either of simple semicircular arches resting on piers, or the interval between two principal piers is divided into three parts by small piers or columns, and the arch covers only the central aperture; a construction which seems to have been copied from some of the colonnades of Dioclesian's Palace. Palladio's windows, though generally terminating above in a horizontal lintel or simple semicircular-headed arch, are sometimes divided into three parts, and have the central division arched in the manner we have just described; and often the windows are only semicircular apertures divided into three parts by two vertical bars or mullions, as in the Churches of the Redeemer and of San Georgio Maggiore, at Venice.

A marked distinction between the mansions designed by Palladio and those of the preceding Age appears in the almost constant application of a pediment to the central part of the principal façade; this is supported on the attached columns of the *piano nobile* and imparts an air of majesty to the whole edifice. The height of the pediment is made to vary from one-fourth to one-sixth of the length of the horizontal cornice, and to depend inversely upon the number of columns below it; a judicious modification, which renders the height of the pediment nearly proportional to that of the building itself. A great departure from the principles of the Art is, however, found in a few of the pediments which crown the façades of Palladio's buildings; we allude to the want of the horizontal cornice that should connect the lower extremities of the inclining rafters; an example of this bad taste occurs in the Villa Pojana which we have above described.

In the Churches which Palladio has erected he seems to have made an effort to preserve the general form of the Basilican or Lombard Churches, and to adapt the Roman Orders to it instead of returning to the form of a Heathen Temple, to which the buildings for Christian worship certainly have no relation. In the Lombard Churches the nave has considerable elevation, and the side aisles are subordinate to it; this form he retains, but he changes the façade with its tiers of arches for a portico consisting of columns mounted on pedestals and supporting an entablature with a pediment above, the apex of which reaches to the roof of the nave. On the two sides of the portico are the extremities of the aisles with those of their inclining roofs; the latter may be supposed to be parts of a pediment-roof once common to the whole building, and cut by the side walls of the central division of the nave: such is the construction of the Churches of the Redeemer, of San Georgio, and of San Francesco alle Vigne, all at Venice. The façade indicates by this form the disposition of the body of the Church; and though a better Taste may condemn the appearance of a double pediment, there is, at least, a reason for employing it.

In dividing the interior of houses, Palladio proposes several different proportions between the length, breadth, and height of apartments. Where circumstances admit it, which he acknowledges to be rarely, he recommends the rooms to be circular; in other cases, he recommends them to have their breadth equal to their length, or in a ratio to it which varies from that of 1 to $1\frac{1}{3}$ to that of 1 to 2, and that their heights should be an arithmetical mean between the length and breadth; in some of his best buildings he has made the ratio of the breadths of the principal apartments to their lengths as 1 to $1\frac{2}{3}$, and the heights equal to the arithmetical mean; the small rooms are square and the length or breadth to the height in the ratio of 1 to $1\frac{1}{3}$. The proportions of doorways are by the Italian artist made nearly the same as those prescribed by Vitruvius for the Doric Order, but the antepagments do not diminish. He makes the height of the windows in the ground story equal to $2\frac{1}{11}$ of their breadth, and the height of those in the second story equal to $2\frac{1}{8}$ of their breadth; consequently, these appear talle than the windows below them; a practice which Palladio seems to have generally adhered to, though in his *Architecture* he recommends them to be shorter by one-sixth.

Modification of the Orders by Palladio.

The modification which Palladio has made in the Tuscan Order does not differ much from that made by Vignola; both have made the heights of the column and of its base and capital to bear the same proportions to the diameter, but Palladio has made the diminution of the shafts greater, the difference of the diameters being one-fourth of the lower diameter. Palladio's capital has the advantage of greater simplicity than that of Vignola, the abacus being without any moulding, and the projection of the ovolo being only equal to about half its height; on the other hand, Palladio's entablature is higher and more complex, its height is equal to one-quarter of that of the column, and the mouldings of the cornice seem too numerous for an Order which should possess the utmost simplicity.

In many of the edifices of Palladio's time we find the shafts of the Tuscan columns occupied at intervals by cylindrical or cubical blocks, as we have already said; this rustication, though hardly to be recommended in any case, is not inappropriate to a building characterised by a certain degree of rudeness, and examples of it are to be found in some of the old Roman works: in one of the aqueducts, the columns, though of the Corinthian Order, have their shafts broken by those heavy masses.

In the Doric Order, also, Palladio has deviated but little from Vignola; the heights and forms of the column and of its base and capital are the same, but the diminution is less, for the difference of the upper and lower diameters is $\frac{1}{7.5}$ of the latter; the architrave is divided into two faciæ, the centres of the triglyphs correspond with the axes of the columns, the metopes are square and ornamented with sculpture; the soffit of the corona is in an inclined plane, and this member has neither the dentels nor mutules which Vignola has given to the Order; in this respect, therefore, Palladio's Order has gained something on the score of simplicity: the height of the whole entablature is $\frac{1}{4.5}$ of the height of the column.

Palladio's practice varied considerably respecting the proportions of the Ionic Order, but one which he has employed more frequently than the rest, and which he has given in his *Architecture*, resembles that of Vignola only in the proportion of the height of the column to its diameter, in the height of the base and capital, and in the form of the latter. Palladio has employed the Attic base with an astragal above the upper torus, and he has given rather less diminution to the shaft, for the difference of the upper and lower diameters is but one-eighth of the latter; the architrave is divided into three faciæ separated from each other by mouldings; the frize is deformed by making its surface convex, which, though justified by many examples of antiquity, is hardly worthy of imitation; and under the corona is a row of plain modillons; the height of the whole entablature is but one-fifth of that of the column, which seems too little and gives an air of meanness to the Order.

Palladio's design for an Ionic capital, like those of the Ancients, and of Alberti, Serlio, and Vignola, represents the planes of the faces of the volutes to be parallel to the face of the entablature, the sides of the capital having the usual baluster form; the volutes, however, of the Italian Architects are invariably smaller than those of the Ancients, and on that account are far from possessing the elegance which characterises the latter.

Subsequently to the time of Palladio, Scamozzi designed an Ionic capital which seems a variation of one of those given by M. Angelo; the planes of his volutes are parallel to the diagonal of the abacus, and the faces of the latter are concave towards the exterior; the stems of the volutes spring from the middle of the capital, and between the lower extremities of the stems is a flower on each face which fills up the void under the middle of the face of the abacus. In this capital the ovolo seems to represent a circular vase placed on the top of the column, and the volutes to represent the curling heads of plants rising from its interior.

The height of Palladio's Corinthian column is but equal to 9.5 diameters, whereas Vignola had made it equal to 10 diameters, which is more agreeable to the practice of the Ancients; the base resembles the Attic, but it has, in addition to the other members, an astragal above and below the scotia and above the upper torus; which is not, perhaps, improper in the Corinthian Order, though it produces a departure from that alternation of rectilinear and curvilinear features which constitutes distinctness and relief. The diminution of the shaft is rather less than Vignola makes it, and the heights of the several members of the entablature bear a lower ratio to the diameter; the architrave is divided into three faciæ, and the frize is connected with the upper moulding of the architrave by a conge or inverted cavetto. The height of the whole entablature is equal to $\frac{1}{52}$ of the height of the column, and the cornice contains both dentels and modillons.

Palladio makes the Composite column equal to 10 diameters in height, like that of Vignola, but the diminution less: the architrave is divided into two faciæ, and the frize resembles that in the Ionic entablature, except that the upper part of the swollen or convex surface projects beyond the lower as much as $\frac{1}{15}$ of a diameter; this practice, which at first seems extraordinary, has probably been adopted, as is observed by Norman in his parallel of the Orders, to reduce the intervals of the modillons in the cornice to the form of exact squares when the centre of a modillon corresponds to the axis of each column. The height of the entablature is one-fifth of that of the column, the cornice is without dentels, and under the corona are modillons which are divided horizontally into two parts by a moulding; the lower part is smaller than the upper.

CHAPTER IV.

Architecture of the Continent of Europe since Palladio's Time.

Decline of Architecture in Italy.

Two Architects who have added lustre to their profession both by their buildings and writings, *viz.* Serlio and Scamozzi, were contemporaries with Palladio, and both practised in the North of Italy during the XVIth century; Scamozzi is particularly celebrated for the Trissino Palace, at Vicenza, the façade of which exhibits two stories, the lower ornamented with Ionic columns, and the upper with Corinthian pilasters. To these names we may add those of Scalfarotto and Tirali, the former of whom built the Church of San Simeone Minor, at Venice, with a façade in imitation of the front of a Roman Temple, consisting of six Corinthian columns supporting an entablature, and crowned by a pediment enriched with sculpture; and the latter subsequently added a portico of a similar kind to the Church of San Nicolo in the same city. These are almost the first of the Italian Churches having that kind of portico; the façades of the others being generally ornamented with three-quarter columns attached to the walls.

But from the end of the XVIth to the beginning of the XVIIIth century, the Architecture of Italy is found to have deviated considerably from the comparative purity of the Palladian School; columns of the Roman Orders were grouped together like those in a Gothic edifice, and they were employed to support the imposts of arches by the side of others which bear an entablature passing above the crowns of the same arches; pilasters were made to project before each other, and the entablatures were broken to correspond with the projections; and lastly, pediments were placed one within another, or were interrupted at the vertex; and an excess of misapplied ornament encumbered every part of the building. It must be admitted that examples of these improprieties are found in the works of the older Architects; but in these they appear but as accidental defects, whereas in the Age we are speaking of they became general.

Borromini.

During this period lived Borromini, against whom is chiefly directed the reproach of corrupting the style of the Italian Architects. This artist practised during the first half of the XVIIth century, and made himself singular by the extravagant caprices which he introduced. The best of his works is the Church of Santa Agnesi in the Piazza Navona, at Rome, the façade of which is a curve of contrary flexure on the plan, and is ornamented with Corinthian columns. Another of his works is the Church della Sapienza, also at Rome, the plan of which, in the interior, is a triangle with a semicircular recess on each side, and having its angles filled up. The lower part of the Church is invisible from without, being surrounded by buildings, but, above, is a cupola, the exterior surface of which is formed in steps surrounding it, except where they are interrupted by counterforts; but the most remarkable object in this building is a spiral turret, approaching to the form of a cone, which crowns the dome.

Palazzo Barberini.

About the same time lived Bernini, who, besides the colonnade in front of St. Peter's Cathedral, built the façade of the Barberini Palace, at Rome. The centre of this building, which had been designed by Carlo Maderno, and partly executed by Borromini, is of a rectangular form, and there are two wings which project towards the front; on the ground-floor of the centre are two parallel rows of arches on piers, forming a vestibule which is covered by a groined vaulting; and in the elevation of the front are three stories, of which the lowest is ornamented with Doric columns and the two upper with columns of the Corinthian Order; and between the columns are semicircular arches springing from imposts. In the front of each of the two wings, are three tiers of rectangular windows, placed in recesses formed by four narrow projections of the wall like pilasters; and above the roof of the central division is a rectangular building called a *Belvidere*, with windows on each side and adorned with pilasters on the exterior. This kind of turret seems to have been affected by the Nobles of Italy at that period, and there is one of a magnificent character above the roof of the Pontifical Palace erected by Fontana; but they are considered by Forsyth as injuring the effect of a building, and as resembling a hut on a house-top.

The Caserta, at Naples.

We may here introduce a description of the Palace of the King of Naples, at Caserta, designed by Van Vitelli, in 1752. This splendid edifice, which from its immense extent produces a sublime effect, consists of four ranges of buildings disposed on the sides of a rectangle 710 feet long, and 610 feet broad, with a square pavilion at each angle rising above the general roof; and the interior is divided into four equal-sized open courts by two lines of buildings which cross each other at right angles in the centre. The entrances are by an octagonal vestibule in the middle of each of two opposite faces; and a grand but obscure corridor extending quite through the building connects these vestibules together. In the middle of this corridor, and in the centre of the whole Palace, is a grand, octagonal saloon, on one side of which is an immense marble staircase, leading to an octagonal landing-place over the saloon. On that side of the landing which is opposite the head of the stairs, is a superb chapel, of a rectangular form, but with a semicircular recess at one end: its ceiling is hemicylindrical, divided into compartments richly gilt, and rises on each side from an entablature supported by coupled Corinthian columns of marble, which stand on pedestals united by balustrades. In the middle of one of the sides of the enclosure is an elegant Theatre.

The exterior façades of the building are 120 feet high from the ground; each consists of three stories, of which the lowest is rusticated, and contains two rows of rectangular windows with three plain entrances covered by semicircular arches. Above this basement is a row of Ionic pilasters standing on pedestals, the faces of which project from a general podium, and above the entablature is a balustrade with statues; between the pilasters are two tiers of rectangular windows, of which the lower only are terminated by pediment-heads; and the centre of the façade is marked by a grand pediment supported by four pilasters and crowned by trophies. The upper part of the pavilion, at each angle of the Palace, is adorned with Corinthian pilasters, and over the centre of each face of the pavilion is a pediment. The whole building stands on a general basement, to which is an ascent by steps extending quite along the front.

Since the commencement of the XIXth century the taste for the classical Architecture of the Romans has more generally prevailed in Italy, and specimens are exhibited in some of the Churches at present in progress; of these the principal are the great Church at Naples, now building by an artist of the Country, and a Church in Lombardy, building according to the design and at the expense of the late celebrated sculptor Canova: the former is crowned by a dome of pumice-stone; and, in the interior, is one great Order rising up to near the foot of the dome, with continuous bas-reliefs above the entablature; on the exterior is a Corinthian portico with a pediment and a Doric colonnade in front like that at St. Peter's Church: the other is executing on the model of the Pantheon, and is to have a Greek-Doric portico in front.

Architecture of France in the XVIth century.

Before we describe the Architecture of the Northern part of the Continent of Europe in the XVIIth and XVIIIth centuries, it will be necessary for a moment, to cast a look back on that which prevailed in France immediately after the abandonment of the Gothic style. The dwellings of the Nobility of France about the time of Francis I. were generally in the castellated style, and though not intended as fortresses, they probably resembled such as were actually places of defence in the turbulent times which preceded that period. The plan was a square or parallelogram, and the whole consisted of buildings surrounding an open court; the windows were high and narrow, and at each angle was a square or round tower, crowned by an embattled parapet, with machicolations, and terminating in a high pyramidal or conical roof. Most of the buildings stood on a terrace, supported by a sloping wall or revetment, and at each angle of which was a *guérite* or watch-tower projecting beyond the wall. Specimens of such edifices, probably in their original state, still exist at Montargis and Verneuil. See Durand's *Parallel of Ancient and Modern Architecture.*

In the beginning of the following century, and probably earlier, a taste for extravagant ornament prevailed on the dwelling-houses both of France and Germany. The old houses yet existing in Normandy, Germany, and Holland have octagonal towers, high roofs, and disproportioned columns with spiral flutings; and the faces of the walls and the *dormers*, or windows in the roofs, are covered with the utmost profusion of sculpture. Some examples of these buildings may be seen in Cotman's *Antiquities of Normandy;* but in the course of that century the Architects, having adopted the style of the Italian School, introduced a taste for greater simplicity and elegance.

The Luxe
bourg.

One of the first examples of this improved style is the Chateau Luxembourg, built by De Brosse, under Mary de Medicis, in 1620; this consists of a centre and two wings connected by arcades; each of the wings is formed by two square pavilions placed at right angles to the front, and in the rear is a square court surrounded by a double arcade. The central building is crowned by a cupola and lantern, and the pavilions by roofs in the form of frusta of pyramids; each consists of three stories ornamented with columns, and coupled half-columns are attached to the faces of the piers supporting the arches which connect the buildings. The chief defect in the design of this building is that the pavilions instead of being subordinate to the centre are both broader and more lofty, and the high, plain roofs seem too heavy for the ornamented walls which support them.

The Louvre and the Thuilleries are two buildings separated only by their gardens; the former consists of a vast quadrangle enclosing a *cortile;* and the magnificence of its principal front, which was built by Perrault, in 1667, renders it one of the finest buildings in Europe; the length of this front is 371 feet, its height from the level of the ground to the top of the cornice is 85 feet 3 inches, and it is broken vertically so as to form a projection in the centre and one at each extremity. The basement constitutes one grand but plain podium, 32 feet 3 inches high, and is pierced by windows, the upper extremities of which are flat segments of circles; in the central division are three doorways, of which that in the middle is more lofty than the others, and covered by a semicircular arch crowned with trophies. Above the podium, the central division and the two curtains connecting it with the pavilions are adorned with coupled, Corinthian columns having fluted shafts; every pair stands on a pedestal common to both, and between the pedestals are balustrades: the columns stand at a distance from the walls, and behind them is an open gallery extending along the front. In the middle of the face of each pavilion is a recess crowned by a semicircular arch springing from imposts; the angles of the pavilions are ornamented with coupled, Corinthian pilasters, and on each side of the recess is a column and pilaster. In the wall of the building, under the colonnade, are niches containing statues, and each niche is crowned by a pediment; above these is a horizontal string, and over it a row of elliptical medallions. The central division is crowned by a magnificent pediment, the tympanum of which is filled with sculpture, and above the horizontal cornice of the rest of the building is an elegant balustrade.

The Thuilleries form one line of building, 1070 feet long, situated at that extremity of the whole which is opposite to the colonnade front of the Louvre. The centre consists of a tower, 74 feet square, crowned by a high dome raised on a square base, and formed of four curved surfaces meeting in as many diagonal ridges, which are ornamented or disfigured by rusticated work; on each side of the centre, a line of building, having an arcade in front, connects that part with each wing.

The façade, which was designed and begun by Philibert del' Orme in the middle of the XVIth century, and continued by Le Vau in the XVIIth, presents the appearance of a mass of discordant parts; that in the centre consists of four stories, ornamented with Ionic and Corinthian columns supporting entablatures, and crowned by a pediment and dome. The arcades in the curtains stand on a podium broken by projections; the faces of their piers are ornamented with Ionic columns, the shafts of which are interrupted by cubical blocks, and above the arcades are two tiers of windows. The façade of each of the wings is broken vertically into three parts, of which that nearest to the centre consists of three stories, with Ionic and Corinthian columns in the lower and second stories respectively, and Attic pilasters in the upper. The parts at the extremities of the façade consist each, also, of three stories; the front is adorned with four Corinthian pilasters extending from the podium to the top of the second story; and over these, are dwarfish pilasters of the same Order, in front of the third story; these extreme buildings are covered with lofty roofs, in the form of frusta of pyramids. The curtain between the two extremities of each wing consists of two stories only, in front of which are coupled, Corinthian pilasters, supporting an entablature above the second story.

In the façade of this Palace there is a mixture of columns and pilasters of various Orders and sizes ranged in the same line; two and three stories are formed within the same height, with entablatures terminating at the point at which the heights of the stories are changed, and the roofs of the several buildings are separated from each other; hence arises the utmost confusion in the system, yet from the great extent of the line an imposing effect is produced.

Palace of Versailles. A still more imposing effect arises from the immense line of buildings forming the Palace at Versailles, which, besides the advantage of greater regularity of design, is without the high naked roofs which deform the older buildings of France and appear like mean additions to the original structure. This edifice was built by Hardouin Mansard in the time of Louis XIV., and consists of a series of buildings divided into two parts by a court; the whole length is 1330 feet, and from the centre projects a mass of buildings about 250 feet towards the garden. On arriving from Paris there is a front court, in advance of the general line of building, with offices on each side, and this leads to an inner court between the two wings; at the bottom of this is the grand portico in the centre of the whole building. The two wings and the centre contain five quadrangular *cortili* surrounded by the apartments of the Palace, and the two extremities of one wing are occupied by a Chapel and a Theatre.

The Escurial. The royal Palace of the Escurial, in Spain, was begun in 1557 for Philip II., by Giovan Battista di Toledo, and finished by other hands after the death of that Architect. It is of a quadrangular form, 680 feet long from North to South, and 558 feet from East to West, besides a Chapel which projects 177 feet beyond the face of the Eastern front; the general height of the edifice is 64 feet, but there are eight towers, each 200 feet high, of which four are at the angles and the rest are symmetrically disposed in the interior. The general plan of the building may be considered as divided into three parts, in directions from West to East; at the Western extremity of the central division is a grand vestibule 252 feet long, and 125 feet wide, the sides of which are ornamented with pilasters supporting arches. Three grand portals lead from this vestibule to the Royal court, which is 262 feet long, and 197 feet wide, including the habitations about it; the façades of the buildings in this court have five rows of windows, ornamented with pilasters or fasces; and at the Eastern extremity is the grand Chapel, which is covered by a cupola 70 feet in diameter, and has in front a portico formed by five arches, the piers of which are ornamented with half-columns of the Doric Order. The Northern and Southern divisions of the interior are occupied by peristyles or arcades surrounded by apartments.

The principal exterior façade is towards the West; like all the others it contains five tiers of windows, ornamented with simple architraves; and it is finished by a horizontal cornice which is continued without interruption round the whole building. It has three portals of entrance, one in the centre and the others equally distant from it and from the angles of the building. The centre of the façade is adorned with two Orders of half columns attached to the walls; the breadth of the lower Order is 149 feet; and it contains eight Doric half-columns standing on plinths; in the middle intercolumniation is the doorway, and in the others are niches. Above the entablature of this Order are four Ionic columns, placed vertically over the four middle columns of the Order below; and the entablature is crowned by a pediment with a globe at each of its points; this second Order is flanked by four obelisks placed vertically over the four extreme columns below; the obelisks are terminated by globes; and in the middle intercolumniation is a niche containing a statue of San Lorenzo; the decorations about the other doorways consist of architraves and pediments.

The size of this building gives it an air of great magnificence, but its long and almost naked façades render it a gloomy pile.*

The high, sloping roofs, which we have described as rising above the walls of the Palatial buildings in France, seem to have been general throughout the North and West of Europe, during the last century, in the palaces, villas, and even the town houses; but this mode of building was carried to excess in Germany, where the roofs were often as high above the tops of the vertical walls as these were above the ground, and contained sometimes as many as five rows of dormer windows.

We add to this Chapter an account of the two principal, modern Churches of France, which are distinguished from those of Italy chiefly by the manner in which the centres of the buildings are covered; instead of the massive double domes which seem to crush the walls of St. Mary's, at Florence, and of St. Peter's, at Rome, the French Churches are crowned by slender cupolas exhibiting, in their construction, examples of refined, mechanical skill.

Church of the Invalids, at Paris,

At the latter end of the XVIIth century, Hardouin Mansard, the Architect of the Thuilleries, built the Church of the Invalids, at Paris, a work of the same character as that of St. Peter's, at Rome, but of smaller dimensions. This edifice is formed on a plan the exterior of which is a square of 342 feet, and the central part in the interior is a complete circle, 85 feet 3 inches diameter; between this circle and the four faces of the building are vestibules, which give to the interior the form of a Greek cross, and the vestibules on the East and West are terminated by porticos. Within each of the four angles of the square, is an octagonal Chapel; and in the Eastern extremity of the Church is a rich baldaquino, the entablature of which is supported by Corinthian columns with twisted shafts.

The body of the Church is covered by a triple dome, of which the lowest has the form of a spherical zone, and rises at 146 feet from the pavement; its height is 36 feet, and it terminates in a circular aperture which permits the second dome to be seen by a spectator below; this second dome, which is nearly a hemisphere, rises from the hances of the former, and its crown is 208 feet from the pavement. Both these domes are of masonry; the lower part of the second is pierced by twelve semicircular-headed apertures. The third or upper dome is of timber, and its vertical section resembles a Gothic arch of the third point; its vertex is 238 feet from the pavement, and it is crowned by an elegant lantern, terminating in a ball and cross, at 312 feet from the pavement: the surface of the exterior dome is divided by twelve ribs, and between these it is ornamented with panels containing painted trophies; the interior surface of the second dome is covered with painting, on which the light falls from the windows in the lantern, and permits them to be seen to great advantage, through the aperture of the lower dome.

of St. Genevie

The Church of St. Genevieve, at Paris, was begun, in 1757, by M. Soufflot, and is remarkable for the boldness of the construction of its upper part, which consists of three domes of masonry raised one on another without any apparent abutment. At the intersection of the body of the Church with the transept, are four piers, ornamented with Corinthian columns; from these piers spring semicircular arches, and between them are pendentives, which terminate in a horizontal circle 70 feet in diameter, with an interior entablature, the cornice of which is 108 feet from the pavement; above the pendentives is a cylindrical wall, in which is another interior entablature, the cornice of which is 155 feet from the pavement. The exterior of this wall is surrounded by a range of Corinthian columns, 37 feet high, and disposed in the circumference of a circle, 110 feet in diameter; from the top of the wall springs the lower dome, which is 70 feet in diameter, and 35 feet high, and has the form of a truncated paraboloid ending at top in a circular aperture, the diameter of which is 30 feet.

On the hances of this dome, and 180 feet from the pavement, springs another parabolical dome, 58 feet in diameter, and 40 feet high, and on the top of this is a lantern, 55 feet high, with a hemispherical top, terminating in a ball and cross. Over the cylindrical wall before mentioned, and on the exterior of the base of the second dome, is another cylindrical wall, crowned on the exterior by an entablature, the cornice of which is at the height of 200 feet from the pavement; from this springs the upper dome, which is 80 feet in diameter, and 40 feet high, and terminates on the exterior of the lantern, at about the middle of its height. A vertical section of this dome presents the appearance of two Gothic arches, the radii of which are each equal to 54 feet.

General style of Church building the Continent.

After the description of the elegant Churches of Italy and France, it will be almost needless to notice those of other Countries on the Continent of Europe, which have been erected subsequently to the abandonment of the Gothic style; some of these, like the Cathedral at Dresden, are crowned by magnificent domes, but in general they are furnished with a square or polygonal tower rising to a great height above the body of the building; the top of this is surrounded by a balcony and crowned by a cupola and lantern, and frequently by a small spire or pinnacle above the latter. In Holland and the Northern part of Germany, an extremely vitiated taste prevailed till lately in Church building; many of the spires, instead of having the simplicity of the pyramid or cone, resemble several spheroids or bell-shaped figures placed one above another, and ending in a very acute pinnacle at the top.

The modern Churches of Spain are not very different from those of the North of Europe; some of them are crowned by domes, but the generality of them have only small slender turrets extravagantly painted and gilt; their marbles and paintings are rich, but are overloaded with garlands and pyramids, broken pediments, and heavy cornices.

CHAPTER V.

Introduction of the Roman Architecture into England.

The introduction of the revived Roman Architecture into England seems to have taken place during the

---

* For particulars of the ESCURIAL less strictly Architectural, see our *Miscellaneous Division, ad v.*

reign of Henry VIII., for this Prince had in his service John of Padua and Jerome of Treviso, two Italian Architects, who were employed in the erection of mansions for the English Nobility; and, though nothing now remains of their works, there is little doubt that they were the instructors of Holbein, who arrived in this Country at or near the same time; and who has left an example of the ancient Orders, but blended with features belonging to the latest species of Gothic Architecture, in the portico which he built for the Earl of Pembroke, at Wilton.

e of ding in time of abeth James I.

s Col-, Cam-ge.

This mixture of styles continued to prevail in the buildings erected during the reigns of Elizabeth and James I., and specimens of it are found in the Colleges at Oxford and Cambridge, several of which were then built or restored; these generally consist of ranges of buildings enclosing quadrangular areas; and the windows, which are rectangular, are divided by mullions and crowned by horizontal tables. Over the gateways are oriels, and along the tops of the walls are several gables, the sides of which are cut in figures fantastically composed of right lines and curves. But in Caius College, at Cambridge, which was erected in 1566, are several semicircular-headed gateways, ornamented with some of the Roman Orders in tiers; and the face of one of them has all the five placed, in succession, above each other. For purity of style these are nearly equal to any examples of the Orders executed by Bramante in Italy.

ools at ord.

The tower also of the Schools, at Oxford, consists of a semicircular-headed gateway with broad windows above it, and the whole crowned by a complex gable; on the face of the tower are five tiers of coupled columns of all the different Roman Orders, from the Tuscan to the Composite, mounted on pedestals. These are supposed to have been executed by Inigo Jones; but they are probably older, and are, evidently, the work of some person who had a knowledge of the Orders, but not of the ancient mode of applying them in a building. Above the second tier of windows is a statue of James I.

abethan sions.

According to Mr. Walpole, the mansions of the Elizabethan Age belong to a style which he supposes to have been invented for the houses of the Nobility, when, on the settlement of the Kingdom after the termination of the quarrel between the Roses, they ventured to abandon their fortified dungeons and consult domestic convenience. At the entrance was a vast hall frequently occupying all the height of the building; from this proceeded a gallery extending through the whole length of the house, and forming a communication among the different apartments. The apartments themselves were great in length and breadth, but the ceilings were low; and those sides of the room which were formed by the exterior walls of the house were almost entirely occupied by rectangular windows: oriels or bowed windows were also very general; these formed recesses in the rooms, and were supported by timbers projecting from the face of the lower part of the wall. The ceilings were divided into square compartments by great timbers under its general surface; the parapets were cut into gables like those of the Colleges above mentioned, and both the interior and exterior of the building were generally loaded with sculptured ornaments resembling those on the houses of the Continent, at the same period.

An Architect named Thorpe designed or improved most of the Palatial edifices erected in the reigns of Elizabeth and James I. Walpole says of him, that his ornaments are barbarous; but he allotted ample spaces for halls, staircases, and chambers of state, and there is judgment in his disposition of apartments and offices. Audley End, near Saffron Walden, and part of Northumberland House in London, were built by Bernard Jansen, a Fleming, in the time of James I. The latter is remarkable for its almost exact coincidence with the style of the Italian Palaces; consisting of a range of buildings surrounding a quadrangular enclosure, with windows towards the interior.

Bernard Jansen.

Brownsholme Hall.

In Britton's *Architectural Antiquities* is given a view of Brownsholme Hall, in Yorkshire, which may serve as an example of the domestic Architecture of the above-mentioned period. The façade consists of a centre and two projecting wings. In the middle of the former, is the doorway which is crowned by a semicircular arch without imposts, and on each side is a pair of fluted columns of an Order resembling the Doric, but with Attic bases, and standing on a common pedestal; the entablature above them extends only over the doorway and columns, and is broken so as to project over the latter; in the frize are triglyphs, but placed without regard to symmetry, for in that part which stands over the capitals of the columns there are two triglyphs, and two metopes, so that at one angle of the projection is a triglyph, and at the other a metope. Over this entablature is a plain rectilinear window, and, on each side of it, a pair of Ionic, fluted pilasters, both standing on one pedestal, the face of which is ornamented with a panel; the entablature above consists of several mouldings, without distinction of architrave or frize. The third story is ornamented in a way similar to the second, but it is not quite so high; over it is a pediment, and, on each side, is a small obelisk, placed on a pedestal.

Improvement of English Architecture by Inigo Jones.

The English mansions of the time of Elizabeth do not appear to have been ever considered as convenient dwellings; Lord Bacon's observations on them are well known, and perhaps there are few persons of the present day who would choose such edifices for their residence in preference to those of more modern construction; the tasteless form of the exterior, the great square windows, and clumsy sculpture, are equally unworthy of imitation; and, we may add, the diminutive columns executed in imitation of the Roman Orders, and placed so that they betray an utter ignorance of the principles which regulate the employment of such members, instead of inspiring ideas of magnificence only excite contempt. But this mixture of styles did not long continue, and the Italian artists, who had been brought into England as early as the reign of Henry VII., having communicated some knowledge of the Architecture of their Country, those of England began to feel a desire to be more intimately acquainted with it, and with the ancient style from which it was derived. By such means Inigo Jones seems to have been led to the study of the writings of Vitruvius and of the Italian Architects; and, thus, to have acquired a great taste for the style prevalent in Italy at that period, which, fortunately, he was enabled to put in practice to a great extent.

St. John's College, Oxford.

In the early part of his professional career, he gave designs for the second quadrangle of St. John's College at Oxford; the lower story of which he made to consist of a range of semicircular arches supporting an entablature ornamented with triglyphs; above this, are windows divided into two lights, and the walls are crowned by battlements. In the centre of one side of the square is a semicircular arch, springing from columns, and on each side of it is a projecting pier with double, fluted pilasters supporting an entablature in which are two triglyphs. In the second story of the same centre, and above the former pilasters, are two similar ones with Ionic capitals; the whole of the centre is crowned by a segmental pediment without the horizontal cornice. About the same time Jones built Heriot's Hospital at Edinburgh, and Sherbourne House in Gloucestershire; these first works, however, have not the correctness observed in those executed after his return from Rome; and Walpole observes that his designs of that time are defaced by the littleness of parts and weight of ornament with which the revival of the ancient Architecture in this Country was, for the most part, encumbered. But, having had an opportunity of consulting on the spot the remains of Roman Art, his taste became purified, and, subsequently, he designed or executed those works which established his fame, and gave a decided turn in England in favour of classical Architecture.

Intended Palace at Whitehall.

King James employed this Architect to give a design for a new Palace at Whitehall, in order to replace the ancient one, which was then in a ruinous condition; and a complete plan and elevation of the intended Palace may be seen in the collection of his designs by Kent: it was to have been of a rectangular form, the whole length, between the river Thames and St. James's Park, equal to 926 feet, and the breadth from North to South 740 feet. This immense edifice, exceeding in magnitude the Palace of Dioclesian, was to be divided into three equal rectangles by two ranges of buildings, extending through the whole depth of the Palace, from North to South; the central division was to form one great court surrounded by a terrace 30 feet wide; but the two lateral divisions were each to be divided into three courts by two ranges of buildings from East to West. In the centre of each of the exterior sides of the building there was to be a grand façade, of which that next to Charing Cross, and the opposite one, were at the extremities of the great central court; the front next to the Park was to lead into a circular, or as it was called, a Persian court, surrounded by an arcade, and forming the middle of the three courts on that side of the Palace; the front next to the river was to lead into a square court, also surrounded by an arcade, and forming the middle court on this side.

Banqueting-house.

The only part of this vast edifice which was executed is that intended to have been a Banqueting-house, but now converted into a Chapel; it forms a very small part of the whole design, and occupies what would have been the Western side of the quadrangle at the North-East angle of the Palace. Its plan is a rectangle 110 feet long, and 55 feet wide, and its longest fronts contain each two Orders of half-columns, above the lowest story, which forms a substantial basement to the whole structure; the lower of the two Orders is Ionic, and resembles that of Palladio in the proportions of the columns, in the convex frize, and in the modillons of the cornice; between the columns are rectangular windows, with circular and rectilinear pediments alternately: the upper Order is Composite; between the columns are rectangular windows, and above the latter are festoons of sculptured drapery: the whole front is rusticated and crowned by a balustrade. The façades of this building produce an imposing effect, and they are so much the more admirable as they are almost the first examples of the Roman Architecture in this Country; they partake, however, of the defects of the Italian school, from which emanated the style they exhibit; the entablature is broken over each column, and there is a cornice to the lower, as well as to the upper Order. But if the whole Palace had been executed, there would have been no ground for the observation of a foreign artist, which till lately was too well founded, *viz.* that the King of England was worse lodged than any other Prince in Europe.

The old Palace at Whitehall, which this was to have replaced, had been originally built by Hubert de Burg, Earl of Kent; it was in 1248 sold to the then Archbishop of York, and it became the town-residence of the Prelates of that See. In 1530, Cardinal Wolsey, who then held it, sold it to Henry VIII., by which it became the property of the Crown: it was finally destroyed by fire in 1698.

York stairs.

That piece of Architecture which is situated on the Thames at the end of Buckingham Street in the Strand, was originally a water-gate in the middle of a long embattled wall, skirting the gardens of the Duke of Buckingham on the river side; and was erected by Inigo Jones in 1626. The façade of this building, next to the street, consists of a semicircular arch in the centre, for a passage, and an aperture of a similar form on each side for a window; the crowns of these are of equal height from the pavement, but as the middle arch is wider than the others, its imposts are lower than theirs, which is a great defect; the face of each pier is ornamented with a pilaster of the Tuscan Order, and, over these, is a general horizontal entablature with stone balls placed as ornaments on its top. In the direction of the length of the passage through the centre, are two semicircular arches on each side, springing from imposts, and resting on a small pillar in the middle. The façade next to the river consists also of three semicircular arches; in front of the four piers on which they rest are four half-columns of the Tuscan Order attached to the wall; the two in the centre stand on the top of the flight of steps which leads from the passage down to the water, and the two others on plain pedestals. The imposts of the three arches are all in one horizontal line; the faces of the piers are rusticated to resemble rough masonry, and there are square blocks also rusticated, at intervals, on the shafts. The columns support an entablature which is broken above their capitals; and over the archway is a pediment formed by a segment of a circle, and having its tympanum ornamented with a shield, for which the horizontal cornice is interrupted.

Church of St. Paul, Covent Garden.

The Church of St. Paul, in Covent Garden, was originally built by Jones, in a style resembling that of the present edifice, which is a restoration executed under the direction of Mr. Hardwick; the old building having been destroyed by an accidental fire in 1795. The Architect seems to have intended to exhibit here the proportions of the Tuscan Temples as they are described by Vitruvius; and the whole building may be considered as very well appropriated to its situation, among the huts of a market-place, which it may be said to resemble in form; it must also be considered as, perhaps, the only existing specimen of an ancient Order, and on that account it is interesting. The plan is a rectangle 133 feet long, including the depth of the portico or pronaos, and 60 feet wide, and, contrary to the general practice in Churches, the altar is at the Western extremity; the height from the ground to the cornice is 35 feet. In front of the pronaos are two columns of the Tuscan Order between the antæ pilasters; all these have considerable diminution, and the sides of the shafts are curved in the vertical direction; the entablature consists of an architrave and cornice, and the latter is supported by cantilivers, or timbers, projecting as much as one-quarter of the height of the column. The façade is crowned by a pediment, the height of which from the horizontal cornice is 21 feet, or nearly one-quarter of the whole horizontal extent of the entablature.

Masonry was thus employed in the time of Inigo Jones for the public edifices of London, but the mansions of the Nobility were then merely of brick, and the houses of the citizens of timber; in the reign of Charles I., however, stone houses were built in London, and the Earl of Arundel was almost the first who introduced the practice of building in that material.

hedral of Paul.

Soon after the time of Inigo Jones the fire, which destroyed nearly the whole of London, was the occasion of bringing forward the talents of Sir Christopher Wren, who, in reedifying the City, had more opportunities of displaying his skill in Architecture than any individual before or since. Besides the restoration of a considerable number of smaller Churches, that distinguished scholar as well as artist, whose mathematical discoveries have merited the notice of Sir Isaac Newton himself, had the glory of erecting the Cathedral of St. Paul, in London, which, next to that of St. Peter, at Rome, is the most magnificent edifice in the modern World. The plan of the building is similar to that of the generality of the Christian Basilicæ; *viz.* a Latin cross; and, in the disposition of its interior, as well as its exterior form, it bears considerable resemblance to the Church of St. Peter, from which, indeed, the idea of the construction is acknowledged to have been borrowed.

Two rectangular parallelograms on the plan cross each other at right angles; the length of the principal one from East to West is 480 feet, measuring from the top of the steps before the Western front to the exterior of the wall at the Eastern extremity; at this end of the building is a hemicylindrical recess, which extends 20 feet further than the wall and contains the altar, so that the whole length is 500 feet, exclusive of the great flight of steps in front; and the general breadth on the exterior is 125 feet. The length of the transverse rectangle from North to South is 250 feet, not including the portico at each extremity, which projects 20 feet further; its breadth is 125 feet; and the centre of the intersection of the parallelograms is 280 feet from the Western front. On each side of the building, at the Western end, is a square tower, one face of which coincides with the plane of the Western front, but on the Northern and Southern, the faces project about 27 feet beyond the general walls of the building, making the whole breadth of the Western façade equal to 180 feet. In the rentrant angles situated between these towers and the main building are formed two Chapels, each 50 feet long and 20 feet broad, open towards the interior of the nave, on which side is a great semicircular arch resting on four columns, two under each foot.

The exterior of the whole building consists of two Orders, one above the other, and the lower stands on a basement 10 feet above the ground on the Western side, where a magnificent flight of marble steps, extending the whole breadth of the front, leads to the pavement of the Church. From this pavement to the top of the entablature of the lower Order, the height is 50 feet, and from this to the top of the entablature of the upper Order, 40 feet; so that the height of the horizontal entablature of the body of the Church from the ground is 100 feet. The Western façade is ornamented with a magnificent portico consisting of twelve columns, in couples, of the Corinthian Order; above their entablature are eight columns, also coupled, and of the Composite Order, besides four pilasters; these support an entablature, above which, and extending over the twelve pillars, is a pediment, the tympanum of which is adorned with sculpture. The Northern and Southern extremities of the transept have porticos, consisting each of six fluted, Corinthian columns, disposed in a segment of a circle on the plan, and crowned by a half-dome, which rests against the wall of the building.

Within the centre of the Western façade is a porch 50 feet long and 20 feet wide, and opposite the interval of the two middle pairs of columns is the grand doorway, leading to a vestibule 50 feet square, which is marked by four piers placed at the angles; the tops of the piers are connected by semicircular arches, and under these are coupled columns detached in front of the piers. The body of the Church is divided into three aisles by rectangular piers, ornamented with pilasters and supporting semicircular arches; and on each side of the porch and vestibule is a passage which leads directly to the corresponding aisle. The Eastern extremity of the Church is also divided into three aisles by similar arcades, and this part is occupied by the choir and chancel.

The entrances on the Northern and Southern extremities of the transept lead each into a vestibule 25 feet deep, and equal in length to the whole breadth of the transept; each vestibule, as well as the nave and choir, communicates with the centre of the Church by three arched passages formed between two immense piers and the walls at the intersection of the arms of the cross: the interior surfaces of the eight piers coincide with the faces of an octagon, and the rentrant angles between the arches are filled up to the level of the crowns of the latter so as to form pendentives which end at top in the circumference of a horizontal circle. Above this is built a wall, in the form of a frustum of a cone, which terminates in a horizontal cornice, at the height of 168 feet from the pavement; from this springs the interior dome, which is of brickwork, 100 feet in diameter where it rests on the cornice, 60 feet high, and in the form of a paraboloid; its thickness is 1 foot 6 inches, and at the top is a circular aperture 24 feet diameter. On the hances of this dome, at 200 feet from the pavement of the Church, rests the base of a cone of brickwork 94 feet diameter at bottom and 85 feet high; the cone is pierced with apertures, and ends, at top, in a vault formed like an hyperboloid, with a circular aperture 12 feet in diameter near the vertex; the top of the cone is 285 feet from the pavement, on it is a lantern 55 feet high, terminated by a hemisphere, and above this is a ball and cross. On the sides of the cone are timbers raised to support the exterior dome, which is made of oak; its base is 220 feet from the pavement, and its crown coincides with that of the cone; its figure is nearly that of a hemisphere, the radius of curvature of its profile being 57 feet, and the centres in a horizontal diameter passing through the foot of the dome. To prevent the cone and the interior dome from exerting a lateral thrust on their supports, a circular groove was cut horizontally in the masonry round their common base, and at three other places at different heights on the exterior of the cone; in these were placed strong iron chains, and the grooves were filled up with melted lead.

The pavement of the Church is of marble, and in the ceilings are formed hemispherical cupolas; all the arches are of stone, but the spandrils are filled with brickwork, and the interior surface of the lower dome, over the centre, is ornamented with paintings.

On the exterior of the building the intervals of the columns and pilasters are occupied by niches or windows with semicircular or horizontal heads, and crowned by pediments; the entablature of the inferior Order is quite plain, except that there are modillons under the corona; and in the frize of the superior Order are high modillons which seem to support the cornice. Each arm of the building is covered by a pediment-roof, and at the extremities on each face are acroteria supporting statues.

Above the roof of the building, is a cylindrical wall, 146 feet in diameter and 25 feet high from the ridge; this surrounds the lower part of the conical wall which rests on the eight piers at the intersection of the arms of the cross; its exterior is quite plain, and it is perforated by two courses of rectangular apertures. Above the wall, is a circular range of thirty-two Corinthian columns, 40 feet high, including their bases and capitals, and supporting an entablature; between the columns, are niches with semicircular heads, and the entablature is crowned by a balustrade. Vertically over the base of the cone, is raised another cylindrical wall, the upper part of which appears above the balustrade; this part is ornamented with pilasters attached to its exterior circumference, and between the pilasters are two tiers of rectangular windows; the exterior dome springs from this wall. The lantern at the top of the dome is of an octangular form; its exterior is adorned with Corinthian columns, and round its base is an iron balcony.

The towers at the extremities of the Western front are 220 feet high and ornamented with Corinthian pilasters; each terminates above the roof of the Church in an open lantern, the lower part of which is surrounded by Corinthian columns, and the upper part by small buttresses which rest upon the entablature of the lower part. A plan, elevation, and section of this Cathedral is given in pl. xxiii.

We must refer to the *Parentalia* for a description of the manner in which the walls of the old Cathedral were demolished and those of the present one were raised; the details are interesting and highly instructive to every one engaged in the practice of building.

This edifice may, for elegance of design, bear comparison with the Cathedral of St. Peter, at Rome, though it is far from being so large; and it even has some advantages over that celebrated structure. The horizontal entablature is less broken, though this bad taste has been carried much too far. The top of the dome is three times as high above the surrounding ground as the entablature of the general roof, while that of St. Peter's Church is little more than twice the height of the roof; consequently, the former dome is better seen by a spectator on the exterior, and appears more like what it ought to be; *viz.* the principal feature of the building. It must be acknowledged, however, that the interior faces of the walls present a naked appearance, and will require much embellishment from ornamental sculpture before they will harmonize with the richness of the exterior. A great defect also arises, in the interior, from that want of connection which is caused by the arcades interrupting the entablatures; and the archivolts of every two of the eight arches which support the dome, meeting together at their lower extremities, have the appearance of standing on points, and thereby excite a perception of weakness, which is not the less a fault for being only apparent.

In buildings of similar forms, it is evident that some criterion may be formed of the comparative merit of their construction, by ascertaining the ratio between the area of the whole plan and the sum of the areas of the horizontal sections of all the piers, walls, and pillars, which serve to support the incumbent mass; for that building which exhibits the greatest ratio between those areas must be the one in which the effect has been produced by the fewest means. Now, the Churches of St. Peter, at Rome, St. Mary, at Florence, and St. Paul, at London, are nearly similar buildings; and we borrow from Mr. Joseph Gwilt's description of the latter the following Table of their proportional areas.

	Whole areas in English feet.	Area of points of support.	Ratio.
St. Peter.......	227069	59308	1 : 0.261
St. Mary.......	84802	17030	1 : 0.201
St. Paul	84025	14811	1 : 0.170

The merit shown in the construction of the above edifices, which is inversely proportional to the numbers in the last column, will, therefore, be respectively in the proportion of 17, 20, and 26, nearly. But if vertical sections be made from North to South through the transepts of those Churches, the case will be found to be different; for the proportions between the external and internal areas of such sections are, according to Mr. Gwilt, as follows:

St. Peter........ 8325 : 10000
St. Mary........ 8855 : 10000
St. Paul .... 6865 : 10000

Hence it appears that St. Paul's Church is far inferior to the others in its interior capacity, which, however, is unavoidable, on account of the sides of its conical dome having considerable obliquity to the horizon, whereas the domes of the other Churches rise nearly vertically; consequently, they have less horizontal thrust towards the exterior, and require less mass of pier to resist it.

St. Stephen's, W brook.

Besides the great work we have just mentioned, Sir Christopher Wren designed or executed most of the public buildings of his time; but he is particularly distinguished on account of the applications he made of the Roman Architecture in his Churches. We have already had a specimen of his taste in this respect, on a great scale; and we purpose to add a short description of St. Stephen's Church, in Walbrook, which was executed by the same artist, and is remarkable for the elegance of its interior ornament.

Its plan is a rectangle, 82 feet 6 inches long and 59 feet 6 inches broad, with a semicircular recess at the Eastern end. It is divided longitudinally into five aisles by four rows of Corinthian columns on pedestals; but near the centre the places of four columns are unoccupied, and on the entablatures of the columns which are left, at the angles of a regular octagon, are raised eight semicircular arches, in the spandrils of which are pendentives forming the circular base of a dome, which rises above them in the shape of a segment of a sphere. The surfaces of the pendentives and of the interior of the dome are beautifully ornamented, and on the open top of the dome is an elegant lantern. The ceiling over the middle aisle from East to West is vaulted with groined-work;

the other parts of the ceiling are horizontal, and formed in panels by the entablatures which rest on the columns. This Church owes all its reputation to the merit of its interior, for the exterior is mean, and the situation of the building among the neighbouring houses is extremely confined.

Mary, oolnorth.

The Church of St. Mary Woolnorth, in Lombard-street, was executed by Hawkesmoor, a pupil of Sir Christopher Wren, and, for the elegance of its interior, is unrivalled by most of those built by that great Architect himself: a description of it is given by Mr. Gwilt, in Britton's *Account of the Buildings in London*, from which we have made the following extract. The plan of the interior is nearly a square, with its North-Western and South-Western angles truncated for the introduction of stairs: twelve fluted Corinthian columns are disposed on the sides of an inscribed square and coupled at the angles, and above them is an enriched entablature. The square space which they enclose is continued above them, and forms a clair-story pierced on each side by a semicircular window: the height of this story with its entablature is equal to half that of the lower Order, and the total height of this central part of the Church equal to its extreme width. In the Eastern end of the Church is a square recess for an altar, covered by a semielliptical ceiling; and on the Northern, Southern, and Western sides are galleries judiciously managed, so that they do not interfere with the simplicity and elegance of the general design.

The exterior is picturesque, and, though far from being in good taste, is well adapted to its situation and aspect; the principal front is towards the North, consequently deprived of the effect which would be produced by light and shade; and to compensate for this defect the artist has given to it great boldness of outline and prominence of feature, consisting of large semicircular rusticated niches standing on lofty pedestals and decorated with an Ionic Order. A block cornice reigns throughout the building, and the central part of the Northern front is surmounted by a balustrade. The same Architect executed the Church of St. George, Bloomsbury, the Corinthian portico of which is esteemed among the finest in London.

eples cuted by C.Wren.

The lofty steeples which frequently crowned the towers of the Gothic Cathedrals continued to be raised over Churches when the Roman style had superseded that which before prevailed, and appear to have been considered as an essential characteristic and ornament of an Ecclesiastical edifice. Sir Christopher Wren, who almost invariably employed the Italian or Roman style in the Churches he built, raised his towers from the ground in front, and placed on them steeples of a pyramidal form and vast height, which he decorated in a manner corresponding to the Architecture of the body of the Church as much as their tapering forms would permit.

ride's.

Of the towers which he built, the most remarkable is that of St. Bride's Church, in Fleet-street, the whole height of which is 226 feet, while the height of the body of the Church from the ground to the cornice is only 37 feet. The lower part resembles a very tall, quadrangular pedestal standing on a great plinth; in this is the doorway, and in the dado is a great double panel containing a rectangular and a circular window. Above the cornice of this dado stands a second pedestal, in the dado of which is a semicircular-headed window, and on each side are two Corinthian pilasters supporting an entablature and a pediment in the form of a segment of a circle, and the ceiling of the interior of this story is a vault in the form of a paraboloid. Above this second pedestal, if it may be so called, are four stories, octagonal on the plan, and diminishing in diameter successively upwards; in each face of these is an open semicircular arch springing from imposts, with a pilaster at each angle, standing on a podium and supporting an entablature; the pilasters in the lowest story are of the Doric Order, and those in the three upper ones are of the Ionic Order. Above the highest story is an octagonal pedestal supporting a pyramidal obelisk, which terminates in a ball: a winding staircase in the interior leads from the top of the rectangular part of the tower to the foot of the obelisk.

The arched openings give a great degree of lightness to the upper part of the fabric; and, in order to afford sufficient security, the stone piers in every story are connected by iron bars extending horizontally through the spire; also iron cramps and chains are imbedded in lead within the stonework in several places.

This spire exceeds in height that of any other Church executed according to the Roman Orders of Architecture, and very few of the Gothic spires are so lofty. Before the Church was struck by lightning, in 1764, its height from the ground was 234 feet, and, in repairing it, it was reduced to its present dimensions. See pl. xxiii.

Bow Church.

The steeple of Bow Church, which was also built by Sir Christopher Wren, rises from the ground in front of the Church to the height of 197 feet. The lower part is a square tower 83 feet high, and the length of each side on the plan is 32 feet 6 inches; at the foot is the doorway, which is contained within a semicircular-headed recess. Above this are three stories, each 38 feet high; the first is raised on a square plan, but is ornamented with coupled pilasters of the Ionic Order, at the angles, and in each face is a semicircular-headed aperture, the archivolt of which springs from imposts; the second story consists of a hollow cylinder surrounded by twelve Corinthian columns, standing on a circular pedestal, and supporting an entablature and balustrade, above which are twelve arched buttresses supporting the base of an octagonal lantern; this is also surrounded by twelve small Corinthian columns, on the entablature of which is a square obelisk 38 feet high. A spiral staircase is carried up the centre of the steeple, from the entablature of the Ionic columns to the base of the lantern.

St. Dunstan's in the East.

The steeple of the Church of St. Dunstan in the East, by the same Architect, is remarkable for its singular elegance, and because it is an excellent imitation of the Gothic style. It is raised from the ground upon a square base, 20 feet each way, to the height of 96 feet, and has, at each angle, a diagonally-placed buttress, terminating in an octagonal pinnacle, 29 feet 6 inches high; this tower contains three stories, in the lowest is the doorway, in the second, a window, and, in the third, an open aperture; each is terminated by an equilateral pointed arch. Above the roof of the tower, and from the four angles, are raised, to the height of 29 feet 6 inches, four arched ribs of stone, which meet over the centre, and form the base of an octagonal spire, the height of which is 54 feet 6 inches: the whole weight of the spire is borne by these arched ribs, and the space included by them is entirely open.

The use of bells to notify the hours of prayer affords a just reason for employing a turret above the Church, when it is not convenient to have a detached building, like the Campanile in Italy, for that purpose. But the great height which is usually given to steeples seems quite unnecessary, except, perhaps, in the country, where such objects may serve to mark the situation of the consecrated building, which might otherwise be unperceived by the traveller. We know but of one example in England in which the bell-tower is detached, and this is the Church of St. George, Bloomsbury, in London; in the same building there seems to have been an effort to make the spire harmonize with the Roman style displayed in the Church, but the success has not been such as to encourage any subsequent attempt to obtain that end.

Royal Exchange.

In the principal commercial cities of Europe, public places have been built in which the merchants assemble for the purpose of transacting business, as in the time of the Roman Empire they met in a part of the Forum or Basilica; and the Royal Exchange in London is destined for this purpose. It was originally built by Sir Thomas Gresham, in 1567, but being destroyed in the great fire of 1666, the present edifice was erected in 1669 by Mr. Jerman, one of the city surveyors. It consists of an arrangement of buildings enclosing a rectangular peristyle or piazza, 144 feet long, and 117 feet wide; this is surrounded interiorly by semicircular arches, springing from the abaci of the columns, which are of a Tuscan Order, and quadrupled at the four angles: the corridor between the arcade and the buildings is covered by a groined vaulting, formed by the intersections of hemicylindrical arches, and having the ridges ornamented by ribs which spring from grotesque heads on the walls, and in the interior spandrils of the arcade. Above this arcade is another, springing from imposts, on piers, the fronts of which are ornamented with attached Ionic columns standing on pedestals, and between the columns are windows or niches containing statues; the whole is crowned by a balustrade, and over the centre on each side of the court is a pediment in the form of a segment of a circle. In the centre of the area is a statue of Charles II., on a pedestal 8 feet high.

On the Northern and Southern sides of the exterior of the building, is a row of semicircular arches springing from piers, and forming the front of a covered gallery extending along each of those faces. The story above contains a row of large rectangular windows, between which are pilasters of a Composite Order supporting an entablature, and above this is a balustrade crowning the building. In the centre of the Southern front is the principal entrance, under a portico 70 feet long; here four lofty Corinthian columns are attached to the piers, and support an entablature; and between the two middle columns is a semicircular-headed gateway, the crown of which is 31 feet from the ground; on each side of this, and between the outer columns, are small doorways with curvilinear pediments, and above are niches containing the statues of the Kings Charles I. and II.

The old tower above the entablature of this front has been taken down, and the present one, which was executed by Mr. Smith, the Architect to the Mercers' Company, is of a different character. The whole length of this façade is 210 feet, and the height from the general pavement to the cornice 41 feet.

The entablature of the Southern portico, not forming part of that on the wings of the same façade, is the principal defect in this building, which nevertheless possesses a certain degree of magnificence, and remains a good specimen of the Architecture of the XVIIth century.

CHAPTER V.

Architecture of England during the XVIIIth Century.

French and German style introduced into England.

In the beginning of the XVIIIth century a taste for the style of building practised in France and Germany, which had been probably introduced by William III., prevailed, for a time, very generally in England, and is exhibited in many of the mansions of that period, particularly in the British Museum, London, and in Blenheim House, Oxfordshire. The façades of such edifices present many of the features of the worst style of Italian Architecture; the columns are of unequal heights, and, consequently, the entablatures on different levels, which give to the different parts of the edifice the appearance of so many distinct buildings instead of the members of one body; the sloping roofs rise to a considerable height above the walls, and the pavilions are crowned by open turrets, profusely ornamented with columns or pilasters, and strengthened by scroll buttresses totally destitute of utility. Lastly, in the interior disposition of the mansions of this period the communications with the different apartments are very defective; instead of a separate access to each, it is often necessary to get at one by going through several others.

Blenheim House.

Blenheim House, executed by Sir John Vanbrugh in 1715, may be considered as a specimen of the style of building of which we have been speaking. Its plan consists of three principal parts, each of a rectangular form, with their longest sides in the direction of the breadth of the building; these are connected together, near the principal front, by a corridor with a vaulted ceiling, and by a suite of apartments next to the garden front. Its whole extent in length is 350 feet, and in breadth 200 feet.

The central division contains two grand vestibules, of which that in the principal front is 58 feet long, and 42 feet wide, and the other, in the garden front, 40 feet long, and 34 feet wide; each of these has a portico consisting of four Corinthian columns, and a detached pilaster in the line of columns, at each extremity. One of the extreme divisions is a grand gallery, the length of which is 200 feet, and its mean breadth 27 feet; it consists of a centre in the form of a parallelogram, with a semicircular projection in front, a square wing at each extremity higher than the rest of the division, and two curtains connecting them. The third division is of the same form, but in its centre is a vestibule, which falls at the extremity of the corridor, and on each side is a bed-room with its anteroom, wardrobes, &c. On each side of the vestibule belonging to the garden front, is an antechamber, a withdrawing room, and a grand bedchamber; and on each side of the central division, between this suite of rooms and the long gallery, is an open court of a rectangular form, 43 feet 6 inches long, and 32 feet 6 inches wide; between this and the vestibule in the principal front are a dining-room and stairs leading to the upper story; on one of the long sides of the court is the corridor, and on the other two sides are dressing-rooms and closets. In each of the rentrant angles, between the corridor and the wings of the building, next to the principal front, are closets, dressing-rooms, &c., disposed upon the circumference of the exterior wall, the plan of which is in the form of a quadrant of a circle, concave outwards.

The columns which support the roof of the portico are 40 feet high from the pavement, and above them is an entablature with a pediment; within this height are two stories, of which the lower contains three doorways, and in the upper are semicircular-headed windows: the piers between the doors and windows very little exceed in breadth that of the columns which stand before them, so that the front wall of the vestibule scarcely appears, and the windows themselves are ill proportioned, being much too broad for their height. Over the vestibule a tower is carried up above the roof of the adjoining part of the building, and crowned by a second pediment. On each side of the portico, and between it and the quadrant, the face of the building is ornamented with three Corinthian pilasters, standing on a podium, the top of which is on a level with the pavement of the portico; the pilasters are of the same height as the columns of the portico, and they support an entablature, above which is a continued pedestal with statues; this part of the building contains two stories, the intermediate floor being on the same level as that within the portico. On the face of each quadrant are half-columns of the Tuscan Order, 21 feet high from the podium; these support an entablature on a level with the floor of the upper story under the portico; and above this is an Attic, crowned by a balustrade, the coping of which coincides with the level of the tops of the capitals of the columns and pilasters. At the extremity of the quadrant is a square pavilion, consisting also of two stories, in which are semicircular-headed windows, and the face of the wall, up to the roof of the second story, is rusticated with horizontal grooves only: above this is a turret with short pilasters in front, and open semicircular-headed arches.

Of each wing of the building the face, which is parallel to the front of the portico, is divided vertically into three parts, that in the centre projecting a little beyond the others, and being crowned by a pediment; and all the angles are ornamented with rusticated pilasters. In the face of the pavilion are two stories, the lower one lofty, and containing semicircular-headed windows, the upper one low, with square windows. The plinth of the wings is lower than the general podium of the body of the building, and the entablature over the second story is on a level with that of the half-columns in the quadrants: above this is a balustrade, and over the centre is an octagonal tower, having segmental pediments on four opposite faces; the turret is carried up above these pediments, and ends in a cone and ball.

Notwithstanding the faults of this building, particularly the want of unity in the design, its magnitude causes it to present a majestic appearance, worthy of the residence of the great Duke of Marlborough, for whom it was built. Sir John Vanbrugh also built Castle Howard in Yorkshire, for the Earl of Carlisle: this edifice is 660 feet long; one of its faces is ornamented with Doric pilasters irregularly distributed; the other with Corinthian pilasters at equal distances from each other, and the whole is crowned by a large cupola.

About the same period the domestic Architecture of England was destined to receive considerable amelioration from the genius of the Earl of Burlington, who, abandoning the caprices of the French School, cultivated a purer style by the contemplation of the remains of ancient Architecture in Italy, and a diligent study of the writings of Palladio. In the year 1717, or 1718, he made designs for the improvement of the mansion built by his father in Piccadilly, which were afterwards executed, probably under the superintendence of Mr. Colin Campbell, an Architect by profession at that time. Since this building exhibits a specimen of the style of Architecture subsequently employed to a considerable extent in the mansions of the Nobility, we proceed to show its character by a brief description.

Burlington House.

It consists of an arrangement of buildings occupying the Northern, Eastern, and Western sides of a court, 122 feet square; on the Southern side is a colonnade of a form nearly semicircular, with its concavity facing the North, and through the centre of this is the grand gateway leading from the street. The dwelling-house, which is on the Northern side of the Court, consists of a rectangular centre, 78 feet long from East to West, and 51 feet wide, and of two wings, each 26 feet broad, projecting 13 feet in front of the centre towards the South. On the Eastern and Western sides of the Court are two rectangular buildings, each 82 feet long from North to South, and 45 feet wide; these are connected with the main building by passages, and contain the offices and servants' rooms.

The Southern façade of the principal building is divided into two stories, of which the basement is rusticated with vertical and horizontal grooves; the doorway is in the centre, and there are four rectangular windows on each side. The upper story over the centre of the building is ornamented by half-columns of the Ionic Order, supporting an entablature broken over each column; and between every two columns is a rectangular window with triangular and segmental pediments alternately. The faces of both wings on this story have a pair of Ionic pilasters at each angle, with a continuous entablature, and between the pilasters is a broad *Venetian window*, as it is called, *viz.* one divided by small Ionic columns into three apertures, of which the middle one has a semicircular head. The whole building stands on a general plinth, and there is an ascent to the pavement of the lower story by steps; the entablature is crowned by a balustrade, the height of which from the ground is 48 feet.

The entrance gateway from the street has a semicircular head; and on each side are two Doric columns on pedestals, with cylindrical, rusticated blocks on the shafts; between each pair of columns is a hemicylindrical niche with a dome head; and above the entablature is an Attic extending over the two middle columns, and crowned by a pediment adorned with sculpture.

Villa at Chiswick.

The Villa belonging to the Duke of Devonshire, at Chiswick, was designed by Lord Burlington in imitation of Palladio's Rotunda at Vicenza.

Gibbs.

The Ecclesiastical Architecture of England, which had been affiliated by Jones and Wren to that of the Religious edifices of ancient Rome, received sundry improvements from James Gibbs, who was contemporary with the Earl of Burlington, and who has left a distinguished monument of his taste and skill in the Church of St. Martin in the Fields, which he completed in 1726.

St. Martin's Church.

Its plan is a rectangle, 79 feet 4 inches wide exteriorly, and 135 feet 6 inches long, not including the portico, which is 24 feet deep. This portico has six columns in front, besides one on each flank between the front row and the antæ pilasters, and all the columns resemble those of the Temple of Jupiter Stator. The

Church is divided into three parts by two rows of Corinthian columns standing on pedestals which raise their bases just above the pews; the columns are not connected by a continued entablature, but have blocks above their capitals in the form of portions of an entablature, from the cornices of which spring semielliptical arches crossing the nave, and others of a semicircular form in the direction of the length of the Church; semicircular arches also extend across the side aisles.

The nave of the Church terminates Eastward in a recess formed, on the plan, by two quadrants of circles and a rectangular part between them; the anterior part of this recess is covered by a portion of a spheroidal vault, and the part beyond by one of an elliptical form. The arches over the side aisles rest on corbels against the walls, and pendentives are formed which serve to support a range of coved vaults over each aisle. The soffit of the portico is richly ornamented with lacunaria, and that of the interior of the Church with paintings.

The exterior of the side walls is ornamented with attached pilasters of the Corinthian Order, standing on a podium, on a level with the pavement of the portico, and the entablature is crowned by a balustrade. Between the pilasters, are two tiers of windows; the upper, which are taller than the lower, are terminated by semicircular heads, and the others by flat segments; the jambs and archivolts of both are rusticated. Both the Eastern and Western extremities of the Church are terminated by pediments, and in the middle of the Eastern end is a large window divided into three parts by Ionic columns; over the two side apertures is an entablature, but that of the centre is covered by a semicircle which springs from the entablature as an impost.

The height of the Church, from the foot of the podium to the top of the pediment, is 58 feet 6 inches. Over the vestibule at the Western end of the Church, is a tower raised on a square base and ending in an octagonal spire, the whole height of which from the foot of the podium is 185 feet; the part immediately above the pediment is plain and resembles a pedestal, in the dado of which is a circular aperture on each side; above this is a division containing a semicircular-headed louvre, with two Ionic pilasters on each side, supporting an entablature; still higher is an octagonal lantern with a semicircular-headed aperture on each face; and in front of the piers are attached Corinthian columns, the entablature of which is crowned by the spire, which is of a pyramidal form and ornamented with panels.

The Churches of this period differ from those erected by Sir Christopher Wren in having a portico at the Western extremity, and in the steeple being raised over the body of the building, so that it appears to stand on the roof instead of resting on the ground; the propriety of this situation of the steeple may be questioned, but from the roof of the portico being a continuation of that of the building, as is the case in these Churches, there results a unity of composition, which is one of their greatest merits, and gives them a character approaching nearly to that of the Religious edifices of the Ancients.

St. George's, Hanover-square. The Church of St. George, in Hanover-square, by the same artist, resembles that of St. Martin, and, on the exterior, it may, perhaps, be said to equal the latter in merit; but the same praise cannot be paid to the interior, where the rich Composite Order is placed immediately above the simple Tuscan, while the organ-gallery is supported by Ionic pillars; thus three different Orders are employed in the same building in circumstances causing them to offend against the laws of simplicity and unity.

Somerset House. The Roman Architecture in England may be said to have arrived at perfection in the latter part of the XVIIIth century; and one of its noblest monuments is Somerset House, which was begun by Sir William Chambers, in 1776, on the site of a Palace built for the Protector, Edward Duke of Somerset, about 1547; this immense pile is almost wholly occupied by Public Offices, but it is not, even now, entirely finished.

The ranges of buildings are disposed on the four sides of a rectangular court, the interior length of which is 319 feet from North to South, and breadth 224 feet; the Northern side is separated from the others by a road 42 feet broad, and directed from East to West, with an arched gateway at each end.

The grand entrance is from the Strand through a triple passage, of which that in the centre is between two rows of Doric columns, coupled in the direction of the length of the passage. On one side of the entrance is the vestibule leading to the apartments of the Royal Academy, and on the other, that which leads to the apartments of the Royal and Antiquarian Societies: all the other buildings, and the remainder of this range, contain various Government Offices, in which there is nothing remarkable except the hall of the Navy Office on the Southern side of the court; this is 57 feet long, 37 feet wide, and its ceiling, which is flat, is supported by eight columns.

The Northern façade, or that which is next to the Strand, is 133 feet long, and consists of three stories; in the centre of the lowest are the passages before mentioned, the entrances to which are separated by two piers, and crowned by semicircular arches: on each side are three semicircular-headed recesses, containing windows, the entablatures of which are supported by Doric columns, and crowned by pediments; the height of this story, with its entablature, is 25 feet 8 inches; the piers, voussoirs, and spandrils are all rusticated, and a simple plinth runs along the foot of the façade. Above this story are two tiers of windows, of which those in the lower tier have entablatures supported by Ionic columns, the upper windows are square, and are surrounded by plain architraves; between these windows, the walls are ornamented with three-quarter columns of the Corinthian Order, standing on plain pedestals, between every two of which are balusters; the height of the columns in this Order is 23 feet of the pedestals, 3 feet 4 inches, and of the entablature, 5 feet. Over the centre of the façade is an Attic story, with four statues in front and two oval windows; and the rest is crowned by a balustrade, the coping of which is 62 feet above the ground. The interior façade of this part of the building is similar to that which has been already described.

The interior faces of the buildings, on each of the other sides of the quadrangle, are broken vertically to form a centre and two wings, which have small projections beyond the faces of the curtains connecting them; the lowest story of the whole, and the upper stories of the curtains, are rusticated; and there are three tiers of windows, of which the lower have semicircular heads, and the others are rectangular. The central part alone is ornamented with three-quarter columns of the Corinthian Order, and the whole is crowned by a balustrade.

The façade next to the river, which is 350 feet long, possesses a character of superior magnificence. Its divisions correspond with those within the Court, but in the centre of the upper story are Corinthian columns detached from the walls, with pilasters behind them; near each wing are columns and pilasters similarly disposed with a pediment above their entablature; and the centre of this line of building is crowned by a hemispherical cupola. Before this façade is a broad terrace supported by lofty arches and protected by a balustrade; in the centre is one great semicircular arch, for the admission of vessels from the river; and near each extremity is a watergate of a similar form, the piers of which are ornamented with rusticated columns.

The entrances, which are at the ends of the street within the Northern side of the quadrangle, consist each of three semicircular arches, of which that in the centre is higher than the others; on either side of this arch the rusticated pier is ornamented with a Doric column, having roughed blocks on the shaft, and an Attic base; and the entablature over the central arch is cut by the voussoirs, so that there appears only part of the architrave and frize with two triglyphs on each side, a deviation from propriety into which it is surprising that an artist of so late a period could have fallen. The cornice is uninterrupted, and is ornamented with modillons.

The Doric columns in the Northern entrance to the building have Attic bases, and the entablature is formed over each pair of columns only; the frize is decorated with ox-sculls instead of triglyphs, and there are dentels in the cornice. The ceilings above the passages are hemicylindrical, and the spandrils are pierced by arches crossing the three vaults at right angles. The spandrils and crowns of the vaults and the soffits of the arches between the columns are ornamented with panels and elegant fretwork margins. The central passage through the Northern building is much too narrow, and it has been observed that instead of the three, which at present exist, there should have been made one grand archway; this would, of course, have required a different kind of façade above; but one might easily have been designed in which such an entrance would have been consistent with equal convenience in the interior of the building.

We are indebted to Sir William Chambers for one of the best written Works on what is called the decorative part of Civil Architecture. In this, the proportions of the Orders are detailed according to the Roman style with some just modifications, and a variety of elegant forms of the different members of an edifice are exhibited and described. We regret only to find in it an unworthy prejudice against the Grecian Architecture, with the character of which the author does not seem to have been acquainted; he even doubts the existence of any considerable remains of that Architecture in the Country of its birth, though during his life the magnificent edifices of Greece were delineated and made known to the World in the splendid publications of Le Roy, Stuart, and other artists. A convenient and elegant edition of Sir William Chambers's Work, enriched with notes, has been published by Mr. Joseph Gwilt; and an outline of the Grecian Architecture, which was much wanting to render the original Work complete, has been supplied by the same gentleman in an introduction.

abers.

Sir William Chambers, in modifying the Tuscan Order, has made its general proportions nearly the same as those assigned by Vignola; the height of the column is by both made equal to seven diameters, but the English Architect has made the diminution rather greater, it being equal to one-sixth of the lower diameter; he has made his entablature equal in height to that of Palladio, *viz.* one-quarter of the height of the column; like Vignola he has made the architrave in one facia, whereas Palladio has divided it into two, which is rather complex for this Order; but he has lightened Vignola's cornice, and has placed above the corona a cymatium instead of the ovolo which occurs in the Italian example; the latter member he considers an improper finish, because it seems as if intended to support something above it where, however, nothing exists.

His Doric Order is like that one which Vignola has given with mutules in the cornice, except that he has judiciously given but one facia to the architrave. The other Orders hardly differ from those of Vignola either in proportion or ornament, except that they all have Attic bases: in the Ionic example, the architrave and frize are of equal height, and the former is divided into two faciæ separated by ornamented mouldings; in the entablature of the Composite Order he has given both dentels and modillons, the latter of which are similar to those in the specimen of the Order given by Palladio, the former rather larger.

Grecian Architecture introduced into England.

From Peacham's *Complete Gentleman*, we learn that Sir Kenelm Digby, in the reign of Charles I., brought some of the marble bases, columns, and altars from the ruins of the Temple of Apollo at Delos; and, at a later period, the travels of Messrs. Wheeler and Spon, in Greece, made the artists of England acquainted with the nature of the buildings yet remaining in that Country; but neither those relics of Grecian sculpture, nor the general descriptions of the edifices, seem to have had any influence on Taste at the time; afterwards, however, when the admeasurements of the ancient buildings of Athens were published by Messrs. Stuart and Revett, a revolution took place. The subsequent publication of the remains of Grecian Architecture in Sicily, Italy, and Asia-Minor seems to have confirmed that preference, and, down to the present day, the greater part of the English buildings are formed on Grecian models with slight modifications. The Work on the Antiquities of Greece, published by M. Le Roy, was, perhaps, the cause of a similar Taste being excited in France; but it was not till after the Revolution that the Grecian Architecture became general there: since that time it seems to have been adopted in almost every other part of Europe.

CHAPTER VII.

Characteristics and Examples of Modern Buildings.

This Chapter will be devoted to a consideration of the nature of such edifices as the present state of Society requires, and to the description of a few of the most important; chiefly those which have been erected in England since the commencement of the XIXth century. For elegant engravings and more ample details, the reader is referred to Britton's *Illustrations of the Public Buildings in London.*

General character of a Church.

An edifice consecrated to Religion should be capable of exciting the most solemn emotions; it should remind him who enters it of the presence of the Deity, and should aid the sentiments with which he is come to present his offering of prayer or praise. It should not only differ in its general form from a building intended for other purposes, but every member which, from necessity, must also enter into the composition of a private dwelling, should, in a Church, be on a large scale, and, from its embellishments, acquire an elevated character. Like every other Public building, it should be situated where access to it is easily obtained; in a city it should be as far removed as possible from the general line of the street, in order that the noise of passing carriages may not disturb the congregation, and it should be elevated a little above the level of the ground, on a substantial basement, with spacious steps at convenient places.

Modern Churches are, mostly, imitations of ancient Temples.

The practice of crowning Churches with domes, which extended from Italy to all other parts of Europe, seems to be abandoned in England, and with it the cruciform plan; we now generally construct our Churches, like the Grecian Temples, on a simple rectangle, with a regular portico in front, and a pediment-roof; but some kind of steeple is still retained and placed over one extremity of the building. The side walls are perforated by windows in two tiers; and those in the lower tier are always made short, because the galleries, for the sake of convenience, must be kept as low as possible. The body of the Church is generally divided into three parts, of which that in the centre is separated from the aisles by columns in two tiers; the lower Order supports the anterior of the gallery, and the upper supports the roof. The altar is enclosed by a balustrade or rail at one extremity, in a recess, the pavement of which is elevated a few inches above that of the Church.

Church of Ayott St. Lawrence,

One of the first Churches in the Grecian style is that which was executed by Mr. Revett, at Ayott St. Lawrence, in Hertfordshire. Its plan is rectangular, and there is a hemicycle at the Eastern end; in front is a tetrastyle, Doric portico crowned by a low pediment; and on each side is an Ionic colonnade, connecting the centre with an elegant cenotaph. This edifice was built near the end of the XVIIIth century; and since that time a considerable number of Churches have been erected in London, and in various parts of the Country, in imitation of different Grecian Temples, but generally with few of the enrichments which are found on the ancient models.

of St. Pancras,

The greatest example of this style in England is the Church of St. Pancras, erected by Mr. Inwood, in 1822, and which is nearly a copy of the triple Temple in the Acropolis, at Athens. Like that building, the plan of the present Church is a rectangle; at the Eastern extremity is a square projection on the Northern and Southern sides, and both these projections have flat roofs supported by Caryatides, exactly similar to those which ornament the Athenian Temple. The Eastern face of the Church is terminated by a semicircular recess, and over the Western extremity is a lofty steeple. The lower part of this consists of an octangular tower ornamented by eight columns, the capitals of which resemble those in the porches of the Temple of the Winds; above this is a similar but smaller tower, which is also surrounded by eight columns, and the whole is terminated by an octangular turret resembling the upper part of the same Temple. The Western front is enriched with a fine hexastyle portico, corresponding in its proportions and embellishments to that of the Erectheum; the Western doorways, and the upper windows on the three sides of the Church, are also constructed in conformity with the corresponding members of the Grecian Temple.

The Roman Architecture is also still employed to a considerable extent in England, in buildings intended both for Ecclesiastical and Civil purposes; the richness of the Corinthian capital and entablature rendering that Order convenient where the highest degree of magnificence is to be obtained. The Church of St. Mary le Bone, built by Mr. Hardwicke, in 1819, is one of the latest examples of this style, and in its plan it deviates considerably from the simplicity of those recently erected in London.

of St. Mary le Bone,

The direction of the greatest length of this Church is from North to South instead of from East to West, which is the general position; its breadth is 70 feet, and its length 122 feet, besides the depth of the portico, which is 18 feet 6 inches. This portico, which is on the Northern side of the building, is hexastyle, and 60 feet wide between the centres of the extreme columns; the columns, which are of the Corinthian Order, are copied from those of the Pantheon at Rome; and between the front row of columns and the pilaster attached to the face of the wall is a column at each extremity of the portico; the entablature is simple and crowned by a pediment. The front of the Church is 110 feet in extent from East to West, and this excess above the general breadth is caused by a wing projecting each way beyond the side walls of the Church; the wings are ornamented with Corinthian pilasters at the angles, and at the extremity of each there are two columns of the same Order standing on tall plinths in a direction perpendicular to the front. Within this front is a circular vestibule, on each side of which are the steps leading to the galleries. The opposite extremity of the Church is formed on three sides of an octagon, and has a large Venetian window in the middle face; on each of the others is a rectangular building, one serving as a side entrance to the Church and the other constituting the Vestry. The height of the Church from the ground to the cornice is 45 feet 6 inches; the top is surrounded by a balustrade, and over the Northern front there is a steeple, the height of which above the cornice is 74 feet. There are three entrances in front, with horizontal-headed doors; above these are semicircular-headed windows, and two tiers of the same kind of windows are formed in each side of the Church.

It has been justly observed that the portico of this Church, by facing the North, is deprived of the brilliant and diversifying combination of light and shade which it would have possessed in any other aspect; it consequently appears sepulchral, gloomy, damp, and cheerless. This disposition has been given to it in order, no doubt, that it may face the high road; but this advantage would have been gained, and the defects avoided, by placing the Church on the other side of the way, where also there would have been more space for it than its present localities afford. It has been observed also, that, in the interior, the twofold tier of galleries, the polygonal recess at the Southern end, and the decorations of the organ-case, being combined with those of the altar, produce an effect which assimilates more closely to the character of a Theatre than is generally thought consistent with that of a Christian Church.

In some of the most modern Churches of England an effort is made to copy the style of our Gothic Cathedrals; but notwithstanding the merit with which many of these have been executed, it is impossible that they should afford the mind an equal satisfaction with that produced by ancient buildings of the same kind, because they want the venerable character which age alone can give, and at once show themselves to be but imitations. Buildings executed on Grecian or Roman models are contemplated with more complacency, because no ancient examples of those styles, with which they may be compared, exist in the Country; the effect they produce on the mind is, therefore, nearly equal to that which would be excited by the view of works possessing a perfect originality of form.

Luke,
lsea.

The parish Church of St. Luke, Chelsea, executed by Mr. Savage, in 1824, may be considered as a good specimen of what is called the modern Gothic style. Its form is rectangular, and the interior is divided into a centre and two side aisles by seven acutely-pointed arches on each side, which spring from clustered columns; the vaulting over the central division is of masonry, and ornamented by cross ribs, diverging from the summits of the shafts, which are carried up the wall of the clair-story from the columns supporting the arcade below.

In front of the Western end of the Church is a square tower raised on four piers connected by pointed arches, of which the two lateral ones form a communication between the tower and an arcade on each side directed from North to South. On each side of the Church are flying buttresses extending over the roof of the aisle, to resist the lateral pressure of the roof, and between these are the windows. The walls both of the nave and aisles are crowned by perforated parapets, and there are two octagonal turrets at the Eastern extremity of the building; these are divided into several parts horizontally by mouldings, a circumstance which is considered as injuring the simplicity of the design.

The archway in the face of the Western tower is ornamented with a pediment moulding, and above it is a tall, pointed window divided by mullions and transoms; still higher is a window of similar form, the crowning moulding of which is adorned with crockets: lastly, the upper story is enriched with a perforated, embattled parapet and with panelling on the walls, and, above the four angles, are pinnacles ornamented with crockets and finials.

I
en
ling-

In domestic Architecture the style of construction should be suited to the quality of the occupier of the building. The cottage of the peasant may be of the utmost simplicity, yet it should be made capable of protecting the inmates from the injuries of the weather, and its external form should be such as to render it an object not unworthy of the scenery by which it is surrounded. The dwelling of a man of moderate fortune should afford all possible conveniences with some degree of ornament. But the mansions of the Nobility, besides possessing superior strength and durability, should contain, in their interior, every circumstance that can contribute to the comfort of the proprietor, and both the interior and exterior should be adorned with splendid and tasteful decorations.

ne

The Grecian Orders were, soon after their introduction into this Country, employed by Mr. Holland in domestic Architecture, and one of the first examples is Melbourne House, Whitehall. In front of this building is a fine Grecian-Ionic portico projecting from the wall and consisting of four columns, which support a pediment-roof; but, from some inattention to the spirit of the ancient style, excusable only in a work erected when that style had been but little studied, we find on each side of the portico two columns of the same Order detached from the wall, and the general entablature broken to project over each, as in some of the Roman buildings. Columns so placed could only have been intended for ornament; but, in the Grecian Architecture, the destination of those members has always a reference to utility, and here, unless we suppose them to serve as buttresses, they appear to have no pretension to that quality. The portico leads to a circular vestibule surrounded by columns, which leave a gallery between them and the interior circumference of the wall, and crowned by a segmental dome: on the side opposite the entrance is a grand flight of steps leading to the body of the building.

Carleton
Palace.

Carleton Palace, which formerly stood in Pall Mall, was also a work of the same artist. Its general plan was rectangular, and in the centre of the façade was a grand and highly enriched portico of the Corinthian Order. In front of the building was a court separated from the street by a screen of coupled Ionic columns similar to those which adorned the Temple on the Ilyssus, near Athens, but with Attic bases; these columns were raised on a high podium, and supported an entablature only. At each extremity of the screen was an arched gateway.

The Royal
Palace in
St. James's
Park.

The new Royal Palace erected on the site of Buckingham House, does not seem by any means worthy of the Architecture of England in the XIXth century, yet, as some notice of the town residence of the Sovereign may be expected, we think it right to give a short description of it in this place.

The general plan of the main building is a long rectangle, broken by projections both towards the front and rear; and from the two extremities proceed wings towards the Park, at right angles to the body of the building, so that the Palace occupies three sides of a quadrangle. In both the façades of the edifice are two Orders of Architecture one above the other; the lower, on the side next to the Park, is Doric, and consists of fluted columns detached from the face of the building, so as to leave a corridor between them and the walls; above the corridor is a gallery protected by a balustrade. The central projection forms a portico consisting of four pairs of coupled columns of the Doric Order, and above their entablature are four pairs of Corinthian columns, supporting an entablature in the same horizontal plane with the general entablature of the building; this upper tier of columns is crowned by a pediment.

The upper part of both façades contains two tiers of rectangular windows, and, between the centre and extremities, each façade is interrupted by two of the projections before mentioned; the lower parts of these, on the side next to the Park, break the continuity of the colonnade, and each presents to the front a plain face, in which is an entrance; the upper part of the front of each of these projections is ornamented with two pairs of coupled Corinthian columns supporting part of the general entablature, and above this is an Attic in the form of a square turret, ornamented in front with panels; similar Attics crown the pavilions at the extremities of the building, and between the Attics is a balustrade over both fronts. The fronts of the two projections just mentioned contain, each, in the upper Order, one rectangular window cut down to the level of the gallery above the lower story, and over it is a small circular window, according singularly ill with the general style of the building.

The Architecture of the wings is similar to that of the façade next to the Park; in the lower part of each is a

Doric colonnade extending the whole length of the wing, and in the centre is a projection supporting Corinthian columns.

The garden front has a rusticated basement which is crowned by an architrave cornice; the central part of the whole façade projects in a semicircular form from the building, and, above the basement, the projection is ornamented with six Corinthian columns bearing a semicircular entablature, over which is part of a cylindrical wall ornamented with statues; the other four projections are rectangular, and each of their faces is ornamented with two pairs of coupled columns of the Corinthian Order.

A terrace extends along the whole of this front and is terminated at each extremity by an Ionic portico; the King's private dwelling-house adjoins the Palace on the Northern flank, and has, in front, a portico, under which the Royal carriage may enter. The approach to this part of the Palace is by a road along the interior side of the garden-wall, at the extremity of which, that is on the South side of Piccadilly, is a grand Triumphal Arch.

The majestic simplicity which should reign in such an edifice as this is destroyed by the narrow projections and the numerous apertures; but particularly by the contracted space allotted to the portico in the centre of the Eastern façade. In this front, also, the employment of the light Corinthian immediately over the Grecian-Doric Order is attended with too abrupt a change in the proportions to be consistent with the rules of harmony; the omission of the triglyphs in the entablature of the latter cannot but be highly objectionable, since the Order is thereby deprived of its essential characteristic; and the wings, by projecting so far towards the front, give the latter the appearance of a secondary instead of the principal object. The garden front seems to be in a better style than the other.

Civil structures for public service.

Buildings intended for the public meetings of the Legislative Body in a State, should be characterised by the highest degree of majesty and splendour, that they may correspond with the elevated rank of the persons composing it, and the importance of the subjects which are discussed within their walls. Their avenues should be spacious, and their interior should comprehend all the apartments necessary for the transaction of business relating to legislation.

The exteriors of the edifices which, in England, serve this great purpose cannot be considered as specimens of what may be expected to meet the eye of a spectator, on approaching the place wherein the Representatives of a great Nation hold their assemblies. One of them is hardly superior, in decoration, to that which encloses the Hall of a trading company, and the other, by the irregularity of its plan and the multitude of its windows, conveys rather the idea of a Hospital than of a Senate House. We, therefore, notice merely the building containing the Offices of the Council and Board of Trade, at Whitehall, executed by Mr. Soane, in 1826; and this may be given as an example of the latest style adopted in the public edifices of the Country.

The Council Office.

The plan of this grand pile is a rectangle, 315 feet long and 75 feet broad; the front is composed of a central part 150 feet long, and of a projecting pavilion 82 feet 6 inches long at each extremity; the whole length of the former part is ornamented with attached fluted columns of the Corinthian Order, and each of the pavilions has six columns of the same Order advanced at some distance before the wall. Six columns also adorn the front in Downing-street; the two remaining sides are connected with other buildings containing Government Offices.

All the columns stand on a stylobata which is broken under the pavilions, and the projections are connected by a balustrade in front of the stylobata of the curtain; the entablature is broken in a corresponding manner and is crowned by a balustrade. The stylobatæ of the front and side of the building form a reëntrant angle at their place of meeting, and the quoins of the pavilions are distinguished by pilasters having Corinthian capitals and plain shafts, which form a judicious relief to the fluted columns. The whole building is divided into two stories with horizontal-headed doors and windows, and above the entablature is an Attic. An oversight has been committed in disposing the plan of this edifice; for if a pavilion should be built at the Northern extremity, to correspond with that at Downing-street, it would fall into and disfigure the street of Whitehall.

To the same class may be referred those edifices which are intended to facilitate the transactions arising out of an extensive commerce, and the communications among the members of a State; and of the buildings executed in London on a great scale, for these purposes, we select for description the Bank of England, and the Office of the General Post. The Royal Exchange might have been introduced in this place, but, being the work of a former century, we have preferred describing it elsewhere.

The Ba of Engl

The Building which contains the public treasure of the State, and the Offices appointed for its management, should, by the splendour of its decorations, be an ornament to the city in which it stands, and by the solidity of its construction, an indication of the security which it affords to the valuable deposits made within its walls. The Bank of England, the destination of which is above expressed, is the work of Mr. Soane, who succeeded Sir Robert Taylor in the superintendence of its Architecture. It consists of a mass of buildings enclosed by a stone-wall, the plan of which is quadrilateral; at the extremities of the faces the wall is rounded, and recesses are formed in it, containing each two fluted Corinthian columns between pilasters, except at the North-Western angle, where, in the recess, are placed four fluted columns arranged on the arc of a circular segment with two plain columns behind them; and where, at each extremity of the segment, is a rectangular projection with two fluted columns of the same Order. The whole wall and its columns are supported by a plain basement and crowned by a general entablature.

The principal front is on the Southern side, in the centre of which are eight fluted, Corinthian columns resembling those about the Temple of the Sibyl at Tivoli; the face of the wall on each side of these is divided into three parts, of which that in the middle is ornamented with six attached columns, and that on each side with four pilasters; between these pilasters are three rectangular recesses with horizontal tops, and that in the middle is higher than the other two. The frize of the building is ornamented with an elegant fretwork, and the corona is supported by modillons, one over each column. Above the cornice, is a row of fleurons on cubical blocks, and at intervals among them are ornamented pedestals crowned with pediments, and having each face of their dado marked by three vertical grooves. In the centre of this front, the building rises a story higher than the entablature of the Order; the face of this Attic story is ornamented with pilasters, between which are recesses, and above the cornice is a parapet supporting a row of vases.

On the Northern side there is, in the centre of the enclosing wall, a recess containing two Corinthian columns between pilasters, and on each side of it a semicircular-headed doorway: one of these leads into a court of an irregular figure, on the right and left of which is a flight of long steps perpendicular to the face of the exterior wall; these lead to a pavement on a level with the floor of the Offices, and on the upper step is a screen consisting of four Corinthian columns, which support only their own entablature and a row of vases: opposite the entrance gateway is a Triumphal Arch leading to the interior.

In the centre of the Eastern side is a range of fluted Corinthian columns, behind which is a shallow recess, and, on one side, is a doorway leading also to the offices. In the centre of the Western wall is a recess with columns similar to that on the Northern side, and over this is a sort of Attic with five semicircular-headed apertures in front; above, and concentric with the intrados of each, is an ornamental groove terminating at the springing in a rectangular fret, and at each extremity of the Attic is a small pilaster ornamented with rectilinear grooves. On each side of the recess, and equally distant from it, is a doorway, vertically over which, and above the general entablature is, instead of a pediment, a curvilinear ornament ending in a scroll at each of the lower extremities. Within the entrance on this front is a vestibule having Grecian-Doric columns in the interior.

Between the Offices are quadrangular areas, and the fronts which look into one of them remain as they were executed by Sir Robert Taylor, with attached Corinthian columns; in another quadrangle the area is sunk below the general level of the pavement; the lower parts of the containing walls are ornamented with vermiculated rustics, and support an open arcade above the pavement.

The entrance on the Eastern side leads between several rectangular halls, on the right and left hand, to a rotunda or circular saloon, above which is a tambour containing the windows, and ornamented with Caryatides supporting a dome. The ceiling of the rectangular halls consists of hemicylindrical or segmental vaulting with panelling in the soffits, and, in some, the cylindrical vault is interrupted by a dome in the centre.

The Western and Northern sides of the building seem particularly intended for the reception of such valuable deposits as are made in large quantities; and the occurrence of casualties, at the time of making them, is entirely prevented by the carriages which convey them being made to enter within the enclosure and there discharge their contents; the interior of the former part, being not frequented by visitors, and only occasionally entered by the officers of the establishment, does not require much embellishment, and, accordingly, it is here that we find the simple Doric Order employed; the other parts, being open to the Public, are more highly decorated. A sober taste may, perhaps, condemn as fantastic some of the ornaments about the exterior of the building.

The new Post Office in London, by Mr. Smirke, is a splendid example of the Grecian Architecture applied to a modern Public edifice. The plan of this building is rectangular, and its front is about 400 feet long; in the centre is a projecting hexastyle portico, 70 feet long, with one column between each of the antæ pilasters and the front columns of the portico; the columns are of the Ionic Order, and resemble those at the Temple on the Ilyssus; they have Attic bases and fluted shafts, and stand on plain pedestals. At each extremity of the façade is a pavilion with four detached columns of the same Order in front; and on the side, two unfluted pilasters.

A continued podium reigns about the building, and there is an ascent to the pavement of the portico by a grand flight of steps. A general entablature crowns the whole edifice, but the upper facia only of the architrave extends over the curtains between the portico and pavilions; the frize is high and quite plain, and there are dentels in the cornice.

In the façade are two tiers of windows with horizontal tops; those of the upper tier in the curtains, and of both tiers, in the pavilions, are crowned by projecting cornices supported by consoles. On the sides of the building, there are three tiers of windows, of which those below are semicircular headed; those in the second tier are rectangular, and the faces of the piers between them have the appearance of broad pilasters with mouldings at the top; and the upper tier of windows is cut in the frize of the entablature of the building. The basement of this edifice is of granite, and the superstructure, of brick faced with Portland stone.

Situation and character of a Theatre.

A Theatre should be situated in some spot to which the inhabitants of the city may easily have access. According to Milizia, it should occupy a spacious area formed by the meeting of several principal streets, and should be surrounded by porticos or arcades of various kinds for the reception of carriages and for the security of pedestrians; the entrances and staircases should be so disposed that the interior of the building may be speedily filled and evacuated; and, above all, the part occupied by the auditory should be such as to permit all persons to see and hear the performers with nearly equal facility. The exterior of the edifice should, of course, be an indication of the agreeable entertainment which is to be expected within.

It is not often that all the circumstances requisite for a perfect Theatre can be obtained, but the principal cities of Europe may now boast of possessing some which unite most of the qualities necessary for internal convenience and external decoration: we must, however, confine ourselves to a description of one example, and we select the Theatre which was erected by Mr. Smirke, near Covent Garden, in the year 1809.

Theatre of Covent Garden.

The plan of the whole system of buildings forming this Theatre is a parallelogram, 209 feet long, and 166 feet wide, exclusive of the portico; the centre is occupied by the auditory and stage, which extend nearly through the length of the edifice from North to South; the staircases and apartments for the performers are on the Eastern and Western sides. The space appointed for the auditory is circumscribed by a parallelogram, 85 feet long and 64 feet wide, within which are three tiers of boxes arranged in the form of a horse-shoe, the extremity furthest from the stage being semicircular, and the sides in the direction of right lines converging to a point beyond the bottom of the stage; over the upper tier of boxes are galleries, also occupying the three sides of the auditory, besides an upper gallery at the extremity; and on the exterior of the boxes, in each tier, is a corridor by which access is gained to the particular seats. In the area included by the boxes is the pit, an inclined plane, lowest towards the stage, and on which the seats of the spectators are arranged in directions parallel to the breadth of the building; in front of the pit is the orchestra, a space for the musicians, 6 feet broad, and 42 feet long, which is equal to the whole interval between the two extreme boxes in the lower tier. The stage itself is contained within a rectangular area, 70 feet deep from the orchestra to the rear, and 82 feet wide; in front is the proscenium, 42 feet wide and 13 feet deep, bounded by the orchestra in front and the drop-curtain in the rear, and at each extremity are two pilasters painted to imitate Sienna marble: the floor of the stage is on an inclined plane rising towards the rear about 3 feet, on which at intervals are parallel grooves for the reception of the scenes, and on each side are recesses to contain the paintings. The interior of the auditory is superbly enriched with gilding; the boxes are supported by slender iron columns, fluted and gilt, and their interiors, as well as the sides of the pit, are decorated with representations of dark crimson drapery, producing a fine contrast to the brilliancy of the front. The middle of the ceiling is circular, and in the centre is a glory surrounded by golden lyres; from this centre depends a superb chandelier of glass illumined by two circles of gas-lights; the remainder of the ceiling is a light-blue sky relieved by delicate white clouds.

The principal façade is on the Eastern side of the building; in its centre is a grand portico of four fluted Grecian-Doric columns, elevated on a flight of steps and supporting a pediment; in the basement story is an arcade on each side of the portico, and the upper part of the building is decorated with representations of dramatic subjects, ancient and modern, in bas-relief. The grand entrance leads to a square vestibule, 37 feet long, and divided into three parts from North to South by two rows of piers. On the Southern side is the aperture leading to the principal staircase, which is 15 feet wide, between two rows of large porphyry columns of the Ionic Order; on one side of the staircase is the doorway leading to the auditory, and in front is an entrance saloon, ornamented with pilasters executed in porphyry. On the Western side of the Theatre, and corresponding to the grand staircase, is another leading to the King's saloon and private box, and a vestibule, the ceiling of which is supported by four columns, which also leads to the auditory. In the centre of the Southern side of the building are two grand saloons one above the other, and each 56 feet long, and 18 feet wide.

The entrance to the stage, and to the apartments appropriated to the performers, is in the Northern front; the latter consist of the dressing-rooms, the green-room, and managers'-room; there is besides a committee-room, a store-room, and, in the middle of the front, a large scene-room.

Characteristics of Hospitals.

The buildings appropriated to charitable purposes constitute one of the chief glories of the present Age; in England particularly, besides asylums for the aged and disabled, almost all the different modes of human suffering are provided against by establishments formed for their prevention or remedy; among which the Hospitals, for the cure of sickness and accidents, hold a distinguished rank. In these buildings every thing like magnificence of construction and richness of ornament would be quite misplaced, and their chief merit should consist in simplicity and convenience. The London Hospitals generally consist of buildings disposed on the four sides of a rectangle, and enclosing a considerable area, and the most considerable is that of St. Bartholomew, near Smithfield. In this, the buildings containing the wards for the patients occupy three sides of the quadrangle; each of them consists of four stories in height, and on each story are four well-aired wards; the fourth side contains the apartments of the principal officers and the committee-room. Behind one of the buildings is situated the Pharmacy and a Theatre for Anatomical Lectures.

St. Barth lomew's Hospital.

A custom prevails in the English Hospitals of placing the heads of the beds against the walls, which often brings them very near the windows, and, consequently, exposes the patients to the danger of taking cold. We know only one building in England in which a better disposition has been followed, and this is the School for the Blind, where the late Mr. Tappen, copying the method adopted in the great Hospital at Lyons, has placed the beds in pairs, with the heads of every two meeting in the middle of the room, so as to leave passages between the feet of the beds and the walls.

Bethlem Hospital.

The Bethlem Hospital, for the reception of lunatics, situated on the Surrey side of the Thames, consists of a line of building 569 feet long, and 60 feet high, and possesses every accommodation which can contribute to the comfort of persons in that unhappy state. It was built by Mr. Lewis, in 1812.

In the centre of the façade is a grand portico, 130 feet long, of Grecian-Ionic columns supporting an entablature and pediment, above which is a double Attic tower crowned by a plain dome; the columns stand on pedestals, and there is an ascent to the pavement of the portico by a flight of steps extending its whole length. On each side of the portico is a curtain, 141 feet long, terminating in a pavilion, 78 feet long in front; the face of the latter projects before the curtain, and is itself divided vertically into three parts, that in the centre projecting before the others: above each pavilion is also an Attic turret of an octangular form. The curtains and pavilions contain three tiers of plain, rectangular windows, and are crowned by a horizontal cornice of stone on a level with that over the portico.

The edifice is enlarged behind by two projections from the main body, one on each side of the centre, and a detached building has been erected behind each of the pavilions for the reception of criminal patients, or those afflicted with infectious diseases.

In the centre of the main building is a grand vestibule, behind which is the principal staircase, and on each side of the latter are apartments for the physician and steward; adjoining these, is a room in which the patients see their friends, and a large store-room. One vast corridor, adjacent to the front-wall, extends quite through the length of the curtain and pavilion on each side of the centre; this serves as a place of exercise for the patients, and along that side of the corridor which is next to the back-front are the cells. In front of each of the two pavilions is a large day-room, in which those patients who are able usually assemble.

Behind the centre is an exercising ground for convalescent patients; and between this and the two detached buildings, are the general exercising grounds, one for the male and the other for the female patients.

Except the portico, which is of stone, the whole edifice is of brickwork; and a critical eye may regret that the simplicity of so extended a line of building should have been destroyed by so many vertical divisions.

Hospital Milan.

The Hospital at Milan is considered as a structure uniting all the conveniences of such edifices in the highest itec- re.

degree, and its plan may, therefore, with propriety be introduced in this place. It consists of one great rectangle divided into three parts, nearly square and equal to each other. The central division is one vast area surrounded by buildings, before which, in the interior, are corridors on the lower and second stories, formed by arches supported on granite columns of different Orders. Each of the lateral divisions is again subdivided into four squares by two ranges of building crossing each other at right angles; within these buildings are the cells for the patients, disposed in two rows, leaving a broad corridor between them; and, at the intersection of the two corridors in each wing, is an altar; at these Divine Service is performed, which the patients can both see and hear without leaving their cells. Each of the courts in both wings of the Hospital is surrounded, in the interior, by two tiers of arcades forming corridors in front of the walls.

A grand vestibule, surrounded by columns disposed in the circumference of a circle, forms the front of the central division of the Hospital; at the opposite extremity of the same division is a large open portico wherein surgical operations are performed.

wich al.

The Naval Hospital, at Greenwich, which was erected on the site of the ancient Royal Palace, is a National Asylum for the reception of seamen who have grown old, or have been disabled, in the service of their Country. It consists of four quadrangular buildings disposed within the limits of one vast rectangle, the sides of which are nearly equal in length to 865 feet; and the buildings are separated by a broad area and a street, which cross each other at right angles. The principal front extends along the Southern bank of the Thames, and before it is a terrace, with steps in the centre to descend to the water.

The North-Western quadrangle was erected in the time of Charles II., from the designs of Webb, the son-in-law of Inigo Jones, and contains the apartments of the Governors, and the Council-room, besides sundry wards for the pensioners; the remaining buildings were begun by Sir Christopher Wren, about the year 1696, but they were finished by other Architects. The North-Eastern quadrangle is similar in style to the other, and having been finished in the reign of Queen Anne, it is called by the name of that Sovereign. The length of the Northern front of each of these quadrangles is 297 feet and the avenue between them is 270 feet broad; each of these fronts consists of three divisions, and in that of the centre is the entrance to the interior quadrangle; one of them is covered by a semicircular arch within the lower story, and the other by the general entablature of the building; each flank division is ornamented with four Corinthian columns supporting a pediment; on the right and left are coupled pilasters of the same Order; and above the whole front is a high Attic, crowned with a balustrade. The Southern façades of the same buildings are exactly similar to those on the North; both are of Portland stone, and rusticated. Each interior side of these buildings has its centre marked by four Corinthian columns supporting a pediment, and in the lowest story are three arched entrances to the quadrangle.

The South-Western and South-Eastern buildings bear respectively the names of William III. and of his consort Queen Mary, the original promoters of this noble institution. These are separated from each other by a square area, on a higher level than that next to the river, with a flight of steps on the Northern side extending the whole breadth of the area. At each of the two angles nearest to the general centre of the Hospital is a grand vestibule, adorned with coupled columns of the Doric Order, but having Attic bases and no triglyphs in the frize, and crowned with an elegant dome. Along the interior face of both the buildings is a double colonnade, 374 feet long and 20 feet high, consisting of coupled columns of the Order named above, and ornamenting a raised terrace. The lower stories of their Northern fronts are entirely occupied by the two dining halls, which are covered by groined ceilings supported on Tuscan columns; above these, in the Eastern building, is the Chapel, built in 1752, in the Grecian style, from the designs of Mr. Stuart, and in the Western building is the Grand Painted Hall: both Chapel and Hall are 106 feet long, 56 feet wide, and 50 feet high; the windows are very lofty, and are placed in semicircular-headed recesses.

Three of the buildings are of stone-work, but of that on the South-West, the two exterior faces, and those within its quadrangular area, are of brickwork. The last edifice was finished by Sir John Vanbrugh, about the year 1725, and contains some features which display the bad taste prevailing at that time: in the centre of one side of its interior quadrangle is a recess covered with an elliptical arch, and ornamented with two Ionic pilasters on each side; within the recess is an arched passage with small Corinthian columns standing on high rusticated pedestals, and supporting a pediment the cornices and tympanum of which are broken vertically into three faces; and, on the Western side of the same building, each of the flanks is crowned with a great segmental pediment.

Characteristics of Prisons.

The aspect of a Prison should be of a severe, and even gloomy character, in order that it may present a picture of the consequences which attend an infraction of the laws. But there are different degrees of crime, and the circumstances of Commercial Nations have rendered it necessary, in some cases, to treat as criminals those who are only unfortunate; hence it follows that prisons should be of various kinds, or, at least, that means should be afforded, in the same building, of keeping the different classes of prisoners distinct from each other.

If we consider a Prison as the abode of felons only, we may conclude that its Architecture should be of the most massive Order, its walls lofty and rusticated, and the faces of the stones rendered rough; the projections great, in order to cast broad shadows; the entrances arched with heavy voussoirs, and, where space can be afforded, it should be surrounded by a broad and deep ditch. The interior, however, should be convenient and salubrious, and, besides the cells, there should be large apartments where the inmates may occasionally meet and see their friends: when the Prison is intended as a place of correction for persons guilty of petty crimes, there must be places where such persons may prosecute their appointed labours, and debtors should have apartments in which they may exercise their callings for their own profit, or the benefit of their creditors

Newgate.

The Prison of Newgate, in London, which was constructed by Mr. Dance, and completed, in its present state, in 1782, forms three masses of building, together extending 297 feet in length from North to South; and the principal façade is in a rectilinear direction on the Western side. The plan of the middle division is a square of 115 feet; the Northern division is also a square of 91 feet; but the Southern is 91 feet long and 81 feet broad. In each of these squares the buildings are disposed about an open, rectangular court, which serves as a place of exercise for the prisoners; that in the centre for those who have not had their trial, the others are for the convicted male and female prisoners, respectively; but there are walls of separation in each, to form distinct places for those of different degrees of criminality. In the middle of the Western side is the Keeper's house, and behind it is a Chapel. For each sex there are two large general sleeping-rooms, a general day-room, an infirmary, and cells for separate confinement; a room in which the prisoners may see their friends; and at the North-Eastern angle of the ground, but quite distinct from the rest of the building, is a general room and separate cells for those who are condemned to die.

The Western or principal façade is rusticated from top to bottom with stones made rough on the exterior, which gives an appearance of rude strength; but the harmony of the Architecture is entirely destroyed by the Keeper's house, which has five tiers of windows in front, while only a few small apertures are apparent in the rest of the building. The Western parts of the Northern and Southern wings have each two projecting piers, with one niche containing a statue in a semicircular-headed recess, and an unbroken curtain between the piers. Between the Keeper's house and each wing is a small rectangular doorway at the foot of a large semicircular-headed recess; over the doorways are fetters sculptured in the wall, and the arched head of the recess is pierced for light. The whole front is 50 feet high.

The building presents an imposing and formidable appearance, and affords a good example of the effect that may be produced by mere magnitude almost without any decoration.

Penitentiary in Westminster.

A few years since a building was erected, by Mr. Hardwick, on Millbank, in Westminster, as a Penitentiary, or place for the reception of criminals who are to expiate their offences by undergoing a course of labour during a certain number of years, after which they are to be restored to Society. This building has been constructed according to a plan proposed by Mr. Bentham, for the purpose of affording a system of constant surveillance by the constituted officers. It consists of six pentagonal edifices, like bastions, disposed symmetrically on the sides of a hexagonal court, in the centre of which, on the ground-floor, is the apartment of the overseer; the whole is surrounded by a polygonal wall. The cells in which the prisoners perform their labours are placed at the gorges of the bastions, if they may be so called, and are open towards the great court, so that the overseer can command a view of all, from the windows in his apartment; above this apartment is the Chapel, to which there is a bridge of communication from the second story of each bastion, so that the prisoners can attend Divine Service without entering the court.

A plain, massive gateway forms an entrance to the building on the side next to the river, and another facing this, between the flanks of two bastions, leads to the hexagonal court. Along the river is a spacious terrace protected by a low wall, and a double flight of steps affords an ascent from the water The whole system of buildings seems well contrived for the accomplishment of its destination; but it may be thought that the rentrant angles between the bastions cause a great loss of space, and the site does not seem to have been well chosen, being so near the river and on a swampy soil.

Courts Justice.

Contiguous to a Prison should be the Court of Justice where the culprits are to be tried; and the most convenient form for a building appropriated to this purpose seems to be that which resembles the Theatres of the Ancients, that is to say, a semicircle, the tribunal of the Judge being placed on the chord of the arc, in the part corresponding to the proscenium. The general style of the edifice should be such as to inspire a sort of reverence nearly equal to that which is felt at the approach of one consecrated to Religion. The Court-house executed at Chester, by Mr. Harrison, is of the form above recommended; the seats of the persons connected with the proceedings rise from the floor in front of the tribunal towards the circumference of the circular part of the building; about them is a semicircular range of Ionic columns, and behind these is the gallery for the spectators. The Prison, which adjoins the Court at the chord of the circular part, is of a quadrangular form, and has in front a Greek Doric portico, the proportions of which are copied from the Propyleum at Athens.

The Court-house, at Warwick, is of a different form. This consists of a great rectangular Saloon, the principal façade of which, on the exterior of one of the long sides, is ornamented in the Palladian style of Architecture: on the opposite side of the Saloon are the Civil and Criminal Courts, one at each end, and on a higher level; these are open towards the Saloon, from which each is separated by a colonnade, and there are flights of long steps to ascend from the pavement of the Saloon to that of the Courts; between the Courts is the Jury-room, to which also there is an ascent by steps.

Bridges.

Bridges form some of the most important objects in Civil Architecture, by affording passages for the heaviest carriages across broad and rapid rivers, which by other means could not be passed but with difficulty and danger; and from the mass of masonry which, with the incumbent weight, is required to be suspended in the air, such a work as a Bridge demands the union of great scientific talent and practical skill in the Architect.

Situatio a bridg

The part of a river in which a bridge may be most conveniently formed is where it is nearly rectilinear, because the current of water being parallel to the banks, the bed is more uniform than in spots at which the river bends, and the piers, therefore, are more easily constructed. Also, the greatest force of the current being in this case in the middle, the vessels keep generally in that part; consequently, if the arches are not all equally broad, that which, on account of the passage of the greater number of vessels, is made the widest, will be in the centre, and the bridge may be symmetrically formed on each side. But when one side of a river is deeper than the other, and the greatest force of the current is near one of the banks, (which is the case when the river bends;) if, for any reason, a bridge should be constructed at that part, it will be proper to make the arch on the deeper side wider even than that of the centre, notwithstanding the want of symmetry thereby induced in the form of the bridge; convenience being attended to rather than beauty where necessity requires a sacrifice of one or the other. Bridges should be approached by long streets, on each side of the river; and, to facilitate the access, the parapet should diverge considerably at each extremity of the bridge.

Form road.

The most convenient form for the road over a bridge is, undoubtedly, a horizontal plane, like that of the Waterloo bridge, in London; but where the lowness of the ground on one or both sides of the river renders this impossible, or too expensive, the road must be of a convex form in the direction of its length, as is generally the case, in order that it may sooner meet the surface of the ground: this form is even considered more elegant than the horizontal plane, because, from an optical deception, the latter seems lower at the middle than at the extremities, when seen from the river in a direction perpendicular to its length.

The breadth of a bridge ought to be sufficient to allow at least two carriages to pass abreast, with a pavement on each side for foot passengers; and the road should be protected by a parapet and balustrade high enough to secure those who pass it from accidents.

Lon-bridge.

Under BRIDGE, in our *Miscellaneous Division*, we have described the principal edifices of that kind in Europe, it will therefore be necessary to mention here only the two of most recent construction in and near London. One of these is a magnificent edifice, now building, of granite, to replace the old London bridge; its length is to be 782 feet, its width 56 feet, and it is to consist of five elliptical arches, of which that in the centre has a span not less than 150 feet in extent, and a rise of 29 feet 6 inches; the others decrease gradually in breadth and height on each side, and the piers which support the central arch are 24 feet wide. It was begun, in 1825, by Mr. Rennie, a son of the engineer under whose superintendence the Waterloo bridge was executed; and it promises to be not inferior, in constructive merit, to that celebrated structure itself.

mer-h ge.

The other is a Suspension Bridge, 823 feet long, at Hammersmith, which exceeds, in the extent of road between the piers, the great bridge over the Menai. The chains, which are eight in number, and of wrought iron, pass, at 30 feet above the road, through apertures, in the upper parts of stone piers distant 400 feet from each other, and their extremities are attached to the abutment on each bank of the river; between these piers the chains assume, by their gravity, the form of catenarian curves, the lowest points of which touch the platform of the bridge over the middle of the river; and from the chains descend vertical rods which carry the timbers supporting the road. The piers rise from the bed of the river; below the bridge they are boldly rusticated, and, above it, each forms a triumphal arch extending across the road: at the angles are Tuscan pilasters standing on a general podium and supporting the entablature; the two sides of the arch spring from imposts which are continued through the pier, and the soffit is ornamented with panelling.

t Ar-cture.

The character of a Nation for good taste in the Arts depending, in some measure, upon the Architecture displayed in its cities, it is evident that the private buildings of which they are composed should be designed according to certain regulations, by which they may be adapted to their situations and be made to contribute to the magnificence of the whole.

Convenience seems to require that the streets should be rectilinear and intersect each other at right angles; but if this method was strictly adhered to, the horizontal lines of the buildings would, to a spectator looking along the street, appear to vanish in one point only, and thus the picture would want variety. Luckily, inequalities of ground almost always oppose themselves to this arrangement, and compel the builder to adopt some other which affords greater pleasure; the various angles at which the streets intersect each other, the interruption produced by great squares, and the judicious introduction of curvilinear forms of building, give to the scene in which they occur a beauty which would be in vain sought for in the appearance produced by two parallel lines of building.

Formerly, town-houses were constructed as independent buildings, and not the least attention was paid to equality or symmetry either in their heights or breadths, so that a street presented the confused appearance arising from two ranges of narrow and irregular fronts. But, at present, there seems to be an effort, wherever inequalities of ground do not prevent it, to give an air of grandeur and simplicity to the streets by uniting the fronts of several houses in one general design. This method was first practised in London, by Messrs. Adam, in the Adelphi and in Portland Place; but the good effect which these buildings might have produced is, unfortunately, injured by the manner in which they are ornamented. In front are pilasters ornamented with panels and sculptured foliage, seemingly in imitation of those which decorate the edifices of Palmyra, but harmonizing badly with the other features of the buildings to which they belong. And it is observed by Mr. Britton, speaking of the works of these artists, that, "in attempting to avoid the heaviness which characterises those of many of their predecessors, they have fallen into the opposite error; their façades are frittered into too many parts, and though the ornaments are occasionally tasteful, they are generally so applied as not only to miss their effect, but impart a trivial appearance to the building."

The principle introduced by Messrs. Adam has been adopted and practised on a vast scale in the buildings of Regent-Street and Regent's Park; but the designs are in a more elevated style, and embrace greater varieties of form. These ranges of buildings constitute what may be taken for a street of palaces, the individual characters of which are such as permit them, by their union, to form one grand system, while they have sufficient diversity to prevent the eye from being wearied, and to produce, together, a picturesque effect.

Modern Villas.

The Palladian Architecture was long employed in England for the general disposition and ornament of the villas, or country-residences, of persons of moderate rank or fortune. In these the principal story, like the *piano nobile* of the Italian mansions, was elevated on a basement, and the communications with the court in front and garden behind were by flights of steps. But it is observed by Mr. Papworth, that, in consequence of the change which has occurred in the habits and manners of the people of England within the last fifty years, this practice is abandoned; the principal apartments are now near the level of the ground, and are made to communicate with each other, so as, on occasion, to form one large apartment. The chambers are placed above these, and the offices are concealed from the view by small trees tastefully planted about them.

CHAPTER VIII.

General Principles of Architecture.

Ancient Architecture requires modification.

In investigating the principles which are to guide us in the execution of such Architectural works as shall fulfil the conditions which the present state of European Society requires, we may avail ourselves of every aid that we can derive from the practice of the Ancients. But our circumstances in respect to Politics, Religion, and Manners are different from those of the Greeks and

Romans, so also are our notions of domestic convenience; therefore it must not be expected that the maxims of building adopted by those People can apply without modification to our own constructions. There are, however, some points which must be common to all, and from these we may proceed to exhibit the grounds of the present practice of building.

Division of Architecture.

As edifices may possess properties which are merely essential to them, such as strength and convenience; or may unite to these, others which are intended to produce a pleasing effect upon the mind of a spectator, Architecture divides itself into two parts, *viz.* the constructive and the ornamental. The former is, in some measure, Mechanical, the latter, more particularly, may be considered as a Liberal Art. Both parts must be equally studied; for, besides paying due attention, in the design of an edifice, to the essential conditions of stability and convenience, it is necessary to render its external appearance suitable to the purpose for which it is intended.

Qualities of a building according to Vitruvius.

Vitruvius, (Book i. chap. iii.) speaking of public buildings, says they should unite in their construction strength, utility, and beauty. Their strength, he says, consists in having their foundations sunk to the solid earth, and in an unsparing choice of materials. Their utility consists in the apartments being properly distributed without obstruction to their use, exposed to the aspects which are convenient, and adapted to their respective purposes. Their beauty consists in the form of the work being agreeable and elegant, and the proportions of the members being correspondent to the rules of symmetry.

Modern buildings less material than the ancient.

With regard to the first of these points the practice of builders has undergone considerable change since the days of Vitruvius; the ancient edifices of all kinds were much more massive than the modern ones, and the Architects of earlier days seem to have been determined to err on the safe side. But now that frequent experiments, expressly made, have shown us, with tolerable accuracy, the strength of materials; and the rules of mechanics have taught us how to employ them in the way in which they are best able to bear the strains to which they may be exposed, we can dispense with a great quantity of material which would have been formerly employed, and which only served to encumber the edifice without adding any thing to its stability. The second part remains as in the days of Vitruvius, and admits of no change in its general expression; though the proper choice of aspects and the manner of adapting apartments to the purposes for which they are designed, vary with all the circumstances of climate and the habits of the People.

Supposed causes of the perception of Beauty.

The third point is more vague; no two persons can agree on what is elegant or agreeable; and, since the revival of the study of Science and Art in Europe, the cause of our perception of Beauty has been a subject of dispute both among Metaphysicians and Artists. Some persons consider our ideas of Beauty to depend upon certain qualities inherent in the object which, by a Law of our Nature, excite the perception as soon as they are apprehended; but that there cannot be such a thing as absolute Beauty will be readily admitted by those who consider that an object which appears beautiful to one person, appears the contrary to another: why this should be it is difficulty to determine, but probably it is on account of some prejudices, arising from early impressions, of which the mind is unconscious.

Others suppose the idea to depend upon the pleasure the mind experiences on contemplating an adaptation of means to an end in any subject; but, that this perception of Fitness should be always the cause of that of Beauty, is doubtful, because we often derive pleasure from the view of objects which do not necessarily involve in their being, an adaptation of means to an end; and when we do, we are often conscious of the perception of Beauty before we have taken time to notice that adaptation.

Our perceptions of Beauty in Architecture, according to Milizia, are founded on Nature and Utility. If it be inquired why a column appears beautiful in particular circumstances, he answers that a column is an imitation of a trunk of a tree employed to support an incumbent weight: but the trunk of a tree in such a case would have a certain figure and proportions, therefore, if the same figure and proportions be given to a column, we shall consider it beautiful, because the imitation of a natural object is always pleasing. He goes so far as to say, that if Nature had made trees equally slender with the stalks of corn, and, at the same time, strong enough to bear the greatest weights, the proportions of our columns would have been drawn from those objects, and we should still have considered them beautiful: but he seems here to overlook the circumstance, that great differences of magnitude and form in contiguous bodies are inconsistent with any of our notions of Beauty.

Lastly, it may be observed that intellectual associations form part of the pleasurable sensations we experience in contemplating certain objects; and this is particularly the case with works of Art. The Architecture and Sculpture of the Greeks and Romans possess an indescribable interest for us, because we always, in imagination, combine them with the circumstances of their Mythology and History, which usually occupy our thoughts at an age when the pleasing ideas they are calculated to excite make an indelible impression on our minds. And the Castlès of the Barons of ancient Chivalry, says Sir Joshua Reynolds, are sure to give delight on account of the veneration we feel for whatever brings to remembrance the manners and customs of our ancestors.

In fact, the mind is affected by objects from various circumstances, and, perhaps, the idea of Beauty may not arise from a single source. If absolute Beauty be not admitted, yet perception of fitness, intellectual associations, and various other causes, may, either wholly or in part, be concerned in the production of pleasurable sensation; and it will, probably, be for ever impossible to determine which of them is predominant in any particular case.

The inquiry into the origin of our perception of Beauty in general, however interesting it may be to the Metaphysician, need not be dwelt on any longer, and we may now direct our attention to the general conditions which are requisite in order to render a building conformable to the ideas of Beauty which we actually entertain.

Conditi
essential
architec-
tonic bea
accordin
Vitruvi

Three qualities are mentioned by Vitruvius as essential to Architectural composition, *viz.* Symmetry, Eurithmy, and Proportion; terms which have given great trouble to his commentators, and which, in fact, seem to be all comprehended under the general term Proportion. He defines Eurithmy to be the beautiful appearance of the members of an edifice, and shows that this is obtained by an adaptation of the heights of the members to their lengths and breadths, and by a correspondence of these to the symmetry of the whole. Symmetry also he defines to be an agreement of the members of a work, and the correspondence of the parts to the form of the whole; which is supposed to signify that some Proportion should subsist between the dimensions of any member and the dimensions of the whole building; but, as this definition falls partly into that which has been given of Eurithmy, it is customary to confine the signification of Symmetry to the corresponding distribution of like members on each side of a centre, as the members of the human body are similarly situated, on each side of a plane passing longitudinally through it. The word Eurithmy not being in use, perhaps it would be better to refer the magnitude and form of the members of an edifice to the term Proportion, and the distribution of them to the term Symmetry; agreeably to the general employment of those terms in ordinary Language.

The elements of architectonic Beauty which we find delivered by Vitruvius, are too general or too uncertain to allow us to consider them as the sources from whence we are to draw practical rules of construction; and we shall find it convenient, for this purpose, to make that Beauty depend upon, at least, four different principles, *viz.* Propriety, Proportion, Symmetry, and Unity.

riety in hitec-

The first principle is evidently conformed to, when the walls of a building have the proper degree of strength to enable them to support the roof, or but little more; when the size and distribution of the interior parts render them fit for the purposes to which they are to be applied; and when the degree of ornament given to the exterior and interior members accords with the importance of the edifice.

Propriety is evidently an essential quality in Architecture, and cannot be dispensed with where the stability of the edifice or the destination of any member is concerned; but it is observed by Sir William Chambers, that in objects merely ornamental, it would be unreasonable to sacrifice other qualities more efficacious, to Fitness alone. That Beauty and Fitness are not always compatible he shows by the example of the Corinthian capital, which represents a slight basket surrounded by leaves, an object certainly not fit to support an entablature, yet it has been admired for Ages, and will probably continue to be admired for Ages to come.

ortion.

Proportion is also an essential part of Beauty in Architecture; and it applies to the mass of the edifice as well as to the internal and external subdivisions. But what that Proportion is on which the perception of architectonic Beauty depends it is impossible to say. Some think it consists in the length, breadth, and height of a building or of any member being equal to three terms of a Geometrical or Harmonical progression; but the absurdity of this opinion is manifest from the consideration that the dimensions of an edifice may differ from those which are assigned by these proportions, without the eye, which is to be the judge of the Beauty of the building, being able to distinguish the difference. It is observed also, by Milizia, that the Beauty which is derived from Proportion in an edifice depends more directly upon the point of sight from which the edifice is seen than upon its absolute dimensions; since, according to the distance of any member, or to its height above the eye, its apparent magnitude, and even its form, is variable.

Experience then seems to be the only source from whence we are to obtain a knowledge of the relations which are capable of exciting perceptions of architectonic Beauty. "When," says Milizia, "we find that any number of parts, disposed in a particular manner, excites, in the generality of judicious spectators, pleasurable sensations, it is prudent, on the occurrence of similar circumstances, to follow exactly the same dimensions though there may be no discoverable relation between them." *Principi di Architettura Civile*, lib. ii.

Symmetry.

Again, Symmetry is also an essential part of Beauty; for that object can rarely excite agreeable sensations which is formed of dissimilar parts on each side of its centre. In the façade of a building, for example, there should be a doorway in the middle, and an equal number of windows, of like forms and dispositions, on either side: again, a bridge should have an equal number of arches on each side of that in the centre, and these should be either of equal magnitude or diminish by equal degrees on both sides. And it is easy to conceive, where absolute necessity does not compel the builder to depart from the principles of his Art, how much disgust would be excited by having a door placed nearer to one extremity of a façade than to another, or by having the principal arch of a bridge on one side of a river; or, finally, in an arcade, by having large and small arches intermingled together.

It is necessary, however, to observe that this Symmetry is only required where the whole object is seen from one point of sight; it would even be improper in an artist to bind himself to a uniformity of design in all the fronts of an edifice when those fronts are to be seen successively; such a repetition would be wearisome, and the spectator would lose that source of pleasurable sensation which arises from the variety exhibited in different fronts on the exterior, or in different apartments in the interior of any building.

Unity.

It is not sufficient that the parts of a building should be symmetrically disposed, there should also be some one part which forms the principal object, and to which all the others should be subordinate: this constitutes what is called Unity in an edifice, for it reduces all the parts under one system, and makes that an entire body which, otherwise, might be taken for a collection of independent members. The same principle requires that there should be but one Order of Architecture employed on the same story of any building; that, where Orders are placed above Orders, the most massive should be the lowest, and the others increase in lightness as they ascend; also that a cornice, since it expresses the termination of a building above, should not be formed between two stories. And it is essential to the unity of the design that no member, either of Architecture or Sculpture, should be introduced which is not consistent with the character of the edifice. Lastly, the different members should present themselves successively to the eye of the spectator in the order of their importance in the edifice; and the disposition should be such that the mind may form a general conception of the whole before it attends to the minute parts. These last, also, should be capable of exciting distinct ideas, and of conveying a notion of the uses for which they are designed.

Supposed standards of Perfection.

Milizia has advanced four different opinions concerning the standard of Perfection in Architecture. The first is, that it depends on popular judgment; but this is immediately dismissed, because it would be found subject to continual change, and a building would cease to be beautiful when its style ceased to be fashionable. The second is, that it depends on the conventions of

Architects; and this seems to be as ill-founded as the former; for not only the proportions assigned by the Moderns to the members of an Order differ from those which are found to exist in the monuments of antiquity, but each Architect, for the most part, has given a system, differing from those given by others both in the minute details and in many of the members upon which the peculiarities of the Orders of Architecture essentially depend. Vitruvius himself prescribes proportions to be employed in the construction of one kind of building which are different from those he recommends in another, though both are formed according to the same Order; and he approves in some places several things which in others he rejects. The third opinion is, that perfection should be sought in the remaining monuments of antiquity; but the diversity in their constructions is so great, that no general rule can be drawn from their dimensions, and the defects they exhibit are such that, if we were to consider them as invariable standards, there is hardly any violation of propriety which might not be justified by an appeal to some one or other of them.

Since, then, neither the authority of the masters in the Art, nor the existing examples, can be considered as infallible guides in the search after real Beauty in Architecture, Milizia is led to suppose that it is only by referring to the origin of the Art that certain constant principles can be elicited, which may be of service in the endeavour to produce such forms as will obtain general approbation; and, perhaps, it may be concluded that there are different styles of building, all equally capable of giving rise to the perception of Beauty, as far as it is founded upon the conformity of the works to the objects from whence they are derived.

General application of the principles of composition.

The following very general rules arise naturally from the principles before mentioned, under the heads of Propriety and Unity. The style of a building should be conformable to the ideas intended to be excited by its appearance; when we would produce perceptions of power, durability, and grandeur, the masses should be great, the subdivisions few, and those marked by transitions sudden and strongly contrasted; but, to inspire ideas of elegance, delicacy, and gaiety, the edifice should consist of many parts, differing by slow and regular gradations, and liberally ornamented. The same rule may be applied to the ornaments themselves, which, in proportion as they are more delicate, are to be formed by lines connected together less abruptly.

Perfect harmony should subsist between the whole edifice and the parts of which it is composed; for the same objects, viewed independently, may please, which, when combined, become ridiculous or disgusting; and even the same combination of parts which excites admiration when made in a work to the character of which they are conformable, may, in other circumstances, produce a contrary effect.

The course to be pursued by an Architect, in designing a public edifice, is to adapt his forms and proportions to the purpose for which the building is to be appropriated; to arrange the plans so that all requisite accommodations may be afforded; and to display the resources of his imagination in embellishing his work with such ornaments as shall be consistent with its destination. He should study examples of all the different styles which have hitherto prevailed, in order to produce an original work which shall unite the principal beauties of each; and he should infuse into his design the general character of the buildings proposed as models, without copying, servilely, any of their individual features.

CHAPTER IX.

Modern Domestic Architecture.

Best form for the pl of a dwel ing-house

A square or parallelogram is that which seems best adapted to the plan of an edifice intended as a dwelling, because it admits of great variety of internal division, and because the perspective of the figure is pleasing. Sir Henry Wotton, speaking on this subject, says the circle is a figure possessing many eminent properties in respect of durability, capacity, and beauty; the latter, inasmuch as it imitates the celestial orbs, and the form of the Universe, yet it is very unfit for private buildings, because it is the most expensive and causes the greatest loss of space from the curved form of the walls. Again he observes, that polygonal figures are more fit for Military than for Civil structures, and, no doubt, they partake of some of the inconveniences of circular forms; they may, however, be employed where the site is irregular, or where a system of buildings is to be disposed about a centre, for the purposes of inspection.

He decides finally for the rectangular form, the right angle affording greater strength than the oblique one; and he inclines to prefer the parallelogram, but recommends that its length should not exceed its breadth by above one-third, otherwise, he says, the beauty of the aspect will be diminished. Perhaps, however, the too frequent repetition of the rectilinear form in our edifices should be avoided, and particularly in country-houses; for, in these, the union of right lines with curves in the plan would create many pleasing varieties, and the inconvenience above-mentioned would be little felt.

General rules for division of houses.

The internal division of buildings, particularly dwelling-houses, may seem incapable of being reduced to rules on account of the infinite variety of situations, climates, and customs; and, perhaps, the only means of acquiring a knowledge of this subject will be to contemplate the plans of the most esteemed buildings which have already been executed. Nevertheless, as some general directions may be expected, the following are proposed; and they may perhaps teach the artist to avoid some improprieties in his designs, if they do not convey any positive information. Both the internal and external distribution of the parts should correspond with the character of the edifice; the divisions of a great edifice should themselves be great; of a small one, they should also be small; for it would evidently be highly improper to fill up a large building with small cells, or to have a large room in a little cottage. Again, it would be highly improper to fill an extensive façade with a great number of little windows, and equally so, to have great doorways and windows in a small house.

Externa dications the floo &c

When a building consists of two or more stories, the floors of those above the lowest should be indicated by the faciæ or entablatures over the corresponding Orders in the façade; and, in like manner, the vertical divisions of the façade should correspond with the places of the interior walls of the edifice. These correspondences cannot, however, in all cases, take place, because in the interior of a building there must be many divisions for domestic convenience which cannot be indicated in the front without impairing its majesty or beauty.

When an Order of Architecture is to be employed in

ice of
Order.

a building, it is evident that that must be chosen which corresponds with the nature and use, and which may appear to be an integral and essential part of the edifice. The columns and their entablature, being the principal ornaments in Architecture, should predominate over all other ornaments in the same building, and they should have sufficient magnitude to make them appear to have a real use; therefore, in small buildings, the regular Orders should not be employed, because they appear unserviceable, and their members become indistinct from their smallness.

ldings
out
mns.

Buildings of great importance and merit are frequently formed without columns or pilasters, which are generally considered as constituting the essence of an Order of Architecture; such buildings, however, admit of differences of style similar to those indicated by the Orders; for they may be either massive or light, or they may possess a character between both; and in those respects they may be compared, respectively, to the Tuscan or Doric, to the Corinthian, and to the Ionic Orders. The parts of which these simple buildings may be composed are basements, entablatures, and pediments, and they may be adorned with niches, balustrades, and various kinds of sculpture about the doorways and windows, according to the character of the edifice.

trances
dwell-
.

The entrance to a mansion should be in the middle of the façade, in order that the communications may be made with equal facility to all the extremities of the building. To form two in the same front would produce embarrassment to a visitor, because he may be in doubt which of them leads to the principal apartments; but, in buildings of great extent, it is usual to have three entrances, one of which is in the centre and the others equally distant from it and from the extremities; in which case the first should be more lofty and adorned in a manner superior to the others.

tibule.

The vestibule should occupy the centre of the line of building, and serve as a general passage to the stairs and apartments on the ground-floor; its form may be rectangular, polygonal, or circular; and if the first, it may be divided into three parts by two rows of columns, which, with their decorations, should be of stone, because the place is much exposed to the air by the frequent opening of the door.

rtments.

In dwelling-houses of considerable magnitude two sorts of apartments are necessary; one, appropriated to the family in general, consists of rooms of moderate capacity, and at a distance from the places occupied by the servants; each should be accompanied by an ante-room, bed-chamber, and dressing-room; and in the same part of the building should be the common dining and withdrawing rooms. The state apartments, which form the other class, are destined for the reception of company; these should be very spacious, and enriched with the highest degree of ornament: all these apartments should communicate with each other, that, on public days, the whole magnificence of the house may be presented at once to the view.

ortions
oms.

The proportion between the three dimensions of rooms are, at the present day, nearly the same as those assigned by Palladio; all rectangular figures, from a square to one whose length is to its breadth in the ratio of 1½ to 1, may be employed for the plan; a greater disproportion ought not to be admitted except the room is intended for a Gallery. Sir William Chambers makes the height various, and dependent on the plan; if this is a square, the proportion between the height and breadth may be between the ratios of 1 to 1¼, and of 1 to 1⅓; if oblong, the height may be nearly equal to the breadth, except in Galleries, in which the ratio of the height to the breadth may be between 1⅓ to 1, and 1½ to 1.

In great mansions, where the rooms are of different sizes, he observes that the heights should also differ; the halls, saloons, &c., should be more elevated than the other apartments, and may, in some cases, occupy two stories; the withdrawing rooms may have horizontal ceilings resting upon the walls; but rooms of smaller size, if they have the same height as those, should have their ceilings coved, or connected with the walls by portions of cylinders, concave towards the interior, in order to diminish the apparent height; where this is not convenient, it is usual, above the smaller rooms, to place *mezzanine*, which are convenient for many purposes.

The state bed-rooms differ from the other state rooms only in being less enriched with ornament; they should look towards the South, and the bed should be opposite the windows; each should be accompanied by an ante-room, dressing-room, and other conveniences, and, when they are made of a rectangular form, they should differ but little from squares.

Galleries.

Galleries are a sort of apartments, in mansions of the first class, for the exhibition of works in Painting and Sculpture, which are placed about the interior faces of the walls; they receive their light from a lantern extending the whole length of the apartment, and raised high enough above the ceiling to prevent the direct rays of the sun from entering the eye of the spectator, after reflection from the Picture, which would otherwise be indistinctly seen. It may be observed here, that the most perfect view of a Picture is obtained when the rays of light fall upon it in different directions, so that many of them may enter the eye in a slightly divergent state from every point of it; and it is to multiply the directions of the incident rays that the glass of the lantern is usually ground with a rough surface. These apartments are generally made much greater in length than in width; that of the Louvre, at Paris, is 1458 feet long and only 80 feet wide.

Stairs.

The construction of a good flight of steps is considered as one of the most difficult works of the Architect. It should be immediately seen from the vestibule, and may be placed either directly opposite, or on one side of the wall facing the doorway, according to circumstances. In large buildings it is frequently double, the two branches meeting on each floor at a sort of vestibule, in which are the doors to the apartments; and besides the principal staircase there is generally another for the domestics of the family.

The best form for a flight of steps is that in which the several inclined planes are rectangular with a square platform at every turn; the curvilinear forms are very inconvenient, because, in addition to the fatigue of ascending, the person is continually turning, and one end of each step being narrower than the other, a great part of its length becomes useless, because the person, for safety, keeps always in the broader part.

In the generality of mansions each step should be long enough to permit two persons to ascend or descend abreast, and, therefore, that length cannot be less than 6 feet; in mansions of a superior order it may be as much as 12 feet. The breadth of the step should be about equal to the length of the foot, and experience shows that, in ascending, it is not convenient to elevate the foot more than 6 inches, nor less than 4 inches; from these data such dimensions may be chosen as will be consistent with other circumstances.

Convenience and security require that the staircase should be well lighted; for this purpose the light should come either from the head of the steps or from the roof of the building, and, on this account, that staircase is the best which may be seen from bottom to top.

Doorways. Doorways, serving for the passage of men, horses, and carriages, should be from eight to ten feet broad, and they must have arched heads, because their breadths hardly permit them to be covered in any other manner. The doorways which are to serve for vestibules may, sometimes, have arched tops, but, generally, they are made rectangular; those which form the entrances to apartments in a house should invariably be so, and of sufficient size to permit any man to pass: that is, their breadths may be from 3 feet to 3½ feet; and the heights of all should be equal to about double their breadths. The Ancients made their doorways narrower at top than at bottom, and we find the same form often adopted in modern buildings; but the only advantage of it seems to be that the doors have the property of shutting themselves. The height of the aperture of a doorway on the exterior of a building should not exceed three-fourths, nor be less than two-thirds of the space between the pavement or floor and the architrave of the Order, in order that there may be sufficient room for the ornaments, and that the wall above the doorway may not appear too naked. The upper extremities of the doorways and windows in the same story should be in one horizontal line.

The decorations of a doorway consist principally in the jambs or side-pillars, and the lintel or architrave; the breadths of these members should depend upon the Order of Architecture employed in the lowest story of the building, as if the jambs were pilasters the heights of which are equal to that of the aperture of the doorway, and their mouldings should correspond with the character of the edifice: over the architrave of the doorway, as if it was that of a complete Order, it is usual on the exterior of a building to place a frize and cornice; the latter supported by consoles which should be placed on the exterior of the jambs, in order that they may not interfere with the latter; and above the cornice is sometimes placed a pediment.

In great mansions the doors of state apartments are generally made from 4 feet to 6 feet wide, with folding-doors, which are thrown entirely open on days of entertainment. When several apartments communicate together, the doors should be as much as possible in a line, in order to permit a free circulation of air when all are opened, and to give a splendid view of the apartments, by exposing the whole suite of rooms. To increase the effect, there should be a window at each end of the suite, facing the doors of communication.

Windows. Windows occurring more often in an edifice than any other object, it is of importance to establish their dispositions and proportions with as much precision as possible. It would seem, at first, that the superficial content of all the apertures ought to be proportional to the magnitude of the apartment; but it will be found, on consideration, that no such proportion can be universal, for it must vary according to the climate, and the exposure to particular points of the horizon.

Mr. Morris, in his *Lectures on Architecture*, p. 109, proposes, for ordinary-sized rooms, the length, breadth, and height of which are in the ratio of the numbers 5, 4, and 3, respectively, that the square root of the continued product of the three dimensions should be taken for the superficial content of all the windows in the apartment. Now, if we suppose all the windows to be formed in one of the longest sides, it will follow from the above rule that the superficies of the windows will be equal to about one-half of that of the whole wall in which the windows are contained; in general, it is equal to little more than one-third.

The breadths of windows should be every-where the same in the same building, but considerable variations are permitted in the heights, which are generally made proportional to the heights of the apartments; and this inequality of size is not considered as detracting from the harmony of the external elevation, perhaps, because custom and a consciousness of convenience has reconciled us to it. In large mansions, where the second or principal story is more lofty than the others, the heights of the windows may be 2¼ times their breadths; in the ground-floor, the height may be double the breadth; and if there is a story above the principal one, the windows in it may be squares, or nearly so. It must also be observed, that the breadths of windows should never be greater than that of the piers between them, lest the wall should be too much weakened; nor should it be less than half the breadth of the piers, in order that the apartment may not be too much darkened; and the distances of the extreme windows from the angles of the building should be rather greater than the interval between two windows, to ensure the necessary strength of the wall in those places.

In the principal front of an edifice it is recommended to have an uneven number of windows, because, as the doorway is or should be in the middle of the front, a pier would otherwise stand over the doorway, which is not admissible. According to Sir William Chambers, the sill of the window should be about 3 feet from the floor, in order to permit a grown person to lean over it, and the top should rise to about 2 feet from the ceiling, in order to leave just room enough for the architrave of the window and the cornice of the room. Those called French windows descend to the level of the floor of the apartment, and are very convenient when they open upon a balcony or a garden.

If a window is contained within a semicircular-headed recess, the breadth of the former may be from ⅗ to 4/7 of that of the latter, and its upper horizontal *moulding* should be on a level with the impost of the arch or foot of the curvature; the bad effect produced by raising it above this level is but too apparent in many of the buildings in London; and if internal convenience will not permit the top of the window to be kept at the proper height, it would certainly be better to form no recess. The window may be crowned by a pediment within the recess; but, in this case, the pediment should be rectilinear, as one of a circular form, not being concentric with the head of the recess, would ill accord with it.

The same kind of mouldings may be given to the windows as to the doors; except when the former are near the roof, in which case there should be no ornament about them, because it might interfere with the entablature of the building. All the windows of any one story should be similarly embellished, but this is by no means necessary with those of different stories; on the contrary, a variety in this respect will be pleasing. The sides of windows are generally splayed or formed obliquely to the front, so that the apertures are larger within than without, in order to give more light and space to the interior of the apartment. When the windows or doors have horizontal heads, and the work is rusticated, the joints are usually made to converge downward to the vertex of an equilateral triangle, the base of which is the top of the aperture.

Palladian or Venetian windows are convenient for giving light to a Vestibule, Staircase, or long Gallery; and, for this purpose, they are still sometimes employed.

hes.

Niches are formed for the reception of statues, either on the exterior or interior faces of the walls of an edifice; their plan is generally semicircular, and the soffit a quadrant of a sphere. The proportion of the height of a niche to its breadth may be the same as that prescribed for a window, and both features may have the same decorations.

When the façade of a building is adorned with circular-headed niches, instead of windows, the former are generally enclosed within a rectangle, having the same proportions and embellishments as the latter; the bottom of each niche should coincide with the base of the rectangle; but a certain interval should be left between the sides and top of the niche and those of the rectangular enclosure.

The interior of the niche should be always plain, as any ornament would partly destroy the effect intended to be produced by the statue; and the latter should be contained within the plane of the general face of the wall.

-places.

In Northern climates, the fire-place of an apartment is an important object, and its disposition and form require some precautions, in order that it may afford the greatest possible degree of comfort.

The best situation seems to be in the middle of that wall which is opposite the windows, because that side is warmer than the others; and, as it has been recommended to place the door in one of the walls at right angles to this, the persons seated about the fire will not be so much annoyed by the cold air introduced on opening the door, as they would be if the fire-place were in any other situation; nor, by this disposition, is the smoke so likely to descend into the room on suddenly shutting the door. The fire-place should never be between the windows, because the recess and funnel would weaken the wall on that side of the house, and the opposite wall of the room would be wanting in ornament.

The aperture of the fire-place should bear some proportion to the size of the room; in ordinary rooms it is a perfect square, in small ones its height is greater than its breadth, and in large ones, generally, the contrary. In the smallest apartments, the width of the aperture is never less than 3 feet or 3½ feet, but, in others, it may be from 5 feet to 5½ feet; and when the room is of such magnitude that one fire-place is not sufficient to give warmth to every part, it is customary to construct in it two, directly opposite to each other.

On the Continent, and in some old English houses, the fire-place projects into the room, but this produces a mean effect; when, however, from the thinness of the wall it is unavoidable, the parts on each side should be occupied by closets; and when several fire-places are situated one above another in different stories, the flues should be parallel to each other, but without any communication, because the smoke from one flue would enter the other by the aperture, and descend into the room. The tops of chimneys must be raised above the roof of the house, and should be concealed, if possible, by the balustrade.

The decorations of fire-places are similar to those of doorways or windows; the jambs consist either of faciæ plain or sculptured, or they are ornamented with columns, pilasters, or Caryatides; above is an architrave, which is frequently surmounted by a frize and cornice, and the upper surface of the latter forms a shelf.

Manner of ornamenting the interior of a building.

In buildings of great magnificence, the interior is frequently decorated with the Orders of Architecture, as well as the exterior; and propriety teaches us that the interior Order ought to be the same as the exterior one on the same story, though the Ancients did not always attend to this principle. The interior faces of the walls are usually adorned with half-columns or pilasters, between which, in the lowest story, are niches; frequently, a portion of the apartment is separated from the rest by a screen of columns, and the upper part of the wall is terminated by an entablature on which rest the beams of the ceiling. An objection has been made to the employment of a cornice in an interior entablature, because its projection, which was intended to protect the lower part of the wall from the rain falling on the roof, is not required where no rain can fall; nevertheless, custom seems to have authorized this deviation from propriety, and the practice has, in some cases, a plausible reason in its favour, since it may be supposed to present a broader bearing for the timbers of the ceiling than would be afforded by the tops of the walls alone: the same reason, however, cannot be given for the introduction of triglyphs and guttæ, as ornaments in such a situation.

When the pavement in one part of the interior of a building is lower than in another, the columns, in the lower part, may stand on pedestals, in order to bring their bases on the same level as those on the higher pavement; in other circumstances, pedestals are unnecessary in the interior, and they are even inconvenient, since they take up more space than can, generally, be afforded. Sir William Chambers considers the plinths of columns in apartments to be also unnecessary, because the pavement will protect the columns from the dampness of the ground, to do which was the original intention of the plinth. Columns cannot with propriety be placed on inclined planes, as along the sides of a flight of steps, because the abaci and plinths, being horizontal members, can only be adapted to such situations by placing a block above the one and under the other with oblique surfaces to suit the contiguous planes, and this gives the columns an appearance of great instability.

In ordinary apartments, the faces of the walls are usually ornamented to represent those of an entire building, with what propriety it may be difficult to say. The lower part has the appearance of a continued podium standing on a plinth, and terminated by a cornice, or, as it is called, a surbase moulding, at about 3 feet from the floor; and the face of the dado is generally ornamented with square panels: the wall above the dado is also ornamented with panels, the breadth of which is equal to that of the panels below, but their height is much greater, since they extend nearly to the ceiling; a cornice is formed at the junction of the walls with the ceiling, so that even in such apartments the idea of an Order of Architecture is preserved, the styles or vertical portions between the panels being supposed to represent columns or pilasters.

Ceilings.

The manner of ornamenting the ceilings of rooms at the present time does not differ much from that practised by the Romans. In lofty apartments, the ceiling is composed of beams framed into each other, so as to form square or polygonal compartments; the sides of the beams are generally adorned with mouldings, and the soffits with guilloches or fretwork; and the surfaces of the compartments with paintings or bas-reliefs, representing figures, foliage, festoons, and the like. When the rooms are low, the ornaments may be in painting or stucco, and the mouldings must have small relief, but they should be well executed, on account of their being near the eye of the spectator.

In mansions of a superior character, the ceilings are sometimes coved; the horizontal part, which, generally, then, forms a large panel, being joined to the walls by portions of elliptical or circular cylinders; the curved part rises from a little above the cornice, and terminates on the margin of the panel.

The soffits of arches are frequently enriched with guilloches or frets, when narrow; but, when broad, with panels, the surfaces of which are adorned with various devices.

CHAPTER X.

Proportions and Distribution of the ornamental Features of Edifices.

Proportions of the columns.

The Orders of Architecture have suffered little modification since the revival of the Roman style, and, from a comparison of many of the best examples executed within the present century, we may consider the heights of columns, when expressed in terms of their diameters, to be fixed as follows. In the Tuscan Order, seven and a half diameters; in the Doric Order, eight; in the Ionic Order, nine; and, in the Corinthian and Composite Orders, ten diameters. In the first three Orders, the heights of the capitals may be each equal to half a diameter, and, in the last two, to an entire diameter; and, except in the Doric Order, which has no base, we may consider the heights of the bases to be equal to half a diameter.

Diminution of the shaft.

The difference of the upper and lower diameters of a column is now usually made equal to one-sixth of the latter; but, if we express the difference of the semi-diameters in terms of the length of the shaft, we shall have for the diminutions in the different Orders $\frac{1}{78}$, $\frac{1}{90}$, $\frac{1}{96}$, $\frac{1}{102}$, $\frac{1}{102}$, respectively; from which it is evident that, in the more delicate Orders, the inclination of the side of the shaft to the axis is less than in the more massive, and the diminutions are inversely proportional to the heights: but, by the laws of Optics, the apparent diminutions of the columns bear some ratio to the elevation of their summits above the eye; consequently, the greater apparent diminution of the higher columns is, partly, at least, corrected by a smaller real diminution. The celebrated Mathematician, La Grange, had the curiosity to ascertain, on analytical principles, whether the practice of enlarging the soffits of the columns at about one-third of their height, according to the supposed precepts of Vitruvius, had a tendency to increase their capabilities of resisting compression in the direction of their length; but his investigations terminated in the proof that a cylinder is the figure which, with an equal quantity of material, presents the greatest resistance; consequently, the enlargement of the columns, if it could be supposed to give elegance to their appearance, adds nothing to their strength.

Proportion of the entablature.

The entablature being borne by the columns, its mass should evidently bear some proportion to theirs, and this is accomplished by making the height of the former depend upon the diameter of the column; for then, if the heights of the columns in all the Orders were made equal, the heights of the entablatures would differ in the same proportion as the diameters, and the more slender columns would have the lower entablatures; consequently, the burthen they have to sustain would be nearly proportional to their strength. This rule of propriety is, evidently, not observed when the height of the entablature is made to depend on the height of the column in all the Orders, as prescribed by Palladio; for, by such means, the burthen bears a higher ratio to the magnitude of its support in the more slender, than in the more massive Orders: as far, however, as appearance is concerned, this evil is, in part, removed; for the richer Orders, having their entablatures broken into a greater number of parts, the apparent heaviness of these members is thereby lessened, and they approximate to the delicacy which should characterise them in those Orders.

Architects of the present day assign to the entablatures in the different Orders heights which vary from 1¾ diameters to 2½ diameters; and the heights of the architrave, frize, and cornice are, generally, in the proportion of 3, 3 and 4, respectively; except in the Doric Order, in which the terms 2, 3 and 3, more commonly express the relative heights of those members.

Improbability that a new Order can be invented.

It has been gravely questioned whether it is possible to invent a new Order of Architecture; and if we consider the attempts that have been made at various times to produce one, and the number of Ages during which the principal Orders already existing have enjoyed universal approbation, we may feel disposed to answer in the negative; perhaps, therefore, an artist would be hardly justified in spending time in an effort so unlikely to be attended with success. No one can deny that it may be possible to give new proportions and new ornaments to the members, but no one is willing to admit that any or all of these will constitute a new Order; such must not only differ from others in the above respects, but it must also possess beauty, and produce in the mind of the spectator a perception of novelty. Even those which are called the Tuscan and the Composite Orders do not universally meet with a favourable reception, and many artists hesitate to consider them entitled to an existence independent of the others. Perhaps the only thing that can be done is to seek in Nature for new ornaments which may be applied to the parts of an Order already in use; the bases, capitals, and entablatures may by such means receive improvement; the shaft seems to admit of none, because its greatest merit consists in the smoothness of its surface, or in the very simple modification produced by channelling.

Gener rules app

The beauty of a composition depends upon the arrangement of its parts and mouldings, in which this general rule should be followed, *viz.* that the straight and curved lines which their sections form should succeed each other alternately, the eye being then able to enjoy the effect of ornament without confusion. In each member there should be one governing feature, to which the others should be subservient; this should generally be some principal moulding which, being caught by the eye, affords a good indication of the use of the whole member, and thus assists the spectator in apprehending the form of the work; and the subordinate members should be such as appear to be intended either to support, strengthen, or protect the principal one: thus, in the cornice, the corona is the principal member; the modillons and dentels are ornaments connected with it; the ovolo supports them; and the cymatium crowns them. The curvilinear mouldings may, in general, be ornamented with sculpture, but the square members, being commonly employed to give distinctness by separating the others, should be left plain, in order that they may more effectually perform their office.

isposition
the orna-
ents.

The greater ornaments should be disposed with a certain regularity, and, in conformity with their intention; thus the middle of a mutule and triglyph, of a modillon and a dentel, should be placed in a vertical plane passing through the axis of each column; exception being made in favour of the Grecian practice, which, in the Doric Order, required the triglyphs at the extremities of the frize to be placed close to the angles, and thus destroyed the regularity of the ornaments, and even of the intercolumniations. This circumstance, however, is only permitted on account of the predilection which the mind feels in favour of the works of that interesting people; for any such liberty in a style of modern invention would be highly reprobated.

asement,
nd the
anner of
nament-
g its front.

Anciently, the basement of a building was a sort of platform elevated a few feet above the level of the ground, and serving as a general plinth or pedestal to the whole building. Round the Temples or porticos of the Greeks and Romans the sides of the basement were, generally, as we have seen, cut in the form of steps, to give access to any part of the colonnade above; and, when those sides were formed by vertical walls, they were without ornament. But the name of basement is now given to the lowest story of an edifice in which there are more than one; and this story being of considerable importance, it becomes necessary to give it a certain degree of embellishment. When any of the apartments for the family are in the basement, this story should be as high as two-thirds of the whole Order immediately above; but when it contains only offices, it may have but half that height. It should never be higher than the Order above, because the latter is always the principal part of the edifice.

The face of the basement, and, it may be added, of the whole building, is frequently distinguished by rustic work; which, originally, consisted in leaving the exterior face of the masonry rough, probably to save expense and time; but sometimes now it is, by way of ornament, purposely executed in imitation of a material so left. Stonework marked in this manner conveys an idea of strength, and it seems most properly to be applied about the gates of Fortresses, the entrances of Prisons, and, in fact, on every building the aspect of which should be rude and strong: it may also be employed on walls rising from a river, or from the sea-coast, as it then gives them the appearance of having been cut from the natural rock.

A work is also said to be rusticated when the faces of the stones are smooth, but the vertical and horizontal joints are marked by channels; and the term is likewise employed when only the stones at the angles of the buildings are so marked; in these cases, the length of each stone between two vertical joints should be three times the height or distance between the horizontal joints. The profiles of the channels are sometimes rectangular, and then the breadth and depth may be each equal to one-eighth or one-tenth of the height of the course; but in the more massive works they are triangular, the rentrant angle being a right angle, and the breadth of the channel from one-fourth to one-third of the height of the course. Occasionally, the vertical channels are omitted, and this kind of work is called French rustication; but it seems less proper than the other, because it takes away the character of masonry, and causes the building to appear as if made of planks.

An arcade is frequently formed in the basement story of an edifice, in which case, instead of an entablature, the story is crowned by a projecting facia, either plain or ornamented with simple mouldings; the height of the facia should be about equal to that of the horizontal courses of masonry, the imposts of the arches may be of the same height and form, and the plinth may be rather higher.

Attic story.

The upper part of an edifice is generally terminated by what is called an Attic Order, consisting of a wall, the height of which is about one-third of that of the Order above which it is placed. The Attic wall is either continuous, with a simple base and entablature resembling those of a pedestal, or it is interrupted at intervals by small pilasters which are sometimes ornamented with bas-reliefs; the dado between the pilasters is also frequently embellished with sculpture or inscriptions. The breadth of the Attic pilaster should be the same as the upper diameter of the column or pilaster below, and its projection should be one-fourth of its breadth. In the interior of a building, when vaults spring from the walls, there is usually employed what is called a false Attic; that is, a sort of continuous pedestal, which is intended to elevate the springing of the arch above the entablature of the walls.

Employment of
Orders in
the front of
a building.

The use of the Orders of Architecture is, undoubtedly, to embellish the exterior of an edifice; and Nature indicates that, when the building consists of but one story, only one Order should be employed; for either the columns of one Order must be higher than those of another, and then the entablature of the shorter columns will be interrupted by the shafts of the others; or, if the heights of the columns of the different Orders are equal, one will appear more slender than the other, and, consequently, unfit to bear the weight which is adapted to the strength of the other; this misapplication of the Orders is, however, very common, and occurs in some of the most magnificent buildings of Europe. But when the building consists of several stories, it is reasonable that a different Order should be employed in each story; and there is no impropriety in employing one or more of the Orders of Architecture in the superstructure of a building when the basement has an arcade in front, since a range of arches has been found to have sufficient strength to support any edifice which it may be convenient to place over it.

A colonnade with its entablature indicating the construction of a whole edifice in itself, it is evident that, where two or more are placed in altitude, there is conveyed a perception of as many edifices piled one on another. Now there is no impropriety in this, when the magnitude of the edifice seems to require it, but it is evident that the design should be formed with regard to the unity of the whole system.

Application of the Orders in tiers.

It has been observed, (in part ii. chap. vii.,) that the strongest Order should be placed lowest in the edifice, and that the others should diminish in strength progressively upward; it will follow, therefore, that the Tuscan or Doric may be employed on the ground story, the Ionic above this, and the Corinthian or Composite may crown the whole. If a heavy Order, like the Doric, were placed above a light one, such as the Ionic, it is evident that there would be produced, if not a real, at least an apparent weakness of construction, and both are equally improper. The repetition of the same Order in two stories of the same building should be avoided, because it would produce an uniformity which is not pleasing; and, since an abrupt transition from one extreme to another is equally disagreeable, it is evident that an intermediate Order should not be omitted.

There is also an impropriety in giving a cornice to the entablatures of the lower Orders in a building composed of several; first, because their projection will conceal the lower parts of the columns or apertures above, from the view of a spectator below, and thus alter their apparent proportions; and, secondly, because a cornice indicating the crowning or upper member of an edifice, should be reserved for the superior Order alone. Architraves and frizes will suffice to form the entablatures of the other Orders, and mark the situations of the intermediate floors.

Lastly, when the columns are detached from the wall, it is an obvious principle that the axes of all should be placed in one vertical line, the stability of the building absolutely requiring that whatever supports a member should be itself supported. When the columns are attached to the face of the wall, an adherence to this rule is of less importance, because the upper members of the edifice are less supported by the columns than by the walls below; in this case, it will be sufficient to make the axes of the columns appear to correspond when viewed in front; and if the upper part of the building is made to retire from the lower, so as to assume a form approaching to that of a pyramid, the columns must retire also, as is the case with those in the upper Order of the Theatre of Marcellus; but the amount of this recession should not be considerable, and perhaps it should be only so much that the front of the plinth of the upper column may be vertically over the face of the top of the shaft below it.

Proportions of columns in tiers.

According to Scamozzi, the lower diameter of an upper column should be equal to the upper diameter of the column below it, as if the whole system of columns standing in a vertical line was one long column cut horizontally at the different floors of the building. This rule, which is derived from that given in the Vth Book of Vitruvius, seems well founded in Nature; and, if the heights of the several columns be determined by the lower diameters of the shafts according to the rule for each Order respectively, and, at the same time, the diminution of each shaft, instead of being in a constant ratio to the lower diameter, were made variable, increasing with the delicacy of the Order, by making it equal to $\frac{1}{8}$, $\frac{1}{7}$, or $\frac{1}{6}$ of the lower diameter in the Doric, Ionic, and Corinthian Orders respectively, as proposed by Milizia, *Principi di Architettura*, p. 149, it will be found that those inconveniences mentioned (part ii. chap. vii.) are in some measure obviated. The breadths of the intercolumniations in the different Orders remain nearly proportional to the heights of the Orders, and the triglyphs and modillons admit of a regular distribution; but, on account of the increase of the intercolumniations in the upper Orders, it will be hardly convenient to have more than two Orders in the same front.

The columns of the upper Orders may be placed on continuous pedestals, or on plinths, high enough to permit the bases of the columns to be seen from below over the projecting members of the entablature. These plinths are preferable to isolated pedestals, because the latter will appear too heavy; but when two tiers of arches are employed, the height and breadth of the apertures above being greater than those below, in order that the upper piers may not appear clumsy, it may be necessary to give pedestals to the columns which adorn the piers, so that those columns may have sufficient height; and, in this case, the cornices of the pedestals should not be continued on the faces of the piers, because the sides of the latter ought to appear uninterrupted from top to bottom.

Intercolumniations.

The different species of intercolumniations employed in the works of the Ancients have been already stated; it remains, therefore, only to explain the practice now generally followed in disposing the columns. When columns or pilasters are near, or are attached to the faces of walls, it becomes necessary that the intervals should be regulated by the breadth of the windows, doors, or niches, the exteriors of the jambs of which should be nearly in vertical planes passing through the sides of the plinths of the columns; at least those jambs should not be concealed by the columns, since the wall would then appear to want solidity. In peristyles and porticos the intercolumniations are either diastyle or eustyle; except when the Doric Order is employed, and then, Sir William Chambers prefers the ditriglyph intercolumniation, or that which admits two triglyphs over the interval. In a portico, the middle interval should be broader than the others, in order the better to distinguish the centre of the façade; but when the columns are coupled this rule may be dispensed with, because the variety would then become too great, and create confusion in the appearance.

Employment of coupled columns.

There are many cases in modern Architecture in which coupled columns or pilasters may be employed to advantage: first, when a line of building is pierced by windows or niches at distances from each other too great to permit the wall to be sufficiently covered by a single column; again, when a front is occupied by single columns, the piers at the extremities being generally wider than those between the windows may require coupled columns, or pilasters, or a coupled column and pilaster, to make their degree of ornament correspond with that of the other piers; and, lastly, when an Order of columns is placed above an arcade, and the width of the piers between the arches is considerable, those columns may be coupled, to procure a breadth of ornament corresponding with that of the pier below. In general, the pairs of columns are situated in a vertical plane coincident with the architrave, but in the interiors of vestibules or courts, we frequently find them disposed in planes at right angles to the entablature they support, in order to unite strength with lightness.

The plinths of the columns in each pair may be brought quite in contact with each other, but it is necessary to avoid making the mouldings of the bases, or the ornaments of the capitals, intersect each other, as this would create a confused appearance, and spoil the effect; still less should it be permitted to make one shaft unite with the other, as is done in the Gothic, and some of the Roman works. The chief difficulty which arises from coupling the columns in the direction of the length of the building is the irregularity it produces in the disposition of the triglyphs and modillons, which can hardly be made to correspond with the centres of the intercolumniations and with the axes of the columns. An approximation, however, must be made to this by altering the intervals of those ornaments in such a way that their deviation from the general rules may be as little perceptible as possible; and the method of doing it is fully detailed by Sir William Chambers in his *Treatise on Architecture.*

asters.

Pilasters are still frequently employed in buildings where columns would be too expensive or inconvenient: they serve the same purposes as columns, and, in modern works, they have, generally, the same proportions and mouldings.

Scamozzi recommends that the shaft should project from the face of the wall so much as one-quarter of its breadth, in order to give it a bold appearance; and that, when it is of the Corinthian Order, the leaves on the flanks may be cut exactly in the middle. But if the imposts of arches, or the cornices of windows or doors, occur between the pilasters, the projections of the latter should be greater than those of the former, in order that the face of the pilaster may not appear to be broken by them.

The reasons which are given for diminishing columns may serve also to justify the diminution of pilasters; *viz.* the pleasure produced by that form, and by the good proportion of its capital, which, without the diminution, would appear too heavy; but when the faces of the pilasters are to be fluted it will not be convenient to diminish them, because the oblique directions of the channels on a plane face would produce a disagreeable effect. The capitals of Ionic pilasters are to be formed with oblique volutes, and agreeably to the rules given for the Ionic columns, in order to permit the ovolo to pass between the interior curl of the volute and the top of the shaft.

Pilasters are no longer placed at the extremities of the front of a portico, because the difference of their apparent thickness, when viewed in front and diagonally, renders it impossible to make their proportions harmonize with those of the columns: but, at the extremities of walls, or at the quoins of buildings, they are sometimes more convenient than columns, because the angle of the entablature projecting beyond the face of the column seems to hang in the air unsupported, when seen obliquely. And when a portico is formed by columns in advance of a wall, it is usual to place pilasters behind them against the face of the latter, in order to serve as a support for the entablature on the flanks; this, however, should be dispensed with when the depth of the portico is small, because of the confusion arising from the mouldings of the columns and pilasters being blended together.

als.

The employment of pedestals by the Ancients has been already mentioned, and we purpose, now, only to show in what cases they are admissible in modern Architecture. When a portico is elevated upon a basement, and a balustrade, serving as a fence, is required for the safety of the persons within, the columns may be raised on pedestals, because the base and cornice of the balustrade can be made to unite with those of the pedestal, which they could not do with the shafts of the columns; and, in this case, the breadth of the dado may be about equal to that of the plinth of the column above it. Palladio makes the height of the pedestal equal to one-fourth of that of the column, and this seems to be the proportion generally followed in the present practice. Pedestals are again admissible when the pavement within or about a building is not on the same level, in order to raise the bases of all the columns to an equal height; and in our Churches, Theatres, and Courts of Justice, pedestals are also necessary to allow the bases of the columns to be seen above the pews, or the heads of the persons assembled.

The objections to pedestals are, that they take from the columns that air of majesty which should accompany them; they diminish the intercolumniation; the angles of their cornices are liable to be destroyed; and, when they are attached to the faces of buildings, their mouldings do not accord with those on the lower parts of the walls.

Employment of arcades.

The wish to avoid the expense of columns for the support of an incumbent mass of building, and to procure larger apertures than could be obtained by them, led, no doubt, to the employment of arches. In ancient buildings, the intrados or inferior curve line of the arch was always semicircular, and the sides of the voussoirs were made to tend to its centre: at present, since, in many cases, very wide spaces are to be covered, and it is inconvenient to give great height to the crown of the arch, the semicircular form often becomes inadmissible, and one approaching to an ellipse or cycloid is adopted; on the other hand, where the required height is greater than half the span or chord of the arch, a parabolical form has been employed. The construction of arches, and the conditions requisite to procure an equilibration of the materials composing them, are given under Bridge, in our *Miscellaneous Division;* we, therefore, confine ourselves here to their application, as ornamental features, in the façades of buildings.

Proportions of arches and piers.

To obtain a pleasing effect, when arches are so employed, Architects recommend that the height of the aperture from the pavement to the crown should be about double its breadth, and that the breadths of the piers should vary with the Order employed in the building; according as the Order is Doric, Ionic, or Corinthian, those breadths may be respectively two-thirds, one-half, and one-third of the breadth of the aperture, and when no Order is employed, the breadths of both may be equal. The thickness of the piers may be about one-third of their breadth.

In edifices of great magnitude, the arch-stones appear in their simple state; and if the façade of the building is rusticated, their joints are also marked by grooves; but in highly-ornamented works the archivolt or exterior face of the arch is enriched by mouldings, and the key-stone, or voussoir at the vertex, is generally sculptured. The line of voussoirs sometimes rises from the top of the pier without any thing to mark its commencement, and, in other cases, an impost, either plain or adorned with mouldings, serves to distinguish the top of the pier from the foot of the arch; the breadth of the archivolt and impost may each be equal to about one-eighth of the breadth of the aperture.

Application of columns or pilasters to arcades.

Columns or pilasters may be employed to ornament the faces of walls in which arches are formed, and, in this case, they should have the appearance of supporting a horizontal entablature above the crown of the arch. The columns should project before the walls as much as one-half, or even three-quarters of a diameter, and the breadth of the pier on each side should, at least, be equal to half a diameter, that the supports of the arch may appear to have sufficient solidity. There should also be some distance between the top of the archivolt and the architrave of the Order, for the wall has an appearance of weakness if the latter rests immediately on the crown of the arch.

The adaptation of the Doric Order of columns to an arcade is a work of some difficulty, on account of the widths of the arches not corresponding to the exact space which any number of triglyphs should occupy; the means proposed have been, first, to diminish the breadths of the triglyphs and metopes; secondly, to increase the heights of the columns by raising them on plinths; or lastly, to omit the triglyphs entirely.

Pediments.

Pediments are the triangular spaces formed at the extremities of a building between the horizontal cornice and the inclining sides of the roof. it is evident, therefore, that they can only be used with propriety at the summit of a building; but, because the windows and doors are surrounded by mouldings which project beyond the face of the wall, it is customary, also, when they are not near the roof, to form small pediments over those apertures, in order to throw off the rain; and, for the sake of variety, when several windows are placed in a row, the pediments are alternately in the form of a triangle or of a segment of a circle. The taste for variety might, perhaps, be correctly indulged this far; but the insatiable desire of novelty has led men to adopt forms which are utterly irreconcilable with any notion of propriety; the first example of which is, perhaps, the interrupted pediment in the ruins of Balbec. In later times, the sides of these broken pediments have been made in the forms of right lines, arcs of circles, or curves of contrary flexure; and Sir William Chambers observes, that they have been formed of two half-pediments with the summits outward. Every attempt to refine upon that form which corresponds to the original intention of the pediment, destroys its effect by causing it to appear useless; for this reason, it is highly improper to omit the horizontal entablature, or even to break it vertically, as is sometimes done.

Proportions of pediments.

Buildings of a curvilinear form on the plan do not admit of a pediment, because the roof can have no such termination; neither can a pediment be introduced in the interior of a building because there is, there, no rain to be thrown off; and it is, evidently, equally absurd to form, on the exterior, one pediment above another, since it would convey the idea of a roof placed over a roof.

Architects differ greatly on the subject of the proportions of pediments, some considering that the inclining sides of all pediments, great or small, should form the same angle of inclination with the horizontal cornice; but Sir William Chambers observes, that one with a short base should be proportionally higher than one the base of which is long, otherwise the tympanum will afford no plain repose for the eye; and, on this principle, he proposes that the height of the apex of the fillet under the cymatium should vary from one-fifth to one-fourth of the base, according to the extent of the latter: it is evident, however, that this proportion can only apply to buildings in which the Roman character is preserved.

When the pediment covers the whole front, there is a difficulty in connecting the inclined cymatium of the pediment with the horizontal one on the flank of the building; because, if both have the same profile, the former is higher in the vertical direction than the latter. To remedy this fault, some persons break the inclined cymatium at the foot, and give the lower part a horizontal direction, in order that it may coincide with the flank cymatium; but this appears a deformity, and Sir William Chambers recommends making them coincide by diminishing the projection of the latter.

Ornam in pe- ments.

If we adhere to the prototype of a building we should say, that as there can be no joists nor planks in the roof above the frize, when the building is covered by a pediment, there ought to be no modillons nor dentels in the horizontal cornice of that member; such ornaments, however, are constantly employed in that situation. Parallel courses of longitudinal timbers above the rafters are also represented by modillons on the sloping sides of the pediment, and are made to stand vertically over the modillons of the horizontal cornice. The face of the tympanum is in a plane coinciding with that of the frize, and, in the manner of the Ancients, it is still adorned with sculpture. At each foot, and at the vertex of the pediment, are usually placed acroteria, or pedestals for statues or other ornaments, the height of which should be regulated by the possibility of seeing those ornaments from the proper point of sight on the ground.

Balustr

Balusters were, originally, a sort of dwarf-columns employed to enclose a space within the interior of some building, or to surround an elevated platform which was intended for a promenade; but, subsequently, they were also used as ornaments on the tops of buildings. Their general form is that which has some resemblance to a pear, with a simple astragal above and below the swell; each has a square plinth resting upon a continued podium, and, at top, is an abacus supporting the general coping of the balustrade. Sometimes, however, each baluster resembles two of the above kind joined base to base, and these, being lighter than the others, are employed in the more enriched works. In most cases they should be about 3 feet or 3½ feet high, so that a man may lean on them; but, when they are placed on the tops of buildings for ornament, or on bridges for the prevention of accidents, they should be higher.

When balusters are applied to a row of arches, they should be placed within the apertures of the latter, in order that they may not interfere with the faces of the piers; the cornice must be on a level with the tops of the pedestals supporting the columns which are attached to the piers, and both that and the base should have the same profile as the corresponding members of the pedestals. On inclined planes, the abaci and plinths of the balusters should have the form of frusta of wedges, that they may be adapted to the plane; but the mouldings should always be horizontal.

Emplo ment o Order circul irregu buildi

The Grecian and Roman Orders of Architecture seem ill adapted to buildings of a curvilinear or polygonal form; for the lateral faces of the abaci and plinths, which should be at right angles to the others, become oblique to the wall; or, if those faces are made perpendicular to the latter, the plans of the members become trapezoids, and, therefore, do not harmonize with the circular mouldings of the bases and capitals. And when columns are disposed in the circumferences of two concentric circles, they not only produce a confused appearance when seen from any point but the centre, but a great embarrassment arises from the intercolumniations in one circle being too great or too small, when those in the other are made conformably to the rule; it has been attempted to palliate this last evil by giving a small increase to the distances of the columns in the exterior circle, and contracting those of the other columns as much as that excess.

When a column is placed at an oblique angle either on the exterior or interior of a building, a certain irregularity is produced in the base and capital; and, to avoid this, it has been proposed to place there a pilaster broken longitudinally in the middle, and forming a face on each side, the breadth of which has the regular proportion to the height; others recommend that there should be no column or pilaster exactly at the angle, and that the last one on each face should be brought as near as possible to it, by which means the want of solidity there will be scarcely sensible.

es.

After the return to the Architecture of Greece and Rome, the prejudice in favour of lofty Churches, which had prevailed in the Gothic times, continued in force; and as this could not be obtained where the roof is supported by columns, the heights of which are limited by the proportions they should bear to their diameters, it was necessary to raise an edifice above the general roof; and thus the dome, mounted on a high cylindrical wall and strengthened or ornamented by columns, may be considered as replacing the Gothic tower over the intersection of the nave and transept. This construction does not involve any great deviation from good principles; but when a low dome is formed over a building which has already a pediment-roof, as is generally the case, it is liable to some objection, because the pediment represents the finish of the building, and the dome becomes superfluous.

In order that a considerable portion of the exterior of a dome may be seen from the ground, and thus produce a good effect, it should be of a spheroidal form with the longest axis in a vertical position; but in the interior this is not necessary, and the deep concavity of the spheroid would even take off from the beauty of the feature by giving it too much the appearance of an inverted well, therefore a hemispherical form is, here, more proper: and it was to obtain both external elevation and internal elegance, that the triple domes of the French Churches, and that of St. Paul's, in London, were constructed. With respect to the double, and nearly concentric domes at Florence and Rome, they have been made to unite lightness with strength; to prevent the humidity of the external air from affecting the paintings on the concave surfaces of the inner ones, and to permit a covered communication from the base to the lantern.

CHAPTER XI.

Materials employed in Buildings.

tra-
ra-
f
t and
s
gs.

It has been commonly observed that the edifices of the Ancients far exceeded those of the Moderns in durability, and the observation has some appearance of truth if the comparison is made between the Grecian or Roman Temples and the dwelling-houses of the inhabitants of modern Europe; but its justice may be doubted in almost every other case. It must be admitted that the Ancients spared neither labour nor skill to construct edifices which should triumph over every accident, and the walls and columns of some of them have stood more than two thousand years, in spite of the injuries of climate and the efforts of Man to destroy them; but it cannot be denied that many of our Churches, Bridges, and other public works possess the quality of stability in an eminent degree, and promise to attain an age equal to that of the edifices of antiquity. The dwelling-houses of the Ancients seem to have had no better pretensions to durability than our own; for, except those which have been preserved under the volcanic matters which overwhelmed them, they have all long since disappeared. And it may be alleged in excuse for the slender construction of modern houses, that their frequent renewal affords opportunities for improvement in taste and execution, which would have been wanting if the works had been originally made more durable.

The Gothic Cathedrals of our ancestors seem, at first sight, far inferior in stability to the Heathen Temples of the Ancients; but this apparent weakness results only from their forms; the area of the horizontal section of a clustered pillar often exceeds that of the most massive of the Grecian columns, though it has a much lighter appearance; there is consequently a probability that it will have a more than equal durability. The roofs and ornaments of our Cathedrals may speedily fail, if not repaired, but the roofs of the ancient Temples have also disappeared; and even the fine climate of the South of Europe has not entirely spared the sculpture which adorned those buildings.

An Architect should be acquainted with the qualities and stress of materials.

The first essential, however, in the security of an edifice is the choice of such materials for its construction as are best capable of resisting the stress and strain to which they are liable; and a knowledge of the nature and properties of bodies, and their capabilities of resisting extension or supporting compression in every direction, is indispensable to every one who aspires to the name of an Architect. This may be added to the other qualities enumerated by Vitruvius.

Since all materials do not possess the same resisting power, and those of the same quality are not equally good for all sorts of work; it is evident that one circumstance to be attended to is the placing materials in such situations that the weaker may be subject to a less degree of force than the stronger. In an edifice too, some parts, as the foundations and lowest parts of walls, have to sustain pressures in vertical directions; others, like the piers of arches and domes, have to resist pressures laterally; some bodies, like the tie-beams in roofs, are subject to the strain of extension; and, lastly, others, such as vaults, roofs, and ornaments, are themselves supported. It is of importance, therefore, to ascertain the species of force to which the part of an edifice will be subject, in order that opposing forces may be applied to it in the proper directions; and the degree of stress or strain must then be determined that the resistance may be adequate to it.

In a general Essay, like the present, it will be evidently improper to enter into a full explanation of the nature of minerals, woods, and metals; such knowledge is not absolutely necessary to an Architect, and we, therefore, confine ourselves almost wholly to an enumeration of those materials which are principally employed in building. The equilibrium of the parts of an edifice is, also, too extensive to be introduced in this place.

Marble.

Marble is a calcareous material forming simple mountain rock; it is of various colours, as white, yellow, grey, green, and red; its structure is always granular, and its uses for statuary and ornamental Architecture are well known. The purest kind is that obtained from the Island of Paros, in the Archipelago, but much use is made of that from Carrara, in the Apennines. Marble, also, of various qualities, abounds in Scotland and in many parts of the Continent of Europe.

Granite.

For those rude works which are to endure for Ages, as bridges, prisons, and the like, granite is the material which should be employed, but its great hardness, and the consequent expense of working it, render it inapplicable to buildings which are embellished with an abundance of sculpture. An inferior sort of granite is brought from Cornwall, but that which is chiefly employed in this Country is obtained from Scotland, and the Aberdeen granite seems to be particularly valued for its hardness, beauty of colour, and capability of taking a fine polish. Some granites have the quality of resisting the action of air for thousands of years, but there are others which are speedily decomposed by it, and reduced to gravel and sand; and this difference of quality is sometimes observed in contiguous portions of the rock.

Portland stone.

That which is called free-stone is chiefly calcareous, but it is often compounded of calcareous, silicious, and argillaceous materials, and it has obtained its name from the facility with which it may be wrought. The best is that which comes from the Island of Portland, which has the quality of resisting corrosion from exposure to the air. It has been in great request in England since Sir Christopher Wren employed it in the numerous edifices which he raised after the fire of London, and it is used in almost every department of the building Art.

Purbeck stone.

The Island of Purbeck furnishes a species of stone, composed of marine remains cemented by calcareous spar. It is harder than Portland-stone, and consequently less easily wrought; being inferior to granite, it is less frequently employed, and chiefly for paving the foot-paths of streets.

Bath stone.

A similar kind of free-stone is that obtained from Bath; it is much used for ornamental work, being soft when obtained from the quarry, but becoming harder when it has been for some time exposed to the air.

Fire-stone.

Fire-stone is a soft kind of free-stone, obtained largely from Ryegate, in Surrey; it has the property of resisting the action of fire, and, therefore, is very fit for the interior of fire-places, but it is not employed for any other purpose.

In choosing stone for building, that is to be preferred which is best capable of resisting compression, which does not splinter by the action of frost or fire, and is not liable to decomposition by the air. Granite and marbles should be employed as soon as possible after extraction from the quarry, because then they may be cut with less difficulty; but the softer stones should be tried by exposure to the air for a considerable time before they are used, in order that their quality may be ascertained, and that they may be perfectly consolidated.

Stone in the quarry is disposed in strata parallel or oblique to the horizon; and it has been observed, that, when employed in buildings, it should be placed in the same situation with respect to the horizon that it occupied in the quarry, being then best capable of resisting compression.

Bricks.

Bricks have been employed in building from the earliest times, either burned or unburned; and the generality of their use is, no doubt, to be ascribed to the facility with which they are formed. Experience only can show what kind of clay makes the best bricks; it should be very adhesive; stones and mud should be carefully taken from it; it should be well worked, with little water, and mixed with ashes or sand. The best bricks give an acute sound when struck; they should not change colour when immersed in water, and they should suffer no alteration after being exposed during winter to the frost. The heavier ones should be employed for foundations, and the harder and lighter for works above ground.

Tiles.

Tiles are manufactured in a way similar to bricks, but of a better material, and their forms are various. Those called plane tiles are rectangular, 10½ inches long, 6¼ inches broad, and ⅝ inch thick; and, when placed on the roof of a building, they are held in their places by pegs which pass through two holes in the tiles and between the laths. Ridge tiles are nearly hemicylindrical, 13 inches long, and 11 inches diameter, and they are placed along the horizontal and oblique ridges of roofs. A coarse kind called pan-tiles, the surface of which is a curve of contrary flexure, is employed for the covering of sheds and other roofs of small elevation. Plain tiles of two different sizes are employed for paving, and the larger of the two is 1 foot square, and 1½ inch thick.

Slates.

Slate is a species of stone of a blue or purple colour, which is split in laminæ of small thickness and of various sizes, from 1 foot square to 3½ feet long and 2½ feet wide. When employed for the cover of a roof, they are placed over a bed of flat boards, and are kept in their places by copper nails passing through holes drilled for the purpose. Next to copper and lead, they form the most durable cover for roofs; but, in this situation, they should be of a kind which will not readily imbibe water, because the water rots the boards under them. Slates are also employed for paving.

Lime, mortar, and sand.

Lime is formed from limestone or chalk, by exposing those materials to a red-heat in kilns, when the carbonic acid is drawn off and the lime remains pure. Upon being wetted it readily falls to powder; this is passed through a sieve or screen of wire, and the finer part being mixed with sand and water, constitutes the mortar employed in building, which becomes hard by exposure to the air. When the mortar is made sufficiently fluid to penetrate the materials which it is to unite together, it is called *grout*. The sand, which is a crystallization of vitrifiable earth in small particles, should be obtained from natural beds in the earth, or from the bed of a river; it must be free from clay or mud, and the particles should be bounded by angular surfaces. When works are to be under water, a different sort is required, and that called *Parker's cement* seems to answer the purpose best, as it hardens quickly both in air and water; it is obtained by burning a sort of limestone found in the Isle of Sheppey.

Oak.

Oak is used in building for beams and joists, for door and window-frames, and, when cut in planks, for stairs and lining the sides of rooms; and on account of its strength and durability, it is preferable to every other kind of timber; but its most important application is in ship building. The name of *wainscot* is given to a sort of oak imported from Holland; this is softer than common oak, but it is less liable to warp and split. Another kind of oak, called *clapboard*, is imported from Norway; but both of these kinds are less used in England now than formerly. In the choice of oak trees, those the trunks of which are most even should be preferred, as swellings in the trunk are symptoms of decay; when cut down, the bark is taken off, and the tree laid for some time in water, to season, before it is squared and cut up.

Three kinds of fir wood are chiefly used in building; one, called the yellow fir, which comes from Scotland, Norway, and the shores of the Baltic; the second, called spruce fir, is a native of Denmark and Norway, but it also grows in the Highlands of Scotland; and the third is the American pine. The best firs which are brought to England are those of Riga, Memel, and Dantzic; and the deals, or wood of the fir-tree cut into planks, are imported from Norway, Dantzic, and St. Petersburg. This kind of timber is used to a great extent for partitions, for lining the sides of rooms, for doors, windows, and the like.

ard oods.

Other timbers occasionally used in England are mahogany, a wood from the West Indies, which takes a fine polish, and is chiefly employed for furniture, but, sometimes, for doors, rails, and the like. Walnut, which is used for cabinet-work and gun-stocks. Chestnut, a wood much resembling oak, and employed for turnery ware and for vessels to hold water. Ash, which is tough and strong, but decays when exposed to the air. Elm and beech, which may be employed for piles if they remain constantly under water. Sundry other English woods might be enumerated as applicable to many useful purposes, and their growth, on this account, is deserving of encouragement.

on.

Cast-iron is now much in use for building, particularly for roofs of houses, bridges, railings, and the like; but, in works of magnitude, the changes it undergoes from variations in the temperature of the air are so considerable as to be very detrimental to the stability of the edifice, and render great precautions necessary to prevent accidents: it is also much subject to decomposition by the air, and must be preserved by varnish or paint.

Wrought-iron is employed for bars, hinges, bolts, screws, and many other purposes, in which its tenacity renders it most useful; but it is evident that its good qualities must depend upon its being well forged.

pper.

Copper is employed in the formation of cramps for stonework, because it resists the action of air better than iron. When alloyed with a quantity of zinc equal to one-third of its weight, it forms brass, which is used for the handles of doors, locks, drawers, &c.: if the quantity of zinc is only from one-fifth to one-tenth of the copper, the mixture forms bronze or bell-metal, which is used for statues, bells, cannon, &c. Copper in the form of sheets is a very durable covering for the roofs of buildings, to which purpose it is frequently applied.

d.

Lead, when reduced to the form of sheets, is, also, much used as a covering for buildings, and as a lining for cisterns, and is bent or cast in the form of pipes for the conveyance of water. It is not much corroded by the action of the air, and it is not at all altered by pure water, but if the water contains any saline particles, a crust is formed on the surface of the lead exposed to it. The sheet-lead is either cast at once of the required thickness, or, after casting, reduced by pressure between rollers; and the latter kind, which is called milled lead, is now generally preferred. For a more detailed account of the materials employed in building, see Gwilt's *Rudiments of Architecture.*

CHAPTER XII.

Part IV.

Practice of Building.

Precautions in building on a rock,

The foundations of a building should be laid upon a bed of great solidity, and if the natural ground is not sufficiently firm, artificial means must be employed to make it so. If the building is to be raised on a rock, it will be necessary to ascertain whether there are any cavities below the surface which may render it incapable of supporting the weight of the walls; if so, piers must be built in the cavities, and arches turned between them to increase its strength; and, before the foundations are laid, the surface of the rock must be rendered rough, if not so naturally, in order that the mortar may insinuate itself, and unite the rock with the masonry placed upon it.

on gravel,

Gravel affords a support nearly equal to rock, and it may be built upon with safety. If cellars, vaults, or other subterranean apartments are to be formed, the whole interior below ground must be excavated; but, if not, trenches only are dug where the walls, both interior and exterior, are to be built; the bottoms of these trenches are to be in one horizontal plane, unless the surface of the ground be considerably inclined to the horizon, in which case they must be formed in portions, with horizontal beds like steps, one lower than another.

Vitruvius and Palladio recommend that the breadth of the foundation at bottom should be equal to double its breadth at the level of the ground; in modern practice the difference between the two is not so great, but it is evident that this must depend on the height of the edifice and the quality of the ground. The depth of the foundation is also variable, but, generally, one-sixth of the height of the edifice.

In good ground, sleepers are laid two feet asunder across the trench; the intervals are filled with dry stone, and, over these, is a floor of planks in the direction of the trench. Upon this the first courses of stone are laid, without mortar, because the lime will corrode the wood; but the next courses, whether of stone or brick, should be disposed with regularity and well bonded together. Whatever precautions are used with the foundations of the outer walls, the same should be used with those of the interior walls, that they may all settle equably; and, for the same reason, the foundations should all be executed at the same time.

on clay,

In building upon clay, the best method is to level it and lay down a horizontal grating of timber rather broader than the intended foundation; the intervals may then be filled with bricks, mortar, and the like, over which boards may be placed and nailed to the grating. The walls are, afterward, to be raised above the boarding as before.

on sand, or on a marsh,

When a substratum consists of sand, common earth, or marsh, it will be necessary to drive piles vertically into it till they reach the solid ground; their tops are then cut off in a horizontal plane, and on them is laid a grating of timber as before, above which the edifice is raised. Where the substratum is marshy, or otherwise defective, and a great weight is to be supported on columns, the following method has been adopted. A hole was dug at the place where the column was to stand, and, into it, a quantity of gravel was thrown to the depth of three feet; on this was laid a block of solid stone, which served to support a pedestal of brickwork, the upper surface of which was on the level of the ground, and the column was placed above the whole.

The foundation walls at the angles of buildings should be thicker than in other parts, and additional precautions should there be taken to render the bearing secure, because a failure would be attended with more serious consequences at the angles than elsewhere. An interesting account of the means taken by Sir Christopher Wren to secure one of the angles of St. Paul's Cathedral is given in the *Parentalia*.

in water.

Foundations may be laid in water by throwing into it stones and cement, in successive beds, with a slope on each side, the base of which is equal to its height, till the mass rises above the surface of the water; and, in this manner, the Breakwater, at Plymouth, was formed. Frequently, in building the piers of bridges, caissons or coffers of wood are moored over the place where the pier is to stand; the building is begun within the caisson, and the weight of the material causes the latter to sink on the spot prepared for it by levelling the bed of the river. When the work has been raised above the level of the water, the sides of the caisson are removed and the piers remain. But the most secure way is to enclose a certain part of the river within a coffer-dam formed by double-sheet-piling: the space between the rows of piling is filled up with bricks or some other material, and the whole rendered water-tight; then, the water being thrown from the interior by engines, the work may be effected as on dry land.

General rules for building above the foundation.

After the foundations have been established, the walls should be raised above them, in vertical positions, by which alone they can have the required stability; their thickness, however, should diminish upward, both from motives of economy and to lessen the pressure on the parts below. No part of the wall should have a false bearing; a pier, for example, should never be placed over an aperture, and, moreover, vertically under the windows or other apertures; inverted arches should be formed below the ground, in order that the pressure of the walls on the ground immediately under them may be diminished by throwing some of it on the intermediate parts.

The lower courses of masonry in a stone wall should consist of large, rectangular blocks, each of which should, if possible, extend quite through the thickness of the wall; or, if stones of sufficient length cannot be obtained, they should be placed so that their long and short sides should be presented alternately to the front; and the vertical line of junction of every two stones in one course should fall over the middle of a stone in the next lower course. This is called *breaking joint*, and it gives a better union to the whole system of masonry in the building

Manner of laying the bricks.

That which is known by the name of *English bond*, and was formerly much used in this Country, consists in disposing the bricks so that those in the alternate courses have their longest sides parallel, and, in the intermediate ones, perpendicular to the front of the wall; all the bricks have their broadest faces placed horizontally, and by these dispositions it was intended to bind the materials well together in the directions of the length, breadth, and height of the building. But the method now employed, which is called *Flemish bond*, consists in placing them in horizontal courses, with the largest surface downwards as before; but in each course, on both faces of the wall, the bricks have their lengths alternately coincident with and perpendicular to the face, and are so arranged that in one face, the *headers*, or those the ends of which are presented to the front, are opposed in the other face to the *stretchers*, or those the long sides of which are in front; the intervals are filled with whole or portions of bricks according to circumstances. A similar arrangement takes place in the different courses, and care is taken to break joint in all cases. It is evident that the method which affords the greatest number of bricks, the lengths of which are in the direction of the length of the wall, will form the best bond longitudinally; and that which affords the greatest number, the lengths of which coincide with the thickness of the wall, will form the best bond in that direction: and it may easily be shown that the Flemish bond has the advantage in the former case, and the English bond in the latter.

Strength o walls.

The thickness of brick walls is made to depend chiefly upon their height; but, where they have only to sustain their own weight vertically, less will suffice than when they have to support arches or roofs which may exert a lateral thrust. The angles at which two walls unite should be well strengthened, and, in rabble work, those parts should be formed of squared stone in order to give beauty and firmness to the building

When the walls are high, the thickness upward is usually diminished at intervals by offsets like steps; in houses, this is usually done on the interior face only, but it would be better to have it done both on the interior and exterior faces, and, to avoid any inelegance of appearance, in the latter situation it may be concealed by ornaments.

Bond tim bers.

Beams of timber are placed longitudinally, at intervals, either in the centre of the wall or close to its interior surface; the former situation seems the most proper for increasing the tenacity of the brickwork, but the latter is more convenient when the apartments are to be lined with wood. In the other case, wooden plugs must be inserted in the walls, in proper places, that to these the wainscotting may be nailed.

The construction of simple arches having been sufficiently described under Bridge, in our *Miscellaneous Division*, it will be only necessary here to add a short account of some other kinds of vaults which are occasionally employed in edifices, and chiefly in parts below the level of the ground.

Groined vaults.

Groined vaults may be imagined to be produced by the hemicylindrical vaults covering two galleries which cross each other at right angles; and, if both are of equal magnitude, the curved sides of the vaults will form, by their intersections, four elliptical ridges, which converge to a point over the centre of the square made where the galleries meet each other.

It is evident that in the ordinary way of building this kind of vault, it is supported entirely by the intersections of the courses of masonry in the lateral vaults, and that these intersections form ribs which rest on the four angles of the walls or piers; the dimensions of the ribs are limited by the thickness of those vaults, which cannot be considerable, and their strength is diminished by the oblique manner in which the stones or bricks are cut at the salient angles of the ribs. Hence this species of vault seems to be the weakest of all coverings, and ought, of course, to be employed only where there is a necessity of having both direct and lateral communications through the interior of a building.

Improv groined vaultin

To procure additional strength in this kind of vaulting, Mr. Tappen proposes to cut off the salient angles of the piers in vertical planes parallel to the diagonals of the vault, and to raise from the tops of the piers two diagonal ribs equal in breadth to the oblique face thus formed on the pier, and of any convenient thickness; the lateral arches which, in this construction, are smaller than those of the common groined vault, are united with, and borne by the ribs, and the latter, instead of being the weakest part of the vault, may be now as strong as the rest. The extremities of the arches between the ribs are made to meet the sides of the latter, at four inches from their faces, by which means the oblique cutting of the bricks at the angles is avoided.

As the area of a transverse section of these diagonal ribs may be easily made two, or even three times as great as that of the intersection of the lateral arches of the common groined vault; it is evident that the strength of the vault proposed by Mr. Tappen may be made to exceed that of the other in the same proportion. We may add that the new method presents greater facility of construction than the old, and it is probable that the vault is not inferior, in power of supporting weights, to that the form of which is hemicylindrical.

Where an extensive area is covered with a ceiling of stone or brickwork, a system of groined arches becomes absolutely necessary; these must be supported on piers, and in order to afford more room and take off the corners, which are liable to be destroyed by accidents, the piers should be of an octangular form: vast ranges of arcades thus formed and supported are to be seen in the subterranean parts of the warehouses at the London Docks.

loister- aults.

A different kind of groined vault has been formed by four portions of cylinders rising from a square base, joined together in four ridges salient towards the exterior, and meeting at the apex of the vault: this, which is called a cloister-vault, was employed in Gothic and Saracenic Architecture; and the dome of the Cathedral at Florence is formed on the same principle, but the cylindrical portions are raised on the sides of an octagonal base.

rumpet- aults.

When a superstructure is to be raised over the rentrant angle between two walls which meet each other, a vault in the form of a portion of a cone is constructed for its support; the vertex is placed in the line of intersection, and the semicircular base of the half-cone is in a vertical plane passing through the outward extremities of the walls. These are called trumpet-vaults, and they were formerly constructed for the support of buildings over the rentrant angles formed between the faces of a bridge and its projecting piers. Vaults of this kind, but of an elliptical form, are much more appropriately employed in supporting the landing-places on the winding stairs, at some of the warehouses before mentioned.

bility of es.

Domes are most conveniently constructed on circular bases, for then their vertical pressure is equally supported at every point, and the voussoirs in each horizontal course are all of the same form and equal magnitude. A dome, having all its parts in perfect equilibrium, might be constructed by giving such a form to its vertical section, that the vertical weight of a stone in any one horizontal course, combined with the oblique pressure of all above, may produce a force acting in the direction of the next course below; but a dome of this form would be one of the weakest, as well as the least elegant, whereas, if the curve line formed by the vertical section were made to fall between the axis and the curve of equilibration, the pressure of the upper horizontal courses would tend to force the lower courses towards the axis; this taking place equally round all the circumference of any horizontal course, the effect would be to keep all the stones in that course more firmly together than if such pressure had not existed. All domes hitherto constructed have this character, but the cone between the two domes at the Cathedral of St. Paul possesses it in a greater degree than any, the forms of which are convex towards the exterior; they exert, however, considerable thrust horizontally round the base, and, hence, it has been found necessary to strengthen them by iron hoops, as we have stated, in speaking of the domes of St. Peter's and St. Paul's.

When a dome is to be raised over a space enclosed by four walls at right angles to each other, the rentrant angles of the walls are filled up by pendentives, as formerly described, the surfaces of which coincide with that of a spherical zone inscribed between the walls; the tops of these pendentives form a horizontal circle, upon which either the dome itself, or the cylindrical wall which is to support it, is erected.

Domes of timber are generally constructed on the same principle as trussed roofs, and the curved ribs are disposed in vertical planes passing through the axis. The boldest piece of carpentry known was the old dome of the Halle du Bled, at Paris, the form of which was hemispherical and its diameter 200 feet; each rib was formed of planks 9 feet long, 13 inches thick, and 3 inches broad, placed three together in the direction of their breadth, and connected horizontally at different distances by purlines and iron straps, which formed hoops to the whole. This roof was destroyed by fire, and it has been since replaced by a dome of iron, of which each rib is composed of frames disposed in a vertical plane, and every two connected together by simple bars; the whole is covered with sheet copper.

CHAPTER XIII.

Modern Architecture in the East.

Little account of the Architecture of the East will be required, it is not probable that Asiatic buildings will afford many subjects for imitation in the Western World; partly from the difference of climate, but chiefly from the differences in the manners and customs of the people; and, perhaps, copies of them will never be executed in Europe, except to gratify the fancies of amateurs. The taste which can be pleased with an imitation, in plaster, of the massive edifices of Egypt, may lead some one to erect a cottage resembling a Turkish Mosque, or a Chinese Pagoda.

Mosque of Sultan Achmet.

From the time that the Empire of the Saracens was at its height, to this day, a style of Architecture, similar to that which we find in the Mosque at Cordova, and in the Alhamra, has prevailed in the edifices of the Mohammedans. These are generally covered by cupolas, and at the angles are slender minarets or turrets, from the tops of which, when the building is appropriated to Religious purposes, the Imaums call the Faithful to their devotions. The Mosque erected at Constantinople, by Sultan Achmet, in 1610, may, perhaps, be considered as the best specimen of the Mohammedan Religious edifices of comparatively recent date; in its plan, it bears considerable resemblance to the Basilican Churches of Constantine, and its roof is evidently copied from that of Sancta Sophia.

The whole building is formed on a rectangular plan, the longest side of which is 270 feet, its shortest 155 feet, and the height of the containing walls 37 feet. It is divided into two equal squares, of which the first, within the entrance, is a court open to the sky, in the centre, but surrounded by a covered corridor, with arcades towards the interior, and in the roof of the corridor on each side of the quadrangle are eight small, hemispherical domes. The second quadrangle constitutes the body of the building; about its centre are four piers, disposed at the angles of a square of 60 feet, and supporting semicircular arches with pendentives; upon the tops of these is a cylindrical wall perforated by semicircular-headed apertures, for the admission of light; and above the wall is the great dome, the exterior surface of which has the figure of a bell, and whose height, from the pavement of the building to its vertex, is 82 feet. Between the four piers, are formed segmental recesses, which are covered by half-domes, the crowns of which are on a level with the base of the tambour under the central dome. In each of the angles formed by the four recesses is raised a slender, octagonal turret to the height of 70 feet; and at each of the four angles of the parallelogram enclosing the whole Mosque, and in the middle of each of the long faces, is raised a minaret 120 feet high; it stands upon a square pedestal, and is divided by two small platforms into three cylindrical portions, of different diameters, and above the uppermost of these is a spire which crowns the whole. The pavement of the Mosque is elevated 8 feet above the ground, and there is an ascent by steps to the entrance doorway, which is crowned by an arch of contrary flexure.

An imposing effect is produced in the interior of buildings of this kind by the tiers of vaults, which rise above each other within one great concave surface, and are covered with the utmost profusion of arabesque ornament; and, on the exterior, the light minarets present a pleasing contrast to the large mass formed by the pile of domes over the centre of the edifice.

Civil edifices of the Turks.

The Turkish dwelling-houses, in towns, are lofty buildings of several stories, crowned by sloping roofs with bold projecting eaves, and have very much the appearance of the houses in Italy. Some are built entirely of timber, with verandas in front, and others have the lower parts of brick, and the upper of wood; the roofs are covered with tiles.

Turkish Fountains.

Elegant specimens of Turkish Architecture are seen in some of the Fountains at Constantinople; one of the finest is of a square figure on the plan, and is flanked by four towers, each of which presents three sides of a hexagon towards the exterior, and is ornamented with columns at the angles. At the top of the building is a broad entablature, with a great projecting roof, the angles of which are cut to correspond with the forms of the towers and columns. Above the centre of the roof, and over each tower, is a polygonal tambour covered with a cupola, and terminated by a small gilt spire. The doorway is crowned by a pointed arch, above which is an inscription in gilt letters; and the entablature is highly enriched with dentels and diamond figures in relief.

Khan of Damascus.

In the façade of the Khan at Damascus is a pointed arch with three polygonal columns on each side; the shafts of these are crossed by zig-zag grooves, and the capitals, which are very tall, are ornamented with long, pointed leaves, like those on some of the Egyptian columns. On each side, are niches with trefoil heads, and above these, are small circular windows enriched with ornaments. Over the door is a flat, segmental arch, and above this is a perforation of a similar form, but inverted. Between the horizontal string above the door and the soffit of the arch is a mosaic-work, representing the interior of a dome. The oblique faces of the voussoirs, instead of being planes tending to the centre of the arch, as is universally the practice in Europe, are cut in mouldings forming deep notches and high projections, which are fitted to corresponding projections and notches in the contiguous voussoirs. This practice, which is very common in the East, and seems to have been borrowed from the ancient Arabian Architecture, has, no doubt, arisen from a desire effectually to prevent the voussoirs from getting out of their places. In Europe, better notions are entertained of the stability of the arch, and, in our buildings, the mutual pressures of the great blocks of stone we employ would presently cause the destruction of all such mouldings.

Persian buildings.

The modern Palaces of Persia are rectangular buildings with flat, projecting roofs, and, in general, they have few pretensions to elegance of design. In the centre is a lofty hall, open in front, and its roof, which constitutes part of the general roof of the edifice, is supported by wooden pillars of square or octangular forms, painted and gilt, and with capitals resembling inverted frusta of pyramids. The dwelling apartments are on each side of the hall; on the wings are rooms for servants, and for the reception of baggage, and the entrances, windows, and other apertures are, generally, covered with pointed arches in the Gothic style. This feature seems now to prevail, in the East, to as great an extent as it once prevailed in Europe; and with similar modifications, being composed of two simple arcs of circles, or two curves of contrary flexure, and, frequently, having the sides cut to form several cusps towards the centre.

The houses of the common people are, generally, square, built of stones or sun-dried bricks, with flat roofs of timber, where that material is sufficiently abundant; but where it is not, the roofs are formed by small brick domes, which cause a village to appear, at a little distance, like a cluster of bee-hives.

According to M. Tournefort, the Caravanserais, or places for the public reception of travellers, consist of a number of apartments, each about 8 feet square, with vaulted roofs, surrounding a great quadrangular enclosure, and elevated about 4 or 5 feet above its level. The chambers are without windows, and receive their light only from the door. In front of each, in the interior of the court, is a small vestibule, about 4 or 5 feet deep, of the same breadth as the chamber, and having a chimney on one side; and, again, in front of these vestibules, is a general corridor, before which the horses are kept. The centre of the court is occupied by a cistern of water, sunk in the ground.

Buildi India.

The reign of the Emperor Akbar, in the XVIth century, is an Epoch from which may be dated the erection of several splendid Palaces and Religious edifices, which yet remain as monuments of the wealth and public spirit of that Monarch. The Palace in the City of Agra is situated in the middle of a large area, surrounded by colonnades, and having six entrances adorned with as many Triumphal Arches. In front of the principal building are two Grand Galleries, ornamented with columns of white marble, with bases of blue granite, and capitals of yellow mica, and, about it, are seven smaller

Palaces. Near this stands the Mosque of Akbar, the walls of which are of red granite, and were covered from top to bottom with gold plates. In the same City were several superb Mausoleums, and the Mosque of Aurenzebe, the roof of which was supported by more than one hundred columns.

The famous Observatory, at Benares, was, also, a work of the Emperor Akbar. According to the description of Sir William Baker, it is an assemblage of stone buildings surrounding several quadrangular enclosures: on the top of one is a terrace, part of which is covered by a dome of masonry turning on a pivot; within the dome are placed several stone instruments for Astronomical purposes, among which are two quadrants 9 feet 2 inches radius, with graduated arcs; and on an open platform is a gnomon or obelisk 20 feet high.

Lord Valentia describes the houses of this city as built of large stones, and some of them six stories high, the separation of the stories being distinguished on the exterior by a band of ornamental carved work; the roofs are flat, and serve as terraces for exercise, and the opposite houses on each side of the streets are sometimes united by Galleries.

In the further Peninsula of India, where the lower grounds are yearly overflowed, it becomes necessary to build the houses on high pillars, to keep the floors above the surface of the water; and this seems to have led to an almost universal adoption of that mode of building. The houses are raised from the ground on posts of bamboo, and the roofs are slightly covered with thatch. The Shoé Dagoon, or great Temple at Rangoon, in Ava, is described by Lieutenant Alexander as an immense edifice of a pyramidal form, entirely solid, and about 330 feet high; the lower part, to about half the height, is octagonal, and its exterior surface is cut in the form of steps about the whole circumference; the upper part is in the form of a bell, and ends in a spire, on the top of which is a sort of umbrella of open ironwork, surmounted by a vane and a globe of glass. Round the base of the edifice are many small pagodas of similar forms.

goda at
oang, in
ina.

The public buildings of China almost invariably consist of a number of apartments or cells surrounding a rectangular area; the general roof of these buildings projects beyond the wall towards the court, and the extremity is supported by a colonnade formed of wooden pillars, standing on marble bases. Such is the great Pagoda at Honang, in the suburb of Conan; its interior area is 590 feet long and 250 feet wide, and this is surrounded by cells for two hundred Bonzes, which have no light, except what is obtained from the doors. The entrance to the quadrangle is by a vestibule in the middle of one of the short sides, and at each angle is a building 30 feet square, for the residence of one of the principal Bonzes. In the middle of each of the long sides is a rectangular area surrounded by cells; one of the areas contains the kitchens and refectories; and the other, the hospitals for animals and a burying-ground.

In the interior of the great quadrangle, are three Pavilions, or Pagodas, each 33 feet square on the plan, and consisting of two stories, the lowest of which is surrounded by a peristyle of twenty-four columns; each Pagoda stands on a basement 6 feet high, to the top of which there is an ascent by a flight of steps on each side, and all the basements are connected together by a broad wall, of the same height as the basement, for the purpose of communicating between the Pagodas without descending into the court. The roof of the peristyle about each Temple is of a concave form on the exterior, and, at each angle, the projection is curved upward, and terminated by some animal figure: the sides of the upper story are formed by wooden posts, between which are open frameworks; round the foot of this story, on the exterior, is a balcony with a rail in front, and the roof is similar to that of the peristyle, each angle being turned up and ornamented. All the buildings are covered with varnished green tiles.

Pagoda at Nankin.

But many of the Pagodas in China are remarkable for consisting of several stories in height; that at Nankin, which has been described by M. Le Compte, is of an octagonal form; the length of each face on the plan is 15 feet, the whole height about 200 feet, and it consists of ten stories, each smaller than the one below it. The whole tower stands upon a basement surrounded by a covered gallery, and the ascent to the platform of the basement is by steps on each side; in each face of the lower story, are three semicircular-headed apertures, and each story is crowned by the usual projecting concave roof, the edges of which turn upward, as if to retain the rain-water. The lower part of the wall is 12 feet thick, and the upper part 8½ feet; its exterior is faced with porcelain, and its interior enriched with Paintings. The walls of the upper stories are pierced with niches which are filled with Idols sculptured in bas-relief and gilt; a cupola is placed above the uppermost story, and from its top rises a great mast to the height of 30 feet above the top of the tower. The floors are of planks supported on great beams which extend across the building, and the ascent from one story to another is by small staircases with high and inconvenient steps. This Pagoda is supposed to have been built about four hundred years since. See pl. xxi.

The Palace at Pekin.

All the Palaces and private dwelling-houses of the Chinese seem to be constructed nearly according to one plan; even the residence of the Emperor himself differs from the others only in being more extensive. From Mr. Barrow's *Account of Lord Macartney's Embassy*, it appears to be a vast enclosure of a rectangular form surrounded by double walls, between which are ranges of offices covered by roofs which slope down towards the interior. The included area is occupied by buildings not more than two stories high, and forming several quadrangular courts of various sizes, in the centres of which are buildings on platforms of granite 5 or 6 feet high; each of these is surrounded by columns of wood supporting a projecting roof, turned up at the angles, as usual: one of these buildings, which serves as a Hall of audience, stands on a platform, like the rest, and its projecting roof is supported by a double row of wooden columns; the intervals between the columns in each row is filled with brickwork to the height of four feet, and the space above the wall is occupied by a lattice-work covered with transparent paper. The courts are intersected by canals, over which are several marble bridges; the gateways forming entrances to the quadrangles are adorned with marble columns on pedestals, and decorated with dragons; and in the courts are pedestals supporting sculptured lions 7 or 8 feet high; at the angles of the buildings surrounding each area are formed square towers two stories high, and crowned by Galleries.

From Sir William Chambers's account of the dwell-

Dwelling-houses at Canton.

ing-houses of the merchants at Canton, they seem to be in the form of a long rectangle on the plan; they are two stories high, and the ground-floor is divided into two nearly equal parts by a wide passage extending through its whole length. In the front next to the street are the shops, and beyond these is a quadrangular, open vestibule leading to the private apartments. On each side of the passage, is a saloon for the reception of visitors, a sleeping-room, and, sometimes, a little closet or study: besides these, there are, on the ground-floor, the dining-rooms, the kitchen, the servants' rooms, and the bath. The saloon is commonly 18 or 20 feet long, and about 20 feet wide; the side next to the vestibule is open, or only occupied by a screen of canework, to secure it from the rain or sun; and in the back of the saloon, are doors which extend from the floor to about half the height of the ceiling; the upper part is a trelliswork covered with painted gauze, which lets in light to the bed-room. The partition-walls, which extend no higher than the ceiling of the ground-floor, are lined with mats to the height of three feet; the rest is covered with painted paper, and the pavement is composed of squares of stone or marble of different colours. The doors are generally rectangular, made of wood, and varnished or painted with figures; but a remarkable circumstance is, that the communication between the apartments is, sometimes, in the form of an entire circle, which has been compared to the aperture of a bird-cage. The windows are rectangular, and occupied by framework representing squares, or parallelograms, polygons, and circles, variously inscribed in, or intersecting each other; and similar forms are given to the rails which protect the galleries about the upper and lower stories; the compartments of the windows are generally filled with a transparent oyster-shell, which admits the light to the rooms.

The upper floor consists of several large apartments, which occupy all the breadth of the house, and, by temporary partitions, are converted into rooms for visitors, distinct from those occupied by the family; over the shops are sleeping-rooms for those who serve in them: the roof is supported on wooden columns; its extremities project beyond the walls, and at each angle is commonly the favourite emblem, a dragon. A plan and elevation of one of these houses is given in pl. xxi.

Triumphal Arches.

Triumphal Arches, or buildings erected to celebrate particular events, are very common in China, and, in the *Account of Lord Macartney's Embassy*, several such are said to have been placed across the principal streets of Pekin: these were all of wood, and each consisted of three gateways, the middle one larger than the others. Those at Ningpo are ornamented with polygonal columns of stone supporting an entablature which is composed of three or four faciæ, generally without mouldings, except the last but one, which is a sort of frize, filled with inscriptions: the buildings are crowned by roofs of the usual form, that is, with broad projections, and the angles pointing upward; and the apertures are either rectangular or terminated by semicircular heads. The use of arched vaults is not unfrequent in China. According to Duhalde, their voussoirs are of stone, about 6 feet long and 6 inches thick, and their sides, instead of being planes, like ours, are cut in curvilinear forms. Probably, they resemble the arch-stones described in speaking of the buildings in Turkey.

Part I

Chinese [illegible]lumns.

The Chinese columns are, in almost every case, of wood; but, when they form the peristyle of any considerable building, they stand on stone or marble bases of various profiles; they are entirely without capitals, unless we consider as such the brackets projecting from the upper part of the shaft on opposite sides, and assisting to support the architrave. The height of the whole column is equal to from eight to twelve times its lower diameter, and the shaft is in the form of a frustum of a cone; the base consists of a square plinth, above which is, sometimes, a moulding, in the form of an inverted cymatium, between two fillets; in other cases, the mouldings consist of the inverted cymatium and a torus, with a scotia and fillets between them; and, occasionally, there is placed, immediately above the base, a polygonal or cubical block, projecting beyond the surface of the shaft. The architrave is a cylindrical beam, like a pole, which passes through a hole bored near the top of each shaft, and is further supported by resting on two brackets, generally ornamented, which are inserted in the shaft below the architrave, and bent upward, so that the architrave may rest on the extremities. See pl. xxi. Above the architrave is sometimes placed what may be called a frize, consisting of an open framework panelling, formed by circles or squares of wood intersecting each other, and the intervals between the panels are ornamented with bells and heads of animals. Over the frize is the high and projecting cornice, of a concave figure, sloping downward in front, and turned up at the angles; the points are ornamented with heads of fish, or with dragons.

Roofs.

Some of the Chinese roofs are of an undulating form, the transverse section presenting the form of a double curve of contrary flexure, highest in the middle; these are supported by several pairs of cylindrical beams or poles notched into each other, and alternately parallel and perpendicular to the length of the building; the longitudinal poles being placed nearer together in proportion as they approach the top of the roof. The upper poles support the materials which form the covering.

Great wall

One of the most remarkable monuments of Chinese Architecture is the great wall, which begins in the sea to the East of Pekin, and extends along the frontiers of three Provinces, often in places which would be inaccessible to an enemy. Near the Eastern extremity it consists of rough stones faced with brickwork; its height is from 20 to 25 feet, and there are towers at intervals along it, which are built of brick on a basement of stone.

Chinese A chitecture derived fr the tent.

On contemplating the buildings of China, we cannot help being struck with their general resemblance to the tents, which we may suppose to have been the dwellings of a nomadic people; and it may reasonably be believed that when the ancient inhabitants of the Country assumed a stationary mode of living, they made their fixed habitations resemble the movable abodes to which they had been before accustomed. The columns which support the roofs are still made of wood; and, instead of the massive entablatures of Egypt and Greece, we find cylindrical rods so slender as to be only capable of supporting a roof of the lightest kind. The external covering of the roof has the undulating form of the cloth which is drawn over the poles of a tent, and its extremities turn up like the hooks to which cords are attached for uncovering them. The tallest Pagodas may be considered as several such tents piled one on another

The Arts of imitation have been stationary in China, probably, ever since the establishment of the Empire.

adition of Arts in ina.

A system of regulations, which it is a crime to infringe, pervades every Art, as well as every branch of Civil and Political economy, represses every attempt at original invention, and prevents any improvement on the ancient practice. Hence it is easy to conceive that all the works of this people will be characterised by a servile adherence to some primitive model, and it can excite no surprise that nothing in them indicates that tendency towards perfection which we observe in the works of European artists.

The case is rather different with the Architecture of India, which is characterised by some of the boldness, originality, and even extravagance of the Saracenic manner; and though arbitrary Governments in India and China have thrown their deadening influence over the minds of the artists of both those Countries, yet since the former is divided into many independent States, the differences of character and talent among the Princes have afforded scope for variety of design which is not to be found in the works of the Chinese, who are all subject to one Sovereign, and governed by unvarying laws.

Architecture.

EXPLANATION

OF THE

CHIEF TECHNICAL TERMS USED IN ARCHITECTURE.

ABACUS. A block forming the upper part of the capital of a column. It is generally rectangular, and its four vertical faces are either plain or moulded; but, in some cases, they are arcs of circles, the concavities of which are towards the exterior.

Acroter. A plain pedestal placed at the vertex, and at each of the lower extremities of a pediment, for the support of a vase or statue.

Alcove. A recess in an apartment for a bed or couch.

Amphiprostylos. A denomination applied to Temples or other buildings having columns at both extremities.

Annulet. A moulding, the profile of which is rectangular, surrounding a column in the base or capital.

Antæ. A denomination applied to pilasters when attached to the extremities of walls. A building the side walls of which are thus terminated, and having no columns in front of such pilasters, is said to be *in antis.*

Apophygis. A projection about the lower extremity of the shaft of a column, connecting the shaft with the base; its profile is concave outwards.

Apteral. A denomination applied to buildings having no wings, and to Temples having no columns along the flanks.

Arch. A series of bricks, stones, &c., generally cut in the form of frusta of wedges, which are disposed in a curvilinear manner, and in a vertical plane. It is denominated a circular, elliptical, cuspid, &c. arch, according to the nature of the curve; and the spandrils are generally included as part of the arch.

The cuspid or pointed arches are said to be of the third point, fourth point, &c., according as the radius of each curved side is equal to two-thirds, three-fourths, &c., of the span or interval between the supports.

Architrave. A beam of timber, or a course of masonry, laid in a horizontal position along the tops of the columns in a range.

Archivolt. The curvilinear course of materials immediately over the aperture of an arch, and supporting the spandrils.

Areostylos. A denomination applied to colonnades, when the intervals of the columns are not less than four diameters.

Astragal. A small moulding generally surrounding a column in the base or capital; its profile is semicircular, with the convex part outwards.

Attic. A story above the general cornice of a building; also a wall, ornamented with pilasters above the cornice.

Baluster. A small column supporting a rail of timber or a course of masonry; it is generally ornamented with mouldings and its profile is a curve of contrary flexure. A series of such columns is called a *Balustrade.*

Band. Any horizontal member in a building, having a rectangular profile and small projection.

Architecture.

Base. That member which is placed under the shaft of a column; it is generally ornamented with mouldings. When it consists of two tori separated by a scotia and fillets, it is called an *Attic base.*

Basement. The lowest story in a building.

Battlements. Indentations, generally of a rectangular form, made in the upper part of a parapet wall.

Bressummer. A beam of timber resting on posts and supporting a wall.

Buttress. A pier of brick or stone work attached to the face of a wall in order to strengthen it. When it has the form of a curve, and is attached to the wall only at its upper extremity, it is called an *arched* or *flying* buttress.

Cabling. An ornament cut in the form of a half-cylinder within the lower part of the fluting of a column.

Cantiliver. A timber projecting from the wall of a building to support the lower part of the roof.

Capital. The upper member of a column or pilaster; it is placed immediately above the shaft.

Caryatides. Sculptured female figures, sometimes employed as columns to support an entablature.

Cathetus. A vertical line drawn through the centre of a volute in an Ionic capital.

Cavetto. A concave moulding generally in the form of a quadrant of a circle, the upper part projecting over the lower.

Caulicolus. A sculptured ornament in the Corinthian and Composite capital, representing the stem of a plant.

Ceiling. The upper surface of the interior of an apartment. It is either *plane* or *vaulted;* but if the central part is horizontal, and the margins are connected with the side walls by cylindrical portions, the ceiling is said to be *coved.*

Cella. The principal division of a Temple within the walls; it is also called the *Naos.*

Coffer. An ornamental panel sunk in the ceiling of a building or apartment, or in the soffit of a projecting member.

Colonnade. A series of columns in line. When an area is surrounded by columns, that enclosure is called a *peristyle.*

Conge. An inverted echinus or ovolo; also an inverted cavetto.

Console. An ornamental projection in front of the keystone of an arch, or on each side of a doorway.

Corbel. A projection from a wall, intended for the support of any object.

Cornice. The upper member of an entablature or pedestal; also a corresponding member at the foot of the roof about the exterior of a building in which no Order is employed, or along the tops of the walls in an apartment.

Corona. The projecting member which forms the upper part of a cornice; it is called also the *drip* and *larmier.*

Corridor. A gallery within or about a building.

Cortile. A court enclosed by the divisions of a building.

Crocket. A sculptured ornament resembling curled foliage placed on the sides of a pediment or pinnacle.

Cross-springers. The diagonal ribs formed at the ridges of a groined vault.

Crypt. The subterranean part of a building.

Cupola. Any dome is so called, but the term is generally applied to one of small dimensions.

Cymatium. A moulding, the profile of which is a curve of contrary flexure: it is of two kinds, denominated *cima recta* and *cima reversa*, according as the upper part is convex or concave outwards.

Dado. The body of a pedestal; its form is that of a cube or parallelopiped.

Dentel. A small block in the form of a parallelopiped. A row of these forms an ornament in the cornice in some of the Orders.

Diastylos. A denomination applied to a range of columns, the intervals of which are equal to from three to four diameters.

Dipteral. A denomination applied to such edifices as have two rows of columns on each flank.

Dome. A vaulted covering placed over the whole or part of a building; its form is either spherical or paraboloidal.

Eaves. The lower extremities of a sloping roof.

Echinus. A convex moulding employed in the capital of a column or pilaster, and in the entablature. Its profile is an arc of some conic section, and the upper part projects beyond the lower.

Entablature. The system of timbers or masonry supported by the columns of an Order, and generally carrying the roof.

Entasis. The protuberance or swell produced by the curved form given to the profile of the shaft of a column.

Epistylium. The same as *Architrave*, which see.

Epitithedas. The upper moulding of an entablature; generally applied to that over the flanks of a building, the extremities of which are crowned by pediments.

Eustylos. A denomination applied to a range of columns, the intervals of which are equal to two diameters and a half.

Extrados. The curve formed by the upper extremities of the voussoirs of an arch, also the superior curved surface of a vault or dome.

Façade. The principal front of an edifice.

Fascia. The exterior, and generally, vertical face of any member which is rectilinear in direction and profile.

Fillet. A narrow and plain moulding, either surrounding a column, or extending along the face of a building; its profile is rectangular. The plain part of the shaft of a column between two flutes is also so called.

Finial. The sculptured ornament resembling a knot of foliage placed at the apex of a pediment or pinnacle.

Fleuron. A sculptured ornament resembling expanded foliage or flowers.

Flutes. The longitudinal channels cut on the shaft of a column.

Fretwork. The denomination applied to a fillet or system of fillets sculptured in lines, waving or broken in directions generally at right angles to each other. When the fillets resemble battlements, the ornament is called an *embattled fret;* and when interwoven with each other, it is called a *guilloche.*

Frize. That horizontal member in an entablature which is situated between the architrave and cornice.

Fust. The same as *Shaft*, which see.

Gabel, or *Gavel.* The triangular part of the wall, included between the extremities of the sloping sides of the roof, on the face of a building. When the triangle is enclosed by regular cornices it is called a *tympanum.*

Girder. The principal beam in a floor, intended to support the joists.

Guilloche. See *Fretwork.*

Guttæ. Pendent ornaments of a conical, cylindrical, or trochoidal form, placed under the mutules and teniæ in the Doric Order.

Hypæthral. A denomination applied to buildings formed partly without a roof.

Hypotrachelion. That part of the capital of a column between the principal ornaments and the mouldings or grooves which mark the top of the shaft.

Jambs. The pieces of timber or masonry forming the sides of a door or window, generally placed in vertical positions.

Impost. The block, or system of mouldings on the top of a pier, which serves for the support of an arch.

Intercolumniation. The interval between the nearest sides of two columns in a range.

Intrados. The curve formed by the lower extremities of the voussoirs of an arch; also the inferior surface of a vault or dome.

Joists. The timbers supporting the boarding of a floor, or to which the laths forming a ceiling are attached.

Key-stone. The voussoir placed at the vertex or crown of an arch or dome.

King-post. The vertical timber between the centre of a tie-beam and the summit of the roof.

Label. A moulding placed above, and concentric with the extrados of an arch or window in Gothic Architecture: when the upper part of the window was rectilinear, the label was horizontal.

Lacunar, or *Laquear.* A coffer or panel sunk in a ceiling of an apartment, or in the soffit of any member; the term has been applied to the whole ceiling or soffit.

Lantern. A small cylindrical or prismatical turret at the top of an edifice.

Lintel. A timber or stone supporting the wall over any aperture, the upper part of which is horizontal.

Listel. The same as a Fillet or Annulet.

Loggia. An open gallery.

Medallion. A circular or elliptical panel in a wall or ceiling.

Metope. The interval between two triglyphs in the Doric frize.

Mezzanine. A story formed in some buildings between two principal ones.

Modillon. A projecting member in the entablature of the higher Orders, placed at intervals under the corona as if to support it.

Module. The unit of length by which the proportions of the members in an Order are expressed: it is generally equal to a semidiameter of the lower part of the shaft of the column, and is subdivided into thirty parts called minutes.

Monopteral. A denomination applied to buildings surrounded by a single, circular colonnade on the exterior.

Mosaic. A species of ornament applied to pavements and the interior sides of walls, formed of inlaid stones or other materials of various colours.

Mouldings. The ornamental projections applied about columns or pedestals, or on the entablatures and walls of buildings.

Mullions. The posts, pillars, or bars placed in the apertures of windows; they are denominated *vertical*, *horizontal*, or *radiating*, according to their position.

Mutule. A thin, projecting member placed at intervals under the corona in the Doric entablature.

Naos. The same as *Cella*, which see.

Niche. A recess in a wall.

Ogee. The same as *Cymatium.*

Opisthodomus. A division of a Temple in which the treasures were kept.

Orchestra. The part of a modern Theatre which is appropriated to the musicians. In the Greek Theatre the dances were performed in it; and in the Roman Theatre it was occupied by the seats of the Senators.

Order. A system of members in Grecian and Roman Architecture, consisting chiefly of the column with its base and capital, and the entablature; and constituting the particular character of the edifice. Five Orders have been invented, which are distinguished by the names Tuscan, Doric, Ionic, Corinthian, and Composite.

Oriel. A projecting window, rectangular or polygonal on the plan, and supported by timbers or masonry inserted in the wall.

Ove. A sculptured ornament resembling an egg.

Ovolo. A convex moulding, the profile of which is a quadrant of a circle, having the projecting part uppermost.

Panel. A shallow recess with a plane surface, and generally rectangular, formed in a ceiling, wall, or piece of woodwork.

Parapet. A low wall surrounding a terrace, or the roof of an edifice, or extending along each side of a bridge.

Parastata. The same as *Pilaster:* the term is sometimes applied to a post placed by the side of a column to support the floor of a gallery less elevated than the column.

Pavilion. A wing of an edifice, connected with the principal part by a wall or colonnade.

Pedestal. A low pillar with vertical sides placed under a column or obelisk; it is usually rectangular, and ornamented with a base and capital.

Pediment. The triangular part of the wall above the general, horizontal cornice at the extremities of a building, when the roof is formed with sloping sides.

Pendentive. A portion of a spherical vault formed at each intersection of two cylindrical vaults crossing each other at right angles, when a circular aperture inscribed in a square vertically over that formed by the intersection of the vaults at bottom, is made on the level of their crowns. The face of the pendentive is thus bounded by three circular arcs.

Pergamena. A small turret crowning a dome.

Peripteral. A denomination applied to such rectangular buildings as are surrounded by a colonnade on the exterior.

Peristyle. A court in the interior of a building, generally quite surrounded by columns.

Piazza. A large area surrounded by buildings.

Pier. A mass of masonry supporting one extremity of an arch or vault; the part of a wall between two windows or doors is so called.

Pilaster. A pillar bounded by plane surfaces; it is sometimes isolated, but generally attached to a wall.

Pillar. The general name for a column or pilaster.

Pinnacle. A small cone or pyramid placed above a turret, buttress, or the roof of a building.

Planceer. The same as *Soffit*, which see.

Plinth. A block, generally bounded by four plain vertical faces, and placed under the mouldings in the base of a column or pilaster, or under a whole building.

Podium, or *Pluteus.* A continuous pedestal supporting columns: also, a parapet wall about a terrace was so called.

Porch. A small covered projection in front of a doorway.

Portico. A term generally applied to the projecting part before the entrance of a considerable edifice, when it is covered by a roof supported on columns. Anciently, the *Porticus* signified any colonnade.

Posticum. A portico in rear of any building.

Pronaos. The division of a Temple in front of the naos or cella.

Propylæum. A portico in front of the principal entrance to a city.

Proscenium. That part of the stage which is in front of the scenery in a Theatre.

Prostylos. A denomination applied to buildings having columns at one extremity only.

Pseudodipteral. A denomination applied to buildings having two rows of columns at each extremity, and only one along each flank.

Pulvinated. A term applied to the frize in an Order when its profile is a segment of a circle, convex outward, so that it appears swollen.

Purlines. Timbers extending longitudinally across the principal rafters to support the smaller ones.

Pycnostylos. A denomination applied to a colonnade, in which the intervals of the columns are equal to a diameter and a half.

Queen-post. A vertical post supporting a rafter, but not placed over the middle of a tie-beam.

Quoins. The salient and rentrant angles formed by the walls of a building.

Rafter. A timber disposed in a vertical plane, and extending from the ridge to the lower extremity of the roof of a building.

Regula. The same as *Fillet*, which see.

Roof. The covering of a building. A *trussed* roof is that which is formed of several triangular frames placed vertically at intervals above the walls, to support the rafters and covering. A roof is said to be *hipped*, when it consists of four planes inclined to the horizon; and it is called a *mansard*, or *curb-roof*, when a transverse vertical section has the form of four sides of a polygon.

Rubble-work. A denomination applied to walls formed of unwrought stones.

Rustic-work, or *Rusticated-work.* A denomination applied to that in which the exterior of the masonry is left rough, or purposely made so. And to that in which the joints of the masonry are strongly marked by grooves.

Scotia. A concave moulding in the form of a segment greater than a quadrant of a circle or ellipse.

Shaft. The trunk of a column; that is, the part between the base or pavement and the capital.

Socle, or *Zocle.* The same as *Plinth.*

Soffit. The inferior surface of any projecting member.

Spandril. The part between the crown and foot of an arch or vault, and above the course of voussoirs. A *pendent* spandril, in Gothic Architecture, is the key-stone of a vault cut in a conical, pyramidal, or bell-shape; its point, which is placed downward, descends below the ceiling at the place of insertion.

Stereobata. The basement, or lower part of a building.

String, or *Cordon.* A projection of masonry, extending horizontally along the face, or entirely about a building.

Stylobata. The same as *Podium*, which see.

Systylos. A denomination applied to a colonnade, when the intervals of the columns are equal to two diameters and a half.

Tabernacle-work. The denomination applied to the rich sculpture about a Tomb, or Shrine.

Tænia. The same as *Fillet.*

Tambour. A cylindrical wall, placed above the general roof of a building, to support a spire or dome.

Tie-beam. A timber, extending horizontally between the tops of two parallel walls.

Torus. A convex moulding about a column; its profile is either semicircular or semielliptical.

Tracery. The ornamental work formed by the intersections of the mullions in windows, and of the mouldings at the ridges, or on the spandrils of groined roofs.

Transept. That part of a Church which is carried out on each side perpendicularly to the length.

Transom. The horizontal bar placed across a window.

Trefoil. An aperture or ornament, bounded by three segments intersecting each other.

Trellis-work. A species of ornament on the face of a wall, formed by courses of fillets crossing each other at any angle.

Triforia. An upper tier of arcades in an Ecclesiastical edifice, when the arches are subdivided into three parts by two columns or posts.

Triglyph. A rectangular ornament, placed at intervals along the frize in the Doric entablature; in its face are cut two vertical channels.

Tympanum. The triangular space included within the horizontal entablature on the face of a building and the cornices of the pediment. See *Gabel.*

Vault. A roof in the form of some portion or portions of a cylinder or sphere. It is said to be *waggon-headed* when it consists of a hemicylinder resting on the walls, and *domed* when it consists of a segment of a sphere or paraboloid.

A *cloister* vault is that formed by four portions of cylinders rising from a square base and meeting in a point at the vertex: and a *groined* vault is one made by two hemicylinders intersecting each other at right angles.

Vestibule. The entrance-hall of an edifice.

Volute. The ornament formed by a moulding bent in a spiral form, which is situated at each angle of the capital, in the superior Orders.

Voussoirs. The stones cut in the form of frusta of wedges, and constituting the curved part of an arch or dome.

Water-table. A sloping surface formed on the face of a wall, buttress, &c., where the projection diminishes.

Weather-moulding. The same as *Label*, which see.

Zophorus. The same as *Frize*, which see.

LIST OF SOME OF THE CHIEF WORKS ON ARCHITECTURE.

Architecture.

A. D.
1431. Architectura Moderna. Hendrich de Keyser.
1485. De Re Ædificatoriâ. Alberti.
1486. De Architecturâ. Vitruvius Pollio.
1537. Architectura. Serlio.
1554. I Quatuor Primi Libri de Archit. Pietra Cataneo.
1559. Livre d'Architecture, contenant les Plans et Desseins de 50 Bâtimens tous Différens. Androuet du Cerceau.
1563. The first and chief Grounds of Architecture. John Shute.
1567. Architecture, with Annotations. Dan. Barbaro.
1569. Règle Générale d'Architecture. Jean Bullant.
1568. Ten Books of Architecture. Philibert de l'Orme.
1570. Architecture. Palladio.
1572. Dispareri in Materia d'Architectura, etc. Martin Bassi.
1577. Architecture de Vitruv. Johannes Frisius Vredeman.
1582. De Compendiosâ Architecturâ et Complimento Artis Lullii. Jordan Bruno.
1593. Architecture. Wendel Ditterlein.
1699. Architecture von Verstungen. Dan. Speckle.
1615. L'Idée de l'Architecture Universelle. Scamozzi.
1617. Instruction sur les Cinq Rangs de l'Architecture. Henry Hondius.
1624. Elements of Architecture. Sir Henry Wotton.
1624. L'Architecture Françoise. Louis Savot.
1631. Regola delli Cinque Ordini d'Arch. Vignola.
1631. Architectura Moderna. Cornelius Danckaerts.
1642. Le Secret d'Architecture. Mathurin Jousse.
1643. L'Architecture des Voûtes. François Derand.
1644. Architectura Politica. Gilbert Chazerat.
1661. The Elements of Architecture. John Evelyn.
1664. Architectura Curiosa Nova.
1669. New Treatise of Architecture according to Vitruv. R. Prike.
1673. Les dix Livres d'Arch. de Vitruv. Claude Perault.
1675. Cours d'Architecture Française. Blondel.
1676. Résolutions des Quatres Principaux Problêmes d'Arch. Blondel.
1676. Plain Description of the Five Orders. Bosbom.
1676. Les Principes de l'Arch. Felibien.
1685. Œuvres d'Architecture. D'aviler.
1687. The Mirror of Architecture. Vinc. Scamozzi.
1691. L'Architecture Pratique. J. B. Bullet.
1696. A Treatise on Architecture. Nich. Goldmann.
1702. Studio di Arch. Civili. Rossi.
1714. Nouveau Traité de toute l'Architecture. Cordemoy.
1714. Traité d'Architecture. Le Clerc.
1715. Les Ouvrages d'Architecture. Pierre Post.
1717. Vitruvius Britannicus. Campbell.
1720. The Orders of Architecture. Palladio.
1720. Opere d'Architectura. Boromini.
1720. Sommaire d'un Cours d'Architecture. Belidor.
1720. Architecture Historique. J. B. Fisher.
1722. The Marrow of Architecture. W. Halfpenny.
1725. Observations on the Orders and Rules of Architecture in use among the Romans. Inigo Jones.
1727. An Essay in Defence of Architecture. Robert Morris.
1728. Book of Architecture. Gibbs.
1728. History of Amphitheatres. Maffei.
1732. General Treatise of Architecture. Thomas Rowland.
1732. Oxonia Depicta. Williams.
1733. Proportional Architecture. Lectures on Arch. Rob. Morris.
1739. Commentarius Criticus de Vitruvii Arch. Poleni.
1745. Livre d'Architecture. Germain Boffrand.
1751. Œuvres d'Architecture. Anthony Le Paute.
1753. Ruins of Palmyra and Balbec. Wood.
1757. A complete Body of Architecture. Ware.
1759. Treatise on Civil Architecture. Chambers.
1762. Antiquities of Athens. Stuart and Revett.
1764. Palace of Dioclesian at Spalatro. Adams.
1765. Observations sur l'Architecture. L'Abbé Logier.
1767. Vitruvius Britannicus. Woolfe and Gandon.
1768. Grecian Orders of Architecture. Stephen Riou.
1770. Les Ruines des plus beaux Monumens de la Grèce. Le Roy.
1772. The Architecture of Vitruvius. Newton.
1773. Le Vignole Moderne. Lucotte.
1773. Works on Architecture. Robert Adams.

Architecture.

A. D.
1779. Monuments of Roman and Moorish Architecture. Swinbourne.
1780. Cours d'Architecture Civile. Blondel.
1785. Principi di Architettura Civile. Milizia.
1786. Dell' Archit. Egiziana, Dissert. Belgrade.
1789. On the Origin of Gothic Architecture, &c. Pownall.
1789. Elementa Architecturæ Civilis. Aldrich.

1830. Ruins of Pompeii. Gell.
1830. Stuart's Athens. Kinnaird.

SCULPTURE.

lpture. ition.

Sculpture, in its strictest and most confined sense, is the Art of carving or cutting any material into a proposed form, or shape, and may be practised in various ways; first, in representing entire or insulated figures, as in statues or groups, denominated by artists "the round:" secondly, in making figures either in high or low relief, (*alto* or *basso rilievo,*) that is, when the object represented is more or less raised, without being entirely detached from a back-ground; (of which some of the Sculptures from the Parthenon, now forming a part of the Elgin collection of marbles in the British Museum, afford excellent examples; those of the metopes being in high relief, and those of the frize in low;) and, thirdly, by cutting or sinking into a ground, making the object represented below the plane of the original ground; a mode of working seldom employed in modern times, but of which many specimens may be seen in Egyptian Sculpture.

sions.

In its more general acceptation, Sculpture is the Art of representing objects by form, and is thus indiscriminately applied to carving, to modelling, (or the plastic art,) to casting in metal, and to gem-engraving in hard or soft stones, as in CAMEI OR INTAGLI.

es.

Sculpture has very peculiar claims upon our regard; and no person interested in the History, the manners, or the customs of the Ancients, will estimate lightly an Art to which the antiquary and man of letters are so much indebted. Monumental remains, whether they contain Inscriptions, or represent Historical or Mythological subjects, have been found valuable landmarks, where no other sources of information have existed; and have often afforded satisfactory illustration of passages in the writings of the Ancients, which, but for such aids, would either have remained in total obscurity, or at any rate have been but partially understood. Ancient Sculpture is, therefore, as highly recommended by its usefulness, as by the charms which all persons of refined taste and feeling must find in it as an elegant Art, and its History cannot be considered a matter of indifference.

sity.

Various opinions have been held respecting the antiquity of the Arts of Design, and particularly whether Painting or Sculpture was first practised; it appears probable, however, from the comparatively easy task of repeating the real shape of any object in a solid material, with that of drawing on a plane its partial view and perspective appearance, (a process that requires some preparatory knowledge,) that Sculpture preceded Painting. The story of the daughter of Dibutades having traced the outline of her lover's profile from the shadow cast on the wall by a lamp, and of the outline being afterwards filled in with clay by her father, and sent with his pottery to be baked, is well known.[*] Such an account of the origin of the Art of Modelling, is very poetical, but not sufficiently probable; the potter's clay must have been one of the most obvious materials for imitative Art, and there can be little doubt that attempts were made to model it into the human shape in the earliest Ages.

Sculpture. Materials employed by the Ancients.

The Ancients appear, in their Sculpture, to have availed themselves of every material which was capable of being applied to the purposes of modelling, carving, or casting. Pliny has supplied us with much curious information on the subject; and Pausanias, and other writers who have interested themselves in Art, have frequently given, with their descriptions of statues and *bassi rilievi,* a particular account of the materials in which such works were executed. It would extend this Essay to too great a length were we to enter into such details, or even attempt to supply a correct catalogue of the materials used; the varieties of wood and marbles, for instance, were almost infinite; we shall, therefore, confine ourselves in this place to a mere general notice of them; referring the more curious reader to the authors who have entered more at large into the subject.[*] In a subsequent page we shall be necessarily led to speak of some of the most important works of the Greek Sculptors, and our attention will then be required to some mixtures or combinations of materials, which will be better considered while treating of the works, than in the present stage of our subject.

For modelling, clay, wax, and stucco, or plaster, appear to have been universally used; the clay, after having been worked into the proposed form, was frequently baked, acquiring by that process a hardness not inferior to stone; in this state, too, it often served for moulds, into which soft clay was squeezed, and thus the object became easily multiplied. A considerable number of ancient specimens of statues, *bassi rilievi,* lamps, tiles, and architectural ornaments, in this material, (called *terra cotta,*) have been preserved, and may be found in most collections of antiquities; in the Museum at Naples, particularly, are some statues from this material as large as life, which were discovered in the ruins of Herculaneum. Marbles, stones, and woods of all kinds, as well as ivory, were employed by the carvers; and all the known metals, wax, plaster, and even pitch, were used for the different processes of casting. There was a statue of amber of Augustus; and at the celebration of *Funeralia,* as in those of Sylla, at public exhibitions, or on other extraordinary occasions, we read of statues having been made of aromatics, and of materials of the most combustible nature; and amongst the odd conceits of the ancient artists, may be mentioned a statue of the all-powerful Goddess of Love and Beauty made of loadstone, which attracted a Mars of iron! The combination of different materials, for the purpose of producing variety of colours, either for drapery or ornaments, was termed *Polychromic Sculpture*;[†] and those works which were composed of a variety of stone or marble, were in like manner called *Polylithic.*[‡] This mixture of materials, which modern taste disapproves, was continually resorted to by the most celebrated artists during the best period of Art in Greece, particularly in colossal

---

[*] Plinii *Hist. Nat.* lib. xxxv. c. 43. *Ed.* Hard.

[*] Plinii *Hist. Nat.* Pausanias. Junius, *De Pict. Vet.* Winckelman, Caryophilus *de Marmoribus,* &c.

[†] From πολὺς, many, and χρῶμα, colour.

[‡] From πολὺς, many, and λίθος, a stone.

works; we shall, however, defer for the present any observations on this branch of our subject.

Obscurity of origin. The History of the earliest practice of Sculpture is so obscure that we are left entirely to our conjectures respecting it; we endeavour in vain to elicit any authentic information respecting its first introduction, from the few notices of it that are scattered over the Works of the Ancients; and, when we consider the very late date of the oldest of those writers, compared with the undoubted antiquity of the Arts of Design, the fabulous accounts of some, the contradictory evidence or total silence of others, on the subject of their early History, will scarcely be wondered at. Of the existence of works of a very remote date, Tradition supplied them with notices; but these, in the course of Ages, had become so changed as they were handed down to succeeding generations, and so subject to exaggeration or misrepresentation, according to the feelings or fancy of the reporters, that but little reliance could be placed upon them at that time, and still less can we build upon them as data.

Probable History. The desire which men have always felt to perpetuate the memory of extraordinary persons, or of actions performed by them, and thus to honour their benefactors or heroes while living, and to hand down the fame of their exploits to future Ages, has been universal, and equally influential in rendering the Arts of Design, even in their rudest state, objects of interest and importance. Their first introduction was, in all probability, for the mere purpose of commemoration, and, in whatever the monument consisted, it was no doubt marked by great simplicity; any accession of importance from form or style was the effect of time, and depended on various circumstances connected with the degree of civilization which the people practising or attempting imitative Art had attained. We read in the oldest Historians,[*] of monuments erected to mark the spot whereon any extraordinary event had taken place; and although, at the early period alluded to, these monuments were only composed of rude blocks, sometimes of mere heaps of stones, still to such a commencement, so simple in the means, yet so important in its object, are we, in all probability, indebted for the existence of those Arts which, by gradual advances, became so universally practised, and in many parts of the World so highly cultivated. Religious feelings, too, had their share in forwarding the progress of the Arts; for uneducated Man, unable to comprehend a Divine Essence, was led to offer his addresses to some palpable substance, as a representative of that Power from whom he felt he derived all Good, or by whose influence he was protected from Evil. But it is conceived this was subsequent to the first and more natural introduction of commemorative monuments. It seems probable, too, that the first statues were of Men rather than of Gods, and that Human Idols preceded those of Divinities. The supposition is strengthened by the fact, that the earliest objects of worship amongst the Heathen Nations were the Heavenly Bodies; and, although there were symbols dedicated to them, or allusive to them, it does not appear in any instance that these were made in the Human form; on the contrary, it is more likely they were mere pillars of a conical or pyramidal shape; and it has been supposed that when such works are alluded to and called "graven images" by Moses, it is in reference to the allegories or hieroglyphics inscribed on them. Traditional accounts of wonderful exploits in arms, the real or fabled History either of a mighty conqueror, a lawgiver, or a founder of a Nation, led probably in the first instance to the attempt at making an image, which a rude and uncultivated people, always fond of the marvellous, would soon learn to contemplate with feelings of admiration and awe as the representative or type of their great Chief. Extraordinary respect for his memory and actions would lead to the payment of extraordinary honours; and as the promotion of Heroes into Divinities offered but little difficulty, when time had obscured the real existence of the objects, the crafty policy of a college or caste of an hereditary Priesthood, (such as existed in Asia particularly,) would soon be led to take advantage of the effect produced upon the imagination of the people by stories attached to rude and frightful attempts at form. Thus an extravagant and monstrous worship was introduced, which soon prevailed over a vast portion of the World in ancient times, and is even now met with in uncultivated regions. The oldest monsters of Egypt, no less than the images of the Buddhists and Chinese, were, probably, in the natural progress of superstition, (fostered by the Priesthood,) the fruits of a similar origin, and, perhaps, the same may be said, in the first instance, of the Gods of Babylon and Nineveh. *Primus in orbe Deos fecit timor*, is perfectly true of the Idol Gods of the East; to increase their effect in exciting terror by additional monstrosities, both of form and attributes, was the object of the Priests, and the only progress in Art amongst them was the introduction of additional incongruities. The general forms once consecrated as symbolical of the attributes, or as resemblances of their monstrous Gods, were afterwards preserved from improvement or innovation by the nature of their hierarchal institutions; and thus, as will be more particularly shown when we come to speak of Egyptian Sculpture, was a barrier raised against any improvement in style in the imitative Arts, which, as long as it was respected, was fatal to their progress.

Inventio the East. To return to our History. It has been contended that the Egyptians were the inventors of Sculpture: the distinction has also been claimed, and with much more propriety, for the Phœnicians, of not only having invented it, but of having extended it and taught it to other Nations. The circumstances which Asia appears to have enjoyed, undisturbed as that portion of the Globe was for a long period, either by intestine divisions or foreign wars, is also favourable to the opinion that the Arts, both useful and ornamental, had their commencement there, and that as it was the first settlement of Man after the Deluge, so it was the cradle of the Arts and Sciences. It is, indeed, more than probable that the Asiatics had made considerable progress in them long before they had any existence in other Countries. It is much to be regretted that our acquaintance with the earlier History and migrations of the Hindùs is so scanty; but we trust the time is not far distant when the laudable exertions of a learned Society, instituted for the express purpose of collecting information respecting the History of the Nations of the East, will be so far crowned with success as to enable the curious in such pursuits to penetrate the thick cloud in which the origin and intention of their Mythology is enveloped; and from which, however they may have been changed subsequently, it is not improbable that much in the Egyptian, and even the Grecian systems of

---

[*] *Genesis*, ch. xxxv. v. 14; *Joshua*, ch. xxiv. v. 26, &c.

worship, was originally derived. Such a knowledge, if the supposition be admitted, would open a wide and extremely interesting field for the antiquary, and, leading to the explanation of the object of their Sculpture, would tend to elucidate much in the practice of the Arts amongst the earlier Nations.

posed Scrip- notices.

It has been asserted by some of the oldest Christian writers that Abraham,[*] as well as his father Thera or Terah, were themselves makers of images. The Scriptures afford us no authority for this supposition; we only find allusion made to their being infected with the extravagant and improper notions that are said to have prevailed in those days, both with regard to image-worship, and adoration paid to the stars. Thus in the Book of *Joshua*,[†] we read, "Thus says the Lord God of Israel, your fathers dwelt on the other side of the flood in the old time, even Terah, the father of Abraham, and the father of Nachor;" and "*they served other Gods*:" and in a subsequent verse of the same chapter they are counselled "to put away the strange Gods" that were among them. It is true that in this place no particular mention is made of the objects which they worshipped; but, soon after this time, we have it very expressly stated, that Rachel, when she left her father's house with Leah and Jacob, carried away the "images," and that Laban pursued them for the purpose of recovering them. This, we believe, is the earliest notice we have in the Holy writings of the existence of such things; and even here no details are supplied by which we can ascertain what they were like, nor of what materials they were formed. That they were but small, is evident from the circumstance of Rachel being able to carry them away unobserved, and afterwards from the facility with which she concealed them when Laban searched for them. One other instance may be mentioned, where Jacob is described as taking all the "strange Gods and hiding them under an oak which was by Shechem."[‡]

lpture ongst the ebrews.

No remains of the Sculpture of the Hebrews exist, but we are assured that, at the time of Moses, they were considerably advanced in their knowledge of, and practice in, some of the most difficult Arts. Of this, the setting up of the Golden calf, and the Brazen serpent, afford ample testimony. It has been well observed by the author of *Sabæan Researches*,[§] that the manner in which the Art of Engraving is spoken of in the Books of Moses, shows that it was by no means an Art of recent invention at those times. The onyxes for the sacred ephod, the plate of gold for the mitre of the High Priest, and the precious stones for his breastplate, were all ordered to be engraven like the engravings of a signet; and this expression is frequently used in the Book of *Exodus*: at chapter xxxix. it says, "they wrought onyx stones enclosed in ouches of gold, graven as signets are graven." The same observation has been made with regard to the Cherubim, which seem to have been well-known figures, in that day, to the Jews; for Moses does not give any particular description of them, nor detail of form, as he does of other things, and yet the Jewish artists appear to have made them correctly. At this time too, at least fifteen hundred years before the Christian Era, we find the names of two Hebrew Sculptors recorded, Bezaleel the son of Uri, and Aholiab the son of Ahisamach, both employed by Moses to make the ornaments of the Tabernacle, and which will be found particularly described in the XXXVIth, XXXVIIth, and XXXVIIIth Chapters of *Exodus*. These, it may be observed, are the earliest Sculptors of whom we have, by name, any authentic record. It is presumed that the Sculpture of the Hebrews bore a good deal of resemblance in point of style to that practised by the Egyptians, and which we shall examine more particularly when we come to treat of that people.

Assyrians and Babylonians.

Diodorus Siculus, describing the riches and beauties of Babylon and Nineveh, says, there were a variety of magnificent works in the celebrated Gardens of Semiramis; *bassi rilievi* of animals, which were richly painted, and statues in bronze of Belus, Ninus, and Semiramis, were amongst the decorations of the Palace. Now, although much exaggeration has in all probability crept into the account of the Historian, and although even a question may arise whether the earliest Sovereigns of the Babylonian Monarchy, are to be here understood (for the names are said to have been common to many of the rulers of that Nation,) still it is evident that the assumption was strong that the practice of the Art was of great antiquity, and that Artists had lived who were capable of producing works of extraordinary grandeur; though we have no means of forming any conjecture on the style of the performance, nor of the manner of executing them.[*] Baruch[†] supplies us with some curious particulars respecting the practice of the Babylonians in image-making at a later period of their History; he notices the materials of which their statues were composed, and the manner in which they were dressed, namely, with real drapery, a custom not unusual in early times. The following extracts are interesting, and throw a valuable light on the state of Art in that part of the World at the period at which the Prophet lived. "Now shall ye see in Babylon *Gods of silver*, and of *gold*, and of *wood*, borne upon shoulders, which cause the nations to fear;" "they themselves are *gilded* and *laid over with gold*;" "yet cannot these Gods save themselves from rust and moths, though they *be covered with purple raiment*;" "neither when they were *molten* did they feel it."

About B. C. 630.

Phœnicians.

It is much to be regretted that no monuments remain, at least no monuments of a sufficiently early date, to throw any light upon the style of the Arts of Design amongst the Phœnicians; for the Carthaginian medals or coins which are preserved merely show us the state of Art in a colony established, it is true, by the Phœnicians, but from which we must not venture to judge of the merit, nor of the extent of skill of their ancestors. That they were an ingenious, highly cultivated, and industrious people, there can be no doubt from the evidence we have, and the mention made of them in the earliest classical writers; their Country seems to have been the great magazine of the World, wherein every thing that could administer to luxury and comfort was to be found; they are celebrated as rich merchants, and bold navigators, and their commercial intercourse was extended to all the neighbouring and even to some very remote Nations. Their acknowledged skill, and their establishment of Colonies in all parts, have led many to think that they

[§] Landseer.

[*] Herodotus, who lived about 450 B. C., writes, that there were statues of gold at Babylon; they were of a late date compared with the works to which Diodorus means to refer, but sufficiently early to render their existence important in an historical point of view.

[†] *Baruch*, ch. vi. v. 4. 8. 12. &c.

first taught the Arts of Design in the Countries which they fixed upon as residences; and although we are not disposed to think this entirely the case, there can be little or no doubt that their fame in all curious workmanship was very great. Homer especially distinguishes the Sidonians for their excellence in the Arts of Design, and calls them Σιδόνες πολυδαίδαλοι:[*] in the passage referred to, he is noticing a goblet elaborately worked in silver, and alludes to the artists who executed it. A Tyrian artist, too, was employed upon one of the most celebrated works of antiquity, namely, the Temple of Solomon; we are informed that "King Solomon sent and fetched Hiram out of Tyre, and he came to King Solomon, and wrought all his works; he made the molten sea, with the twelve oxen supporting it, Cherubim," &c. &c.: this was about one thousand years before the Christian Era.

Persians.

It appears that Sculpture was known and practised by the Persians at a very early period of their History, though it is likely that the Art never attained any very great degree of excellence or beauty amongst them; it was in all probability confined to architectural purposes, and the following causes would operate in no slight degree in arresting its progress towards perfection. In the first place the Persians highly disapproved of statues for Religious purposes, that is as objects to be worshipped, because they did not believe, as the Greeks did, that the Gods had the Human form; and we are informed by Diogenes Laertius, and Clemens Alexandrinus, that as they allowed Fire and Water to be the only emblems or representations of the Divine Power, so did they condemn all statues and images whatever; and Xerxes is said even to have destroyed all the Temples of Greece at the instigation of the Magi, because the builders of those edifices impiously presumed to enclose within walls, the Gods to whom all things are open and free, and whose proper Temple is the whole World. Various authorities might be added to these, in proof of the constant war which the Persians carried on against images, and every emblem of Idolatry differing from their own. Another reason for the slow progress of the Art in that Country was the horror they appear to have entertained of all naked figures; and as it would have militated decidedly against popular prejudice or feeling, no Sculptor would dare to represent any figure without its appropriate drapery. Under these circumstances, so unfavourable to the progress and improvement of Sculpture, we cannot be surprised at finding all the figures which have reached us, closely draped, and stiff and awkward, from the ignorance of the artists, who had no opportunity of studying the human form, nor of acquiring that knowledge of its structure which would have enabled them to show the play and variety of the figure under the dress in which they enveloped it. The *bassi rilievi* which have been found amongst the ruins of Persepolis show the general state of Art in Persia at an early period, and will be found to correspond with the character which we have drawn of it. These works bear so strong a resemblance, in many respects, to those of the Egyptians, that they have been thought to be the performances of artists from that Country, carried into Persia, probably, by Cambyses, when he returned thither after having subjugated Egypt; and, certainly, at a later period, the Persians seem to have employed artists to execute their coins who were entirely unacquainted with the improvements which had taken place in Art in the neighbouring States; as may be inferred from the pieces of money, called Darics, of which many, both in gold and silver, are extant, and which exhibit as much poverty in the design and style as ignorance and clumsiness in the execution. Representations of the Human figure, with accessories of a more elevated character of Sculpture, are frequently met with, as the Persian Divinity, Mithras, with his various symbols; but there can be no doubt that these statues and *alti rilievi* are the works of foreigners, Greek or Roman artists, and of a comparatively late period. One proof of this is, that the Persians are said to have sacrificed a horse to this object of their adoration, understood to be typical of the Sun; but in the monuments to which we allude, the victim is a bull, and the place in which the action is being performed is a cave, and we are informed, (in confirmation of our supposition,) that in those parts of Italy in which this worship was introduced, the ceremonies were always carried on under ground, or, in fact, as these Sculptures represent, in caves.

General remarks.

The foregoing general survey of the practice of Sculpture amongst the earliest Nations was necessary to our purpose in giving the History of the Art from the first accounts we have of it; but it has been our endeavour to render it as succinct as was compatible with the subject, being fully sensible that where there are no monuments existing, but little knowledge can be obtained of the styles of Art practised; and that but little light can be thrown on its History, or any peculiarities attending its first introduction, where books of a late date are our only authorities or sources of information. In considering the Arts, and more particularly Sculpture, as it was practised in other Countries, of which it is next proposed to treat, namely, Egypt, parts of Asia Minor, Greece, Italy, and their dependencies, a much more satisfactory field is opened to us; for in each, or nearly so, we shall be able to begin, if not with its birth, at least with its infancy, in point of style, and to trace it progressively to its perfection, decline, and fall. That of Egypt will, perhaps, be the most difficult, as the early History of that most interesting Nation is most lost in obscurity. But as the progress of the Arts, the particular object of the present inquiry, did not keep pace with the improvements of the people in other respects, we shall not have to regret the scantiness of our information on that head so much as might at first be apprehended.

Before we enter upon this part of our History, it may not be improper to observe, that in beginning with the Egyptians, our object is not to derive Sculpture from that, nor any other particular Country, for it does not appear at all necessary that the Art should have been transplanted from one Nation to another, in order to have become so universally practised as it is proved to have been from concurring testimonies and still existing monuments. Migrations of Nations, and the establishment of Colonies from more civilized Countries, would naturally have great influence in introducing improvement in most things; and Religion, customs, and with these the Arts of Design, would, probably, undergo considerable change. But we have undeniable evidence, in our own times, that Sculpture, as well as Painting, have been cultivated in Countries newly-discovered by us, and uninstructed, as far as we can find, by any other People, in these Arts. In Mexico, and the South Sea Islands, as well as in other places, Idols and Pictures have been found, which bear

---

[*] *Iliad*, lib. xxiii. v. 743.

undoubted marks of originality, rudely copied from Nature, and to be traced by their symbols, or the subjects they illustrate, to their origin in the tradition of real or pretended exploits of the ancestors of the people who possess them. The Arts of Design, as has before been observed, have owed their birth to necessity and to the desire of commemoration: their cultivation and improvement to pleasure.

The leading styles of Art amongst the Ancients are divided into Egyptian, Etruscan, Greek, and Roman. We may almost say, each of these has its Epochs, and each Epoch its distinguishing character, and in the Greek School each character its author; for we are furnished with the names, peculiarities of style, and, what is still more fortunate, with the works of many of the great masters of Sculpture in that favoured Country, which enable us to judge with tolerable accuracy at what times, as well as under what masters, various interesting changes in the Art took place.

Egyptian Sculpture.

ochs ording to ckel- n.

The History of the Arts of Design in Egypt has afforded a wide field for speculation, but few satisfactory conclusions have been arrived at respecting their origin and earliest practice. Winckelman* ventures to mark three distinct periods or Epochs of Art amongst the Egyptians, making the first include the time that elapsed from their origin in that Country to the reign of Cambyses, in the LXIId Olympiad, or 526 years before the Christian Era. This he distinguishes as the "Ancient Epoch;" "the Middle," according to his classification, embraces the whole period during which Egypt was under the dominion of the Persians and Greeks; and the third or last, which he terms the Style of Imitation, was about the time of Hadrian. In another place, however, the German antiquary seems disposed to fix the commencement of the second Epoch considerably later; namely, at the establishment of the Greeks in that Country, under Alexander the Great and his successors.† The Abbate Fea, the learned editor of the latest edition of Winckelman's Work, endeavours to establish no less than five periods: the first of which lasted from the origin of the Arts in the Country to the time of Sesostris; the second under Sesostris, during twenty-four years of his reign; the third from Sesostris to Psammetichus; the fourth, the period of imitation of Egyptian Art in Rome; and the fifth, that of Theodosius the Great: this classification, and particularly that of the first periods, is too chimerical to be depended upon. A third arrangement of periods of Egyptian Art may be noticed here, by M. Millin, the well-known author of various learned and interesting Works on Art and antiquity; the first is brought down by him to the time of Psammetichus, during whose reign the Greeks were received and treated with favour; the second commenced with the reign of that Prince, and had its duration till the Conquest of Cambyses; when a further change took place by the mixture of the Persian style with the original Art of the Country, marking the third Epoch; which lasted from Cambyses to the reign of Alexander the Great; the fourth was of the time during which the Egyptians were subjected to the Greek Kings, and M. Millin calls the style of this period the Græco-Egyptian; the fifth is the Style of Imitation, and commenced, as in Winckelman's division, with the reign of Hadrian. This classification is more satisfactory than that of the Abbate Fea; but it is a question whether the changes, which the different antiquarians have fancied are to be observed in Egyptian Art, are really sufficiently developed in the monuments which are come down to us, to allow of our making such distinctions. The most objectionable part of these divisions seems to us to be the fixing changes so early as those adopted by Fea and Millin;* for although Cambyses endeavoured to abolish the customs and even the Religion of the Egyptians, we are not informed that he made any changes in the Arts, or in the treatment of artists; and it is but fair to believe that had he entertained such a wish, the Persians had no Art which they could substitute superior to that which they found in the Country they had subdued. It is important too, while considering this subject, to bear in mind that the changes that Cambyses wished to effect, and perhaps did partially effect, were of no great duration, as we are informed† that his successor, Darius, permitted the Egyptians to return to their own usages; and it is remarkable, and offers some confirmation of this position, that Plato, who lived about 120 years after Cambyses, speaks of the attachment which the Egyptians cherished for all their most ancient customs, observing, that no change had taken place for Ages.‡ Under these circumstances, we should be disposed to consider the second opinion of Winckelman as the most satisfactory; namely, that the first style of Art, such as it was practised in the earliest times, lasted with but slight variations until the general introduction of Greeks during the reign of Alexander the Great, when a change took place in most of the institutions of the Country, and the Arts of Design, naturally enough, underwent some alteration from the introduction of the purer taste of the conquerors. But it will be remarked, that the characteristics of Egyptian Art are peculiarly its own; and although some general resemblance to it may be found in some stiff and hard first efforts in other Countries, and although, in the course of Ages, the practice may have been influenced, in minor details, by correspondence with foreigners, sufficiently perhaps to enable careful observers to distinguish the variations of the periods alluded to, yet the leading character of all Art in that Country remains the same; and whether it be of the most remote period, or of the Ptolemies, or of the time of Hadrian, it bears a style or manner which alike stamps it as Egyptian.

B. C. 330. and sub.

Causes of slow progress in Egypt.

It excites our astonishment that a Nation so distinguished, so superior indeed to other Nations in Science, should have made so little progress in the Arts of Design; for we cannot but be struck by the fact that their improvement in them, and especially their imitation of the Human figure, did not keep pace with their advancement in other respects. In the Arts of Design, though their works were surprising and magnificent from their scale, they seemed destined never to arrive at perfection; and it becomes an inquiry of interest to endeavour to

---

* Winckelman, *St. delle Arti del Disegno*, lib. ii. c. 1.

† Ibid. *Opere inedite*, *Trat. Prel.* ch. ii.

* We have thought it right to notice the opinions of the above ingenious writers, but the reader who desires to enter more particularly into the subject of Egyptian Art and antiquity is referred to the works of Zoega, Hamilton, Bankes, and especially the late researches of Young and Champollion.

† Diod. Siculus.

‡ Plat. *De Leg.* ch. ii.

discover an adequate cause for this failure. One of the principal reasons which has been adduced is the absence of beautiful forms amongst the Egyptians, either in face or figure. Ælian observes that, in his time, it was rare to find a well-made or beautiful woman; and another writer* says of them, *Homines autem Ægyptis plerique subfusculi sunt et atrati, magisque mæstiores, gracilenti et aridi*, &c. It is well known that they had no public Games, like the Greeks and Romans, for the exercise of their bodies, by which their artists could have the opportunity of studying the actions and variety of the figure; causes sufficiently powerful to prevent their imitative works possessing much excellence of form. The artists too, it must be remembered, were altogether precluded from studying Anatomy, so essential to the perfection of the Fine Arts and of Sculpture especially, by the extreme respect, approaching to veneration, that was paid to the dead. So jealous were they of any indignity being shown to the bodies of the deceased, that they considered the common and necessary offices which were performed as having something revolting in them; and, consequently, the persons appointed by law to embalm the dead and prepare them for interment were looked upon with horror and detestation, and were obliged to seek safety by flight from the indignation and excited feelings of the surviving relatives. The next cause that may be assigned for the little progress that was made in the Arts, was the strong and unconquerable attachment they had for all their most ancient customs; which has led some writers to suppose that the artists were forbidden to depart from established rules applied to the representation of the human figure. From the comparative skill which they have evinced in executing animals, it seems more than probable that it was in these inferior objects alone that they were permitted to exercise their own judgment or skill; while statues or pictures of men and women, appropriated to purposes of Religion, and confined to the representation of Divinities, Kings, and Priests,† were not to be elevated at the will of the artist beyond the character left by the Ancients, and, therefore, established as by Law. We must also notice another influential cause, the division of the people into castes or professions, which obliged a son to follow the trade or calling of his father, whatever it might be;‡ by the same rule it was prohibited for any person, however decided his disposition for them might be, to practise the Arts of Design, unless he had an hereditary right so to apply his talents. One more cause for the slow progress of the Arts in Egypt—more influential perhaps than any other in a profession which requires for its consummation and perfection much nursing and protection—was the little esteem in which artists were held in the Country; they were classed in the lowest rank, and neither had opportunty nor permission to rise above it. Thus their practice was merely mechanical, unaided and unenlightened by the mind or sentiment which a student, who feels he may arrive at distinction by excelling in the higher branches of his Art, would endeavour to throw into his works. The statues and *bassi rilievi* remaining, even at the present day, are almost without number; and wherever ruins have been discovered, whether of Temples, Tombs, or Obelisks, there also have Sculptures or Paintings been found. The continual practice, therefore, which such a vast quantity of work afforded must, under any other circumstances, have occasioned improvement; and were it not for the paralyzing influence of the causes above enumerated, we should be utterly at a loss to comprehend how it was possible, in a Country where Art was so extensively cultivated, that it should have remained so stationary in point of style.

The general characteristics of Egyptian Sculpture are extreme simplicity or uniformity in the composition of the lines, want of variety of action, and the absence of sentiment or expression in the heads. Their statues are standing quite upright, or sitting with all the limbs at right angles to the body, or kneeling on both knees; the arms are generally attached to the body, the hands close to the thighs, though in female figures one hand is frequently placed across the breast; in the kneeling figures, the hands are brought a little forward on the front of the thighs, and support a box containing idols; the backs are uniformly supported by a sort of block or pilaster, which is generally covered with hieroglyphics; the feet are for the most part parallel and joined together, though this is not always the case, for in standing figures one foot is sometimes slightly advanced before the other. The statues of men are entirely naked, excepting that a sort of apron is folded across the loins; those of females were dressed in one long and simple garment, fitted close to the body; there are no folds in it, and it is only to be distinguished from the figure by a slightly raised border at the neck and feet; the form of the breasts is sometimes indicated by their natural projection being circumscribed by an indented line. It has been remarked, and with great justice, that the Egyptians appear to have paid great regard to decency, and have preserved more modesty in their figures than any other people who have practised the Arts; occasionally, works of a different character are met with, but they may always be fairly attributed to a late period. The heads, when they are human, are sometimes uncovered, but more frequently they are surmounted either by an emblematical head-dress, in which is distinguished the lotus, a globe, a serpent, or some sacred symbol, or that more generally found in representations of the human figure in Egypt consisting, as is well known, of a sort of close cap or head-piece, entirely concealing the hair and falling in broad flaps upon the shoulders. The foregoing observations are principally applicable to their statues; but the Egyptians also worked a great deal in *basso-rilievo*, as almost all the Tombs and Temples which have been discovered are richly decorated with Sculpture of this sort. They do not of course differ very materially from the statues as far as regards general character, but they are somewhat varied in treatment. It will be found that there is frequently greater attention paid to details of costume, as in expressing more folds, and a bolder attempt at action is observable in them, as if the artists were not so strictly confined in their works in this style as in statues. This is particularly striking in some *bassi rilievi* on one of the great Temples at Thebes. The principal of them represents a battle, or the exploits of some hero who is destroying his enemies; he is made of colossal proportions compared with the other figures in the scene, and there is an attempt at composition, and even beauty of form, in the heads of some of the combatants, which offers ground for curious speculation as to the period at which the work

---

* Ammianus Marcellinus.

† Herodot. lib. ii.

‡ Diod. Sic.

was executed, and the subject to which it relates. We shall here point out a peculiarity in the execution of some of the Egyptian *bassi rilievi* still preserved to us. A ground was sunk below the face of the stone to be employed, preserving, however, a margin of the original face all round; the figure or subject to be represented was then worked within this, so that there was no relief or salient part beyond the original plane, which formed as it were a protecting frame round it. It may be observed too, that it was by no means uncommon amongst this people to paint their *bassi rilievi*, and indeed their Sculpture in general; as has been ascertained by the discovery of works either accidentally buried or enclosed in Tombs; on which, from the atmosphere having had no influence in decomposing them, the colours have been found as vivid as when first applied. Although the additional splendour of effect obtained by it for decorative works, was probably the principal cause for introducing Painting upon their Sculpture, other and considerable advantages were also gained by its adoption: first, the Sculpture was longer preserved, from its surface being so defended; and next, their works, by the union of the two Arts, became much more complete, as the artists were enabled to add many details by painting them which were altogether omitted in the Sculpture: it will be seen, however, that painting statues and works in Sculpture was not confined to the Egyptians, but was general in other Countries.

The above remarks apply to the *general* characteristics of Art in Egypt; before we dismiss this part of our subject, we shall point out some of the peculiarities which are offered us in the details of their works, and of which the interesting specimens preserved in England, particularly those which have been added within a few years to the collection of Sculpture in the British Museum, afford us numerous and highly valuable examples. In the first place, the form of the face is rather short or round, the eye, large and pointed at the extremities, has a slight inclination upwards at the outer corner; it is not sunk into the head, as is observable in Greek Sculpture, but projects as far forward as the brow, which is merely indicated by a slightly raised line or sharp edge; the nose is much rounded at the point, somewhat flattened, and rather wide at the nostrils; the projection of the cheek-bones is considerably marked, but with great roundness, and this it is which gives the fulness to the upper part of the face; the character of the mouth is peculiar, the lips are heavy or thick, and slightly turned up at the corners, casting a simpering or silly expression over the countenance; the mouth too is always represented closed, differing in this respect from the early works of Greece and other Countries, where we find the mouth generally, if not always, slightly opened; the chin is rather small, and without that projection which gives so much beauty to the face, especially in the profile view of it; in the placing of the ear there is also a remarkable peculiarity in Egyptian statues, it being situated so high up that in many instances the lobe or lower part of it ranges nearly in a line with the eyes. The hands and feet of their figures are long and flat, the nails are rudely marked, but there are no indications of knuckles nor joints, which gives, even to the most highly finished and best preserved works, the effect of having had the extremities worn or smoothed down; the toes are rather long, and the smaller one, instead of being turned or bent, as in Greek statues, is extended, and has the same pressure on the ground as the others. It has been observed in some statues, which are represented standing, that the feet are not of equal length; one is generally a little advanced before the other, and the hindermost, on which the figure rests, is made the longest; the navel, in figures of both sexes, is strongly indicated.

late I.
ig. 1.

We wish in the foregoing observations to be understood as speaking of works distinctly Egyptian, applying that signification to the style of monuments believed to belong to their first or ancient period, as Winckelman has denominated it; original and unmixed with any of the styles of the more enlightened people—(enlightened with regard to their taste and knowledge in the Fine Arts)—who subsequently gained power in the Country.

Materials.

The Egyptians used a variety of materials for the purposes of Sculpture; we find works in wood, baked clay, some few in ivory, in metal, in a variety of marbles, in basalt, granite, alabaster, a sort of sandstone, serpentine, &c.; for their colossal works they employed the sandstone, basalt, porphyry, and granite; and Herodotus says, that at Sais and Thebes there were also colossal statues in wood.* There are none of large dimensions in bronze; the works in the other materials are for the most part very small, having the appearance of Lares or household Gods, either under the human form or that of animals.

The clean execution and exceedingly fine surface so remarkable in Egyptian Sculpture has excited the attention of the curious; and it leads to the belief that their knowledge in hardening metals must have been very far beyond ours, to have enabled them to produce such carefully finished works in materials which almost defy our best-tempered instruments. It is a remarkable fact, that when the colossal head, called that of the Young Memnon, was placed in the British Museum, and it was found necessary to make some holes in it for the insertion of irons to join two of the pieces together, the hardness of the granite was so great that six or eight blows rendered the tools employed perfectly useless.

Etruscan Sculpture.

Etruscan.

The next School of Sculpture which offers itself to our notice is the Etruscan. Its early History, its origin as a School of Art, and the Nation from which it was derived, have afforded subject for much discussion amongst antiquaries; but nothing very satisfactory has been adduced by which we can form any decided opinion upon it previously to the emigrations by which the Greeks obtained an establishment in Etruria. It is not intended here to question the possibility, or rather the probability,† that there was some original Art in Etruria before the arrival of the Greek colonists; some of the monuments, indeed, which have come down to us have been produced as instances of original works of an extremely early date They bear no allusion to the Greek fables or mythology, consisting of figures of men, of Genii with and without wings, ceremonies, &c.; but in the greater part of those that have reached us there is such strong evidence of Greek origin, (in their subjects rather than in any distinguishing style of Art,) that we are justified in considering them as drawn from Greece. We

Origin.

---

* Herod. lib. ii.

† Niebuhr, *History of Rome*, vol. i.

would, however, here observe, that the works of ancient Greece and of the Etruscans have been frequently confounded from the similarity of their style alone; but it must be remembered that this style is nothing more than the general characteristic of all Art in its infancy, the same in Greece, in Etruria, as in all other Countries; or, as it has been observed from the learned Lanzi, in speaking of the conjecture that the Art of the Etruscans was brought from Egypt originally, *La supposizione che gli Etruschi traessero dagli Egizj le loro Arti e il loro disegno è priva di fondamento, poichè come avvertì il Lanzi, la rigidezza e il rettilineo dei segni non hanno bisogno di venirci dal Nilo, e nei principj delle Arti presso tutte le Nazione si vede lo stesso carattere* essendo quello stile non tanto Arte, quanto mancanza di Arte.[*] These observations, however, are only intended to apply to the earliest works, in which the mere similar rudeness of execution has been erroneously considered a corresponding style of School. Strabo[†] has a passage in which the resemblance of the works of the Egyptians to those of the Etruscans (or Tyrrhenians) and the early Greeks, is in like manner noticed; but we certainly are not led to infer from it that there was any communication of first principles between the three Nations. A distinction, as Lanzi observes,[‡] must be made between the Etruscan style and works executed by Etruscan artists, which will be found on examination to be very necessary to enable us to comprehend and judge of the productions of this School. The "Etruscan style" was a peculiar manner of treating Art, which was retained by those attached to this School from its foundation down to a very late period; it was particularly distinguished by the Latins, and called by them *Tuscanicus;* it was applied exclusively to Art, and always signified a *style*, and its practice was not necessarily confined to natives of Etruria. All works executed in the hard and dry manner peculiar to this School, were, therefore, called *opera Tuscanica.* A passage from Quinctilian will illustrate still more strongly the application of this style, where he is speaking of the works of some of the most celebrated Greek Sculptors: *Duriora et* Tuscanicis proxima *Callon et Egesias; jam minus rigida Calamis; molliora adhuc supradictis Myron fecit.*[§]

Connection with the Greek style.

Some difference of opinion has arisen respecting the dates of the various migrations of the Greeks, but the earliest, generally believed to have taken place about fourteen centuries before the Christian Era, was that of the Pelasgi, or as they are also called, Tyrrhenians.[||] Subsequently, about 600 years after the first, another very considerable colonization of Greeks took place;[¶] and to this much of the improvement of the inhabitants of Etruria in the Arts of Design is attributed. It is moreover extremely probable that the Arts were practised to a great extent in that Country, where for a long period they were enjoying repose, while in Greece, from a variety of causes, (amongst which may be particularly noticed their internal and external divisions and wars,) they were neglected and most probably suffered to fall to decay. The various representations of subjects from the Greek History and Fables, found in Etruria, and supposed to have been executed at a period when there was no Art in Greece, have been adduced in support of this opinion; amongst them may be particularly noticed the celebrated Gem formerly in the collection of the Baron Stosch, representing five of the seven Chiefs who conducted the expedition against Thebes; a remarkable event in the early History of Greece, and of which there is no equally early representation found amongst the works of the Greeks themselves. If this Gem be indeed of the high antiquity ascribed to it, it offers a remarkable confirmation, we think, of the Etruscans having practised the Arts when they were neglected in Greece; but we are aware that its antiquity has been questioned, and its execution attributed by one writer[*] to so low a date as subsequent to the Vth century of Rome. Judging however, generally, from the monuments of Etruscan Art which have come down to our time, they may be fairly considered as derived from the Greek School; not, as we have before stated, from any distinguishing style, but from the subjects chosen for illustration; other works may have existed, perhaps do now exist, which may have been executed by the original inhabitants of the Country, but the monuments that we have naturally lead to such a conclusion.

Characteristics.

With respect to the characteristics of the style of Etruscan Art, it will be observed that a certain variety exists: in some of their works the forms are undefined, the hair and drapery stringy, and arranged with the utmost regularity and stiffness;—in others there is a studied affectation of execution, with an exaggerated and forced action of parts even to the fingers, the ends of which are turned up in the most unnatural manner; but with this difference in execution one peculiarity will be found to pervade all the works of the School, namely, a general absence of grace and character. Unlike the Greeks, they do not appear to have founded their practice on Nature, and the consequence is a want of beauty and appropriate expression or sentiment in their works. It will also be observed that the Etruscan artists continued, long after they had had opportunities of improving themselves in that respect, to execute in the same hard, dry, severe manner, by which, in other Countries, only the earliest works are characterised: Winckelman[†] has adduced reasons for this fault, but they do not appear sufficient to account for the almost Egyptian pertinacity displayed by the Etruscan artists, in following the model of style which their precursors left them. That they had vast practice in the Arts, and particularly in Sculpture, may be inferred from the quantity of works of

[†] Strabo, lib. xvii.

[‡] Lanzi, *Notizie sulla Scultura.*

[§] Lib. xii.

[||] It is not necessary here to enter into an inquiry of the particular distinction between the Pelasgi and the Tyrrhenians, though it is probable that the terms have been used indiscriminately by those who have spoken of these colonies. A variety of Works may be consulted on the subject; amongst them those of Raoul Rochette, *sur les Colonies Grecs;* Clavier, *sur les Premiers Temps de la Grèce;* Lanzi, Winckelman, Niebuhr, &c. &c. It appears probable too, that other Greeks came over and settled amongst the Etruscans during the long interval between the two principal emigrations.

[†] Winckelman, lib. iii. It is worthy of remark that the Etruscans, like the Egyptians, had a powerful hierarchy, for their chiefs, "Lucumones," were Priests as well as Governors, and they may have exercised an influence in preserving the forms once consecrated by Religion from profane innovation. That this prejudiee, if it did exist, was not so strong as that which was submitted to in Egypt, is evident from some varieties in the Etruscan work, but it may have operated to some extent in checking the progress of style.

pture.

various kinds that have been found in their Country, as well as from the accounts of some of the ancient writers;[*] if the statue of Romulus was of his time, as was pretended, it must have been by Etruscan artists. We read too of their efforts in the plastic Art, in a statue of Jupiter of clay, which was painted red, also of a Hercules in the same material; and it is said that when, after having sustained many long and troublesome wars against the Romans, they were finally subdued by that people, and became a Roman Province, (which event happened about two hundred and eighty years before the Christian Era,) so many as two thousand statues were taken from Volsinium alone![†]

Grecian Sculpture.

The Art of Sculpture, though every where of equal importance, perhaps, in an antiquarian point of view, does not afford us the same interest, nor excite the same feelings, when we are examining its practice in other Countries, as it does in Greece and its colonies. The associations connected with that Country, added to the peculiar excellence which the Arts of Design, and particularly Sculpture, attained there, are sufficient to account for this difference; and we cannot but feel that the real History of Art, as a refined and intellectual pursuit, can only be known by tracing its progress amongst that favoured and gifted people; by whom, in a few centuries, it was carried to such wonderful perfection. In other Countries in which Sculpture was practised, it seemed destined never to go beyond certain limits, and if it did sometimes rise superior to the rudeness of first attempts at form, still it never attained strength sufficient to step beyond a wretched mediocrity. Mere representations of objects were produced, unelevated by the introduction of sentiment or feeling. It was in Greece alone that the advance of the Fine Arts, and particularly of Sculpture, was progressive towards perfection; it was here that it rose superior, and became something beyond a mere mechanical pursuit; it was here that Mind was made to illumine Matter, and that the conceptions of rich and glowing fancies were embodied in the productions of their artists.

es of
ian su-
rity.

The extraordinary superiority of the Greeks in this respect over all other nations, a superiority so decided and so universally admitted, that the terms Greek and perfection are, as applied to works of Art, almost synonymous, is a phenomenon which has engaged general attention, and has been attempted to be accounted for in various ways, morally and physically. But no sufficient reason has yet been assigned, we think, for an excellence which, even amongst them, was partial, and confined to some States or particular parts of the Country. By some writers, the great excellence of the Greeks in the pursuits under our consideration has been attributed to the fineness of climate which they enjoyed; but it requires no argument to show that such a cause is inadequate to produce such extraordinary effects; other Countries have had equal advantages in this respect where the Arts have comparatively had no existence. An ingenious author[*] has even gone so far as to assert, on the authority of ancient writers, that the climate of Greece, generally, was very unequal, that they were often visited by fogs, that the cold of winter was in many parts extremely rigorous, and the heat of summer excessive, and that in Attica, especially about Athens, they were afflicted by a peculiar and annoying wind; and although, in some spots, vegetation flourished in the greatest luxuriance, that in others the earth was perfectly naked. It is not, however, intended here to prove that the climate of Greece was bad, but merely to observe that it had its inconveniences, and to reply to those who are disposed to attribute an all powerful influence to climate alone. By some again it has been supposed that the beauty of form of the people amongst whom the Arts were practised, affords a sufficiently powerful reason for the success which attended them; but we do not conceive that that circumstance would have all the influence which its supporters would derive from it; besides, we are not told that the people who most excelled in the Fine Arts, (namely the Athenians,) were the handsomest of the Grecians. Cicero,[†] speaking of the youths he saw at Athens, says he observed few who were really handsome; and although we will not infer from this that they were none of them so, especially when we have the names of so many handed down to us as celebrated for this quality, yet we may fairly conclude that the Fine Arts owed their superiority in Athens to some other cause than the universality of beautiful forms. We would remark too at this place, and it is a curious circumstance, that those women especially whose celebrity for beauty has reached us, were none of them natives of Attica, the State in which Sculpture most flourished. Phryne, for instance, was of Thebes, Glycera of Thespiæ, Aspasia of Miletus, and the masterpiece of Xeuxis was an union or combination of all the beauties afforded by the study of seven virgins of Crotona. The admiration of beauty amongst the Lacedæmonians is well attested,[‡] but the Fine Arts were proscribed at Sparta. Neither does a peculiar form of Government afford a sufficient reason for their success; for we find they flourished where there were essential differences in this respect. They were not fostered in the most powerful States, as may be inferred from the circumstance of Sicyon, the feeble Sicyon, holding, together with Athens, the first rank in the cities of Art, whilst the rich and magnificent Corinth was only of secondary consideration in this respect. In fact, if wealth, pomp, and luxury had been necessary to their developement and success, it is natural to believe that Asia, and not Greece, would have been the seat in which the Arts would have established themselves.

Grecian.

Perception of Beauty.

Thus it does not appear that the aptitude (if we may be allowed the term) of the Greeks for the Fine Arts depended upon those circumstances to which their success has been so generally attributed, and upon which, however useful and important they may have been as assistants, too much stress has been laid; it must therefore be sought for elsewhere, and we are led to think it arose out of the particular constitution of the people; principally it may have been owing to the love of simplicity which for a long period was so general

---

[*] M. Emeric David, *Essai, &c.*

[†] *Quotus enim quisque formosus est? Athenis cùm essem e grege epheborum vix singuli reperiebantur. De Nat. Deor.* lib. ii. c. 79.

[‡] Ælian. *Var. Hist.* lib. xiv. c. 27. Athen. lib. xii. c. 2.

amongst them, and which seems to have pervaded their language, and even to have extended to their actions and their feelings, united to a quickness of perception and admiration of that which is admitted to constitute Beauty, possessed by them beyond any other people, and which influenced them in all they did. The artists in their choice, as well as their treatment of subjects, seem to have been careful never to lose sight of this principle, nor to express any passion or feeling so violently as to be at variance with the laws of Beauty, united with simplicity; and as *extreme* expression would have interfered with its existence, it will be found that the Ancients studiously avoided it in their works. Laughing or crying figures can have the effect of being so excited but for a moment, afterwards the expression is but grimace, as may be seen in many productions of the later schools of Sculpture. In all the varieties which have come within the scope of their practice, even in subjects of the greatest excitement, from the convulsive struggles of a Laocoon to the equally intense but quiet suffering of the Dying Gladiator,* this solicitude will be observed. It is true a restraint was sometimes put upon them by their Religion, which obliged them to represent their Deities according to rule, founded on ancient and established usage or popular belief; or to accompany them with attributes destructive to, or at least materially affecting, that beauty and simplicity which constitutes the charm of Art; but in prescriptive works, for to such the last observations are intended to apply, we are not to look for the real feeling of the artist, and it is only when unfettered by restraint that even the Greek could act up to the impulse of his mind, and follow that Beauty which filled his imagination, and which was the first and favourite object of his pursuit. A further proof of the attention which the Ancients paid to Beauty in works of Art, applying equally to the choice of subjects and to the manner of treating them, is the contempt and derision to which those were exposed who confined themselves to representing common or inferior objects. We are told that an artist named Pyreicus,† who painted barbers' shops, and such trifling subjects, with all the care of one of the Flemish School, got the nickname of *Rhyparographus;* and it is said that the Thebans had a law which applied particularly to artists, who were subjected to a fine if the works they executed fell short in beauty of the objects they professed to imitate. In Greece, personal beauty was considered to confer a title to distinction, and the estimation gained by its possession is everywhere attested by ancient writers. We are informed, that the Priests of the young Jupiter at Egea, those of the Ismenian Apollo, and those of Mercury at Tanagra, were youths to whom a prize of beauty had been awarded.‡

Advantages derived from Public Games.

Though we have observed, that the natural constitution of the Greeks was particularly favourable to the success of the Fine Arts, we must not omit to notice, at the same time, that they were assisted by a variety of other circumstances highly propitious to their advancement, and which did not exist to the same extent in any other Country. Principally, then, the public Games and combats, in which the competitors were for the most part naked, offered great advantages to the artists of Greece, and were of vast assistance in enabling them to carry Sculpture to perfection. The value put upon distinction in these exercises, for which the most exalted characters of the Country were ambitious of contending, and the honour that was conferred even upon a City or State, by merely having given birth to a victor in the Games, rendered the education of their youth a subject of the first importance and interest. The Gymnasia or Schools in which they were trained were the resort of men of rank and talent. Personages of the highest consideration in the State, as well as Philosophers, Poets, and Artists, were in the constant habit of attending them, and were thus accustomed to the contemplation and study of the human form in all its varieties, whether in repose or in action; they became well acquainted with the beauty and with the capabilities of the human figure, and, consequently, fair and competent judges of imitative Art. But the Sculptor especially benefited by these establishments, from the intimate knowledge he acquired of the formation, as well as the active powers of the figure. The causes of the superiority of the conqueror in the race or wrestling-match were diligently sought after, and the properties discovered most generally to exist in those who excelled in the various exercises, were presumed to be best adapted for the purposes required, and were therefore adopted by him into all representations of the human figure in which the character demanded these qualifications. The wide shoulders, for instance, and spacious chest of the brawny wrestler offered to the Sculptor the properties essential for the statues of Hercules, and others of that class in which physical strength was to be portrayed; the clean legs and light proportions of the victor in the race, gave the character of the messenger of the Gods; and the union and judicious combinations of strength and agility afforded the characteristics of the general athlete, or, modified into all their varieties, produced that Beauty, called *ideal,* which peculiarly distinguishes their sublimer productions, and their statues of Demigods and Heroes. By these means, that pervading harmony, the natural and unfailing result of propriety, was attained, which gives so peculiar a charm to almost all the works of the Grecian School, without which no production, however beautiful it may be in detail, can ever please. It must be remembered too, before we leave the subject of the Public Games, that, in witnessing them, nothing (during the best times of Greece) was ever presented to the spectators that was capable of doing violence to the finer feelings; no barbarity disgraced these amusements; for the introduction of the disgusting exhibitions of Gladiators and the fights with wild beasts were reserved for a later period. It was highly conducive also to the advancement of Sculpture that statues were erected to those who excelled in agility and strength of body; and the greatest distinction that could be conferred, (an honour only permitted to those who had conquered a certain number of times,) was the right of dedicating an Iconic (or Portrait) Statue, which was erected in the most sacred place for such a purpose, the Altis, or Sacred Grove, near the Temple of the Olympian Jupiter; to be seen and admired by the crowds who

---

* It may be objected here that these works are of a later date than the finest Greek productions; this is still a question, and it is immaterial, as the principle of which we are speaking exists in so remarkable a degree in them, that they fully merit the distinction of being so noticed, whether the learned agree in allowing them to be really Greek or not.

† Plin. *Nat. Hist.* lib. xxx. c. 37.

‡ Pausanias, lib. vii. and ix.

Early Sculptors.

Dædalus.

The first Sculptor who gained sufficient celebrity to have his name handed down to posterity is Dædalus; his era, however, is so remote, and the statements respecting his adventures and discoveries in Sculpture, as well as the more mechanical Arts, so mixed up with the marvellous, that it may be justly questioned how far any of them are worthy of credit; and as Dædalus was in all probability a distinguishing name given in the Ages of antiquity to all artists who had produced any work out of the common way, it is easy to conceive how the inventions and improvements of many became, in subsequent times, attributed to one. As some account has already been given of Dædalus in the BIOGRAPHY OF THE EARLY SCULPTORS OF GREECE in a former part of this Work, it is unnecessary to dwell in this place upon his history or productions. There were, however, several Sculptors of the same name, and the Athenian has in some instances been confounded with a Dædalus of Sicyon, who lived nearly 700 years later. As the style of Art of this more modern Dædalus would not, it is conceived, be very dissimilar to that attributed to works of a much earlier time, the productions of this Sculptor might easily have elicited the remarks which Pausanias and others have made upon them, under the impression that they were works of a still more remote antiquity.

Smilis.

The next Sculptor who occurs in the annals of Grecian Art, after Dædalus, is Smilis,[*] or Scelmis, a native of Ægina, and son of Euclides; he was said to be contemporary with Dædalus, and was considered the author of a statue of Juno, at Samos, and which, according to some traditions, had been brought from Argos by the Argonauts who dedicated the Temple; a circumstance which has occasioned the antiquity of Smilis to be doubted, the Argonauts not having visited Samos till very long after the time at which Smilis is said to have lived. This, however, is not sufficient to affect the antiquity of the work, for the Argonauts might have brought an *ancient* statue with them; the circumstance of its being composed of gold and ivory has much more weight in leading us to attribute a later date both to the statue and to the artist who executed it.

Endœus.

Endœus,[†] a native of Athens, was a scholar of Dædalus, and is said to have followed his master to Crete, when he fled to that Country after the murder of his nephew Talus. He appears to have been very extensively employed, and amongst other works Pausanias particularly mentions a statue of Minerva in wood, of colossal dimensions; he is also said to have executed others in marble and ivory, but there is every reason to believe that many of the works attributed to this Sculptor are of a much later date. The author of the observations prefixed to the valuable Work on Ancient Sculpture published by the Society of Dilettanti, in 1809, remarks, that a head of Minerva on a silver tetradrachm of Athens, which is engraved in that publication, is probably copied from the above figure of Minerva by Endœus, it being by far the most Archaic of the heads of that Goddess observable on Athenian Coins. This learned Writer thinks that the Sculpture in *alto rilievo* over the gates of Mycenæ, representing two lions rampant against a sort of pillar or column, is the most ancient specimen of the Art extant; it is still in the situation in which it was originally placed, being built in with, and forming part of the walls, and on that account, as well as from the interest it possesses as a specimen of very early Sculpture, has great claims upon our regard.

Grecian Archaic.

The chain of Sculptors in Greece is here interrupted, (and the existence of the last mentioned is even doubted by some,) owing to our imperfect information, or, as is more probable, to the invasion of the Dorians on the return of the Heraclidæ, comparatively a more barbarous race, to Peloponnesus. It appears that the Arts were now practised with success deserving notice by a distant people; for we find that the next Sculptors who are recorded are the Telchinians of Rhodes,[*] who seem for many years to have enjoyed a high reputation in Sculpture; but no monuments of any description remain of this people, or of that time, by which any estimate can be formed of the merit of their productions; it is impossible, therefore, to offer any account of their style or of the character of their works. The next best accredited remains of Grecian Art are Coins; and although it is extremely probable that the general Sculpture of different Countries varied from and had improved upon the stamps used for money, (which as an established and well-known device were most likely preserved for the sake of convenience or policy,) yet, in the absence of other monuments, we must be content to seek information from them. In those extant of the earliest period in which the human head is exhibited, the eye has a very remarkable character, being represented large, and in the *front* view, while the rest of the face is in profile; in other respects, and wherever the whole figure is introduced, the style was energetic, the execution turgid, and corresponding very nearly with the description which has been already given of Archaic Art. It would be extremely difficult, perhaps impossible, to explain in a satisfactory manner to the reader the slight variations in style and treatment which took place in Coins as knowledge in Art advanced; the Coins themselves should be studied, the best engravings of them generally failing to give the details so essential to the right understanding of works of this minute description.

Early Coins.

Plate I. Fig. 2.

Phido. B. C. 869.

Phido of Argos is said to have struck the first money in Greece in the Island of Ægina, about 869 B. C., and there are some Coins of that Island extant, which, from the rudeness of the Sculpture, and the imperfect execution, are considered to be of nearly as early a date; but it must be confessed that they throw but little light upon the state of Art of the period to which they are attributed, their device being merely a tortoise. The employment of metal in Sculpture probably took place soon after the striking of money under Phido, and we, therefore, find that Gitiadas,[†] the next Sculptor whose name is recorded, made various statues in brass. Gitiadas was a native of Sparta, and exercised, as was frequently the case, the two professions of

Gitiadas. B. C. 740.

---

[*] Paus. lib. vii. c. 4.

[†] Ibid. lib. i. c. 26. and lib. vii. c. 5.

[*] Winckelman, *Storia delle Arte di Disegno*, ix. l. *Prelim. Dissert. Dillet.*

[†] The dates of Gitiadas and Learchus are by no means ascertained. The former is placed thus early on the strength of a passage in Pausanias, which makes his date, it is conceived, quite independent of the Æginetan Sculptor, with whom he has usually been considered contemporary. Learchus should follow Dipœnus and Scyllis, (if their date be, as we suppose, above 700 B. C.) but we have noticed him here as a distinguished artist in the early History of Sculpture in metal, and unconnected with any other Sculptors; if he were the Scholar of Dipœnus and Scyllis, they must have flourished much earlier than Pliny says; the reason will be obvious if the reader will consult Pausanias.

earchus.

Sculpture and Architecture; the period at which he lived is not precisely ascertained, but there is reason to believe that he was flourishing about the time of the first Messenian War, or about 740 years before the Christian Era; there were works remaining at Lacedæmon in the time of Pausanias, which were attributed to this artist.[*] Pausanias also mentions having seen at Lacedæmon, a brass statue of Jupiter by Learchus, a Sculptor of Rhegium, which, he says, was the most ancient statue known in that material; this has led to the inference that the Arts were in a more advanced state in Italy at that time than in Greece; and judging from some Coins which remain, it has been thought that the state of Art in all the Colonies was more flourishing at this early period, namely, the VIIIth century before Christ, than in the Mother Country. It must be acknowledged that there are many inconsistencies in the accounts we have of Learchus, and chronologers and antiquaries have differed considerably in deciding upon his date; but there can be no doubt that he lived at a very remote period, certainly not very much later than he is here placed.

elecles.
hœcus.
heodorus.
ibutades.

Passing over names of minor importance, we arrive at Telecles, Rhœcus, and Theodorus, who appear to have introduced great improvements into the practice of Sculpture; their dates are of considerable importance in the History of the Art, as they have been thought early enough to have been the inventors of various branches of it. Pausanias says, they first cast brass statues; and tradition, according to Pliny,[†] attributed to them the invention of the plastic Art, though the Corinthians claimed the distinction for Dibutades: at what time Dibutades lived is uncertain; he was a Sicyonian by birth, and exercised the trade of a potter at Corinth, but, as we have before observed, so simple a discovery as modelling figures in clay was, in all probability, made in the earliest stage of Society, and is not to be attributed to any one in particular. Rhœcus and Theodorus are mentioned by Herodotus, Pliny, and Pausanias; Rhœcus is said by Herodotus[‡] to have built the Temple of Juno, at Samos; he was also the author of a statue of Night in the Temple of the Ephesian Diana;[§] Pausanias says, that he was unable to find any of the productions of Theodorus; but Herodotus, and, subsequently, Pliny, allude to works by a Sculptor of that name. As there were at least two so called, who were living about the same time, some confusion may very easily have arisen amongst the Ancients in speaking of them; one, we are told, was a son of Rhœcus, another of Telecles. According to Herodotus, Theodorus engraved the celebrated ring of Polycrates, Tyrant of Samos, so remarkable in History for the good fortune which always attended him; he also made one of the magnificent vases which Crœsus, King of Lydia, presented to the Temple at Delphi. Pliny records a remarkable instance of minute execution by Theodorus; he says, he cast a brass statue of himself, holding in one hand a file, in allusion, probably, to his profession; and in the other a *quadriga*, so small that a fly could cover it with its wings. Great difficulties occur in fixing the dates of these artists; Pliny says, they lived long before the expulsion of the Bacchiadæ from Corinth; an event which took place in the XXXth Olympiad, about 659 years before the Christian Era; but the Author of the preliminary dissertation to the Dilettanti Work on Ancient Sculpture, observes, that if the presents offered by Crœsus at Delphi were made for the purpose, as was most probably the case, Theodorus must have been living above a hundred years later than Pliny has placed him. But it is possible that Crœsus may have had the vase already in his possession, and, without having had it made purposely for him, may have considered it, from its magnificence, worthy to be dedicated with his other presents to the Temple. There were two vases, one of gold, the other of silver; the artist who executed the latter is alone mentioned, and that, very probably, owing to its being a more ancient and celebrated work; had they both been executed at the same time, that in the most precious material would, in all likelihood, have been noticed more particularly: it is conjectured, therefore, that these artists lived between seven and eight hundred years before the Christian Era.

Employment of metal.

The introduction of casting in brass, if indeed it were introduced into Greece so early, forms an interesting and important epoch in the History of Art; and it may not be improper to offer some observations in this place on the manner in which it was practised in the first Ages; it must be premised that Pliny's accounts of this subject are not very consistent, and we must therefore be careful how far we admit the traditions mentioned by him. The earliest works in brass appear to have been executed in hammer-work, (called by the Ancients Σφυρήλατον,) that is, beaten out with hammers into the shape proposed, and the Statue of Jupiter, by Learchus, before alluded to, was made in this manner. Pausanias is very particular in his description of this work, and says, it was formed of pieces which were afterwards fastened together by means of pins or keys. Another mode of executing figures appears to have been by beating pieces of metal together in the solid till the surfaces became well fitted to each other; the features and parts were then hammered or hewn out of the mass. Two statues, probably of high antiquity, are noticed, of solid gold, one of Bacchus,[*] at Thebes, the work of Onassimedes, and another of Diana Anaitis; these were most likely beaten into form, and worked up according to this process. Pliny's expression[†] respecting the solidity of the Statue of Diana is remarkable. It has been conjectured that the method above described was practised by the Egyptians; a quantity of metal was also saved by beating it out and plating it upon wood, instead of hammering the whole out of a solid mass, and an interesting specimen is shown, in an engraving in the Dilettanti Work on Sculpture, of a small head of Osiris, in which the nucleus, or centre of wood, is still remaining. Homer, when he speaks of works in metal, always refers to this manner of working, that is, by beating it out, and the hammer is invariably the instrument with which he furnishes Vulcan; he also alludes particularly to the custom of plating sheets of metal on a solid body, when Laertes, at the desire of Nestor, comes to gild the horns of a bull about to be sacrificed.[‡] At what time the Art of casting statues in brass into moulds, taken from models, was introduced is uncertain, but it was, probably, of a

comparatively late date in European Greece. The artists who were most distinguished for their success in the Art, even if their claim to having first discovered it be questioned, were, undoubtedly, Rhœcus and Theodorus, who were both Samians; and the first European Greek, if we except Gitiadas, (whose date is hardly ascertained, and of whose practice but little is known,) who is recorded as having excelled in this branch of Sculpture, lived many years after them; this was Glaucias, the Æginetan, who was employed by Gelon, King of Syracuse.

Dipœnus.
Scyllis.
B. C.
776.

The History of Dipœnus and Scyllis will be found in the Biographical notice before alluded to, where they are placed at 776 B. C. These artists were distinguished for their skill (extraordinary at that time) in working marble;* and appear to have been employed in many important works at Argos and Sicyon. They had many scholars, and we read of the names of Tectæus, Angelion, Doryclidas, Medon, and others, of whom it is not necessary to enter into any account here.

Bupalus.
Anthermus.

The names of Bupalus and Anthermus, who lived soon after Dipœnus and Scyllis, deserve, however, to be more particularly noticed, as they distinguished themselves by a variety of works of a high character, which were preserved at Chios and other places. A group of the Graces by Bupalus, at Smyrna, is highly spoken of, and it is worthy of remark, that at this period the Graces were always represented draped. Pausanias says, Bupalus was an able Architect as well as Sculptor.

Bathycles.
B. C.
600,
to
B. C.
550
or
530.

Bathycles the Magnesian, who is celebrated as the author of the Throne of Apollo, at Amyclæ, is supposed to have lived about 600 years before the Christian Era; some writers have brought his date down rather lower, and have placed him at about 530 B. C.

The Plastic Art was carried into Italy, according to Pliny,† about this time, or rather earlier indeed, by Demaratus, who, accompanied by Euchirus and Eugrammus, two Corinthian artists, fled from Corinth after the usurpation of Cypselus, and the consequent expulsion of the Bacchiadæ; but it must have been known in Italy, it is conceived, at a much earlier period.

The time at which we have now arrived is one of the most remarkable in the History of Greece, whether it be considered with reference to the progress of Philosophy, its political changes, or to the general advancement of Science, Art, and Literature. Pythagoras and the Sages of Greece appeared; Solon legislated; Pisistratus obtained the Government of Athens; and Cypselus usurped that of Corinth: Tragedy was improved by Thespis, and, from being a mere rude Chorus without arrangement, became regularly organized and subjected to rules; the sublime Poems of Homer were now first collected and arranged, and publicly read to the Athenians; the Panathenaic Games were instituted, and the magnificent Temple of the Olympian Jupiter was founded at Athens. About this time also, the custom of permitting statues to be erected and dedicated by the conquerors in the Public Games was introduced, from which, as has before been observed, the greatest advantages resulted to the Art of Sculpture.

The Arts, which had been making rapid progress in the Colonies in Asia, received about this time a paralyzing check in consequence of the unsuccessful revolt which had been attempted by them against Darius Hystaspes. The Cities and Temples of the offending colonists were entirely demolished, the inhabitants were distributed over the Country, became slaves, and were otherwise subjected to the most degrading punishments; but as Art fell in Asia, so it appears to have gained fresh vigour in Europe; the Schools of Ægina, Sicyon, and Corinth sent forth a vast number of eminent artists, who diffused the principles of an improving and grand style throughout the neighbouring States, and we find the Italian and Sicilian Colonies shortly became so distinguished that they were on a level with the Mother Country.

Sculptur
from
Ægin.

To a period not very remote from that under consideration may be attributed the very interesting remains of Sculpture discovered amongst the ruins of a Temple, in the Island of Ægina, which are now in the King of Bavaria's collection, at Munich; they decorated the pediments of the Temple, and, as they were found immediately under the situation which they must have occupied originally, their arrangement and composition were easily ascertained.*

The subject to which the statues refer has engaged the attention of many of our men of letters and verts, but no satisfactory opinion has yet been given of them. All the figures of the Western pediment were found, and, as is evident from their actions, are engaged in some important contest; the figure of Minerva occupies the centre of the pediment, forming the apex or highest point of the composition; she is not only raised on a sort of plinth, but is of larger proportions† than the figures about her, and appears to be presiding over the events taking place in the field of battle. She is represented fully armed; her helmet on, the ægis covering her breast, and her shield on her left arm. The right arm is bent and crosses the body; in her hand she probably held a spear. Immediately in front of the Goddess, appears a dying warrior, who is extended at her feet; another advances towards him, apparently for the purpose of rendering him assistance, while a third figure, with his spear raised, seems to rush forward from behind the wounded man to prevent his approach; the rest of the figures are engaged in various ways with bows and arrows or spears, and the ends of the pediment are occupied by wounded and fallen warriors; the whole, exclusive of the Minerva, amounts to ten statues. Of the figures in the Eastern pediment, but five‡ were found, and they also represent persons engaged in

---

* *Marmore sculpendo primi omnium inclaruerunt Dipœnus et Scyllis geniti in Cretâ insulâ.* Plin. lib. xxxvi. c. 4. This is Pliny's account, who gives their date, *Olympiade circiter* L. Pausanias, however, says, they were considered by some to have been the masters of Learchus, of Rhegium, which would make them considerably earlier. Their having been called the scholars of Dædalus leads also to the probability of the earlier date of Pausanias being correct. Paus. lib. iii. c. 17. Flaxman places them at 776 B. C., though he admits, generally, the chronology of Pliny. (*Lect.* p. 75 and 79.)

† Plin. lib. xxxv. c. 12.

* An account of this discovery, which was made in the year 1812, by Messrs. Cockerell, Foster, and the Baron Haller, with some interesting observations on the marbles, is given in the *Quarterly Journal*, No. XII. 1820.

† The colossal dimensions of the Divinities, compared with mortals, are quite consistent with the descriptions of the Poets; in the combat between Minerva and Mars, (Hom. *Il.* lib. xxi. v. 409, *et seq.*) the Goddess throws an enormous mass of rock at her opponent, which strikes him to the earth, and Homer says, he covered seven acres. "Ἑπτὰ δ' ἐπέσχε πέλεθρα.

"Thund'ring he falls, a mass of monstrous size,
And seven broad acres covers as he lies."

‡ That is, but five statues sufficiently preserved to lead to the assurance of their original destination and design; the fragments of twenty-five statues were found on the whole, besides four female statues which adorned the acroteria.

culpture.

combat. It is remarkable that they are all of larger proportions than those of the other side, and that the conception and execution of the statues at this end are of a grander and higher character than those of the Western pediment.

ate III. g. 1

These Sculptures offer many peculiarities of manner and execution, and are highly deserving the attention of the curious. The general style is what is termed Archaic, but the statue of the Goddess is much more so than the rest of the figures; she is entirely draped down to the ancles; the feet, which are raised as if on sandals, are shown, and are both turned in the same direction, as if the figure were standing sideways; the folds of the drapery, which has the appearance of starched or stiffened linen, are thin, and arranged with great regularity, running in parallel lines, the zig-zag edges corresponding on each side; the ægis is smooth, but scales were originally painted or gilt upon it, and some faint remains of the colours are still visible. The extremity or outer edge has a sort of border of snakes, which at regular distances are terminated by small pieces of metal, some of which are still remaining twisted in a corkscrew shape; the helmet also of this, as well as of the other figures, appears to have been decorated with metal, as the holes for its insertion are evident in many of them. It may be observed here, that, with respect to costume, these marbles offer some of the most interesting details of any monuments which have come down to us: some of the figures are completely armed in cuirasses, greaves, and helmets, and the manner of buckling and fixing on the different parts is very carefully represented. The fastenings appear in most instances to have been made of metal; unfortunately the pieces are lost, but still sufficient remains to show the way in which it was done. The costume of one figure is peculiar, the dress is apparently composed of leather; it covers him entirely from the throat to the ancles, fitting closely, and without folds, to the body; his head-dress resembles a high Phrygian cap, and he is kneeling on one knee in the act of discharging an arrow.

ate III. g. 3.

In the execution of these Sculptures considerable skill is indicated, and an advanced state of knowledge in Art is exhibited both in the style which pervades the work generally, and in the understanding and expression of form; there is a grand division and breadth of parts, though the details are not always graceful, and in the articulations of the bones, and the nicety of execution of the joints, there is much to admire. The heads are uniformly in the same style, and of a much earlier character than the body and limbs; and this confirms an opinion which has been before hazarded, that in works of a certain class, illustrating the actions of Divinities or Heroes, (as appears to be the case in these marbles,) or connected in any way with Religion, the treatment of the heads was prescriptive, and, however artists might have ventured to improve upon the less important parts of the figure, that the character, and even the details of the head, handed down through a long course of time and sanctified by usage, were not permitted to be altered; the features are sharp, the eye long and narrow with considerable projection of the upper and lower lids, the mouths in all slightly opened, wide, and, whatever the employment of the figure, smiling; the chins long and pointed, and the edges of the lips, eyelids, and *os frontis* very strongly and sharply marked; the hair is in small curls or knobs, like shells, arranged with great regularity, and falling in long, waving, and wiry lines down the back, corresponding, in fact, to the general mode of treatment which, from Coins and description, we know to be the characteristic of works of the earliest date. The exact period of the execution of these Sculptures has not been ascertained, but judging from the style, which approaches very nearly to that found in the works of the artists who immediately preceded the School of Phidias; considering also the high character of the Æginetan School, and the eminent artists who composed it, it may be inferred that they were not very remote from the period which our History has now reached, namely, between five hundred and six hundred years before the Christian Era. The learned Müller, indeed, inclines to an opinion that they were of a considerably later date than that to which they are here referred; he draws his conclusion from the style of the Architecture of the Temple to which they belonged, and also from the costume of the archer, which he considers Persian, and says they were subsequent to the battle of Salamis.*

Grecian Archaic.

Sculpture from Selinus.

Amongst the remains of Sculpture of a very early date which have reached our times, may be reckoned the fragments found, in the year 1823, at Selinunte, in Sicily.† Two English Architects, prosecuting their studies in that Country, were induced to make some excavations amongst the extensive ruins of the Temples there, and the result was the discovery of several pieces of Sculpture, forming part of the metopes of the Temples. The originals are now in the Royal Museum at Palermo, but casts from them are preserved in the British Museum. There are some peculiarities about these specimens which seem to offer characteristics of two different styles of Art; those which belonged to one Temple (called the Eastern) having much of the character of Æginetan Sculpture, while those of the Western have the appearance of coming from a more barbarous School. It is difficult, without having the works before us, to describe those slight variations in the treatment, as well as execution, which have led to this opinion; but a careful examination of them, and a comparison of what remains of the Minerva, and the head of the dying or wounded figure, with some others of the collection, will explain the grounds on which it is presumed they were executed by different artists. The head of the dying figure resembles very nearly the character of the Ægina warriors, though there is certainly a superiority observable in the expression of the face; the anatomy again is inferior; in the other figures the anatomy is very similar to that on the earliest Coins, but still varying in some respects from the Greek Sculptures; and there is a plump and short character of face approaching in some degree to the Egyptian. At first sight, they strike as being decidedly a branch of Æginetan Art—short proportions, the fleshy portions of the thighs overcharged—the hair dressed in knobs corresponding very nearly with the works of that School; but there still are variations, which, if they were executed at

Plate I. Fig. 5, 6, and Plate III. Fig. 3, 4.

---

* *Illas enim post bellum Salaminium factas esse tum ædis cujus in fastigiis positæ erant Architecturæ ratio, tum vestis sagittarii Persici in Paride diligenter repræsentata, mihi quidem persuasere.* C. Odof. Müller, *de Phid.*

† An interesting account of the excavations, embellished with accurate engravings of the more perfect Sculptures, has been published by Mr. Angell, one of the gentlemen to whose exertions the discovery of these interesting works is owing. The drawings were made on the spot, by his companion, Mr. Harris, an Architect of great promise, who unhappily fell a victim to the malaria of the Country, soon after the successful termination of their labours at Selinunte.

the same time, induce us to believe they were not by Sculptors educated in similar principles. At a much later period than that to which these Sculptures are referred, artists from Ægina were employed by the Tyrants of Sicily; and it is, therefore, highly probable that in more remote times, when Sculpture must have been still less known and practised in the Island, that foreign practitioners would be called in to assist in decorating the principal Temples of a newly-founded city: some of the artists so called upon were in all probability from Greece; others may have been brought over from the opposite coast; and their being Carthaginians would, perhaps, account for a certain Egyptian character pervading the faces of some of the figures.

Phigalian Sculpture. The Sculptures in *alto rilievo* in the British Museum, known as the Phigalian Marbles,* are from the Temple of Apollo Epicurius; the subjects they represent are the battle of the Centaurs and Lapithæ, and the contest between the Greeks and Amazons. There is great ability displayed in the execution of these marbles, although some heaviness and disproportion are observable in the figures; the conception of the whole, and composition of the various groups are, however, remarkably fine, and compensate in a great measure for the defects alluded to. The circumstance which renders these marbles particularly interesting, is the knowledge of the time at which they were executed; for Pausanias† says that the Temple of Apollo Epicurius was built by Ictinus, the Architect who superintended the construction of the Parthenon at Athens; and though the Phigalian Marbles want the purity of design and execution which distinguish the Athenian works, the high qualities they do possess claim the second place for them in our estimation.

Sicyon and Ægina were the most celebrated places in ancient times for the production of works in brass. Of the former School we have already had occasion to mention some very distinguished members. **Callon.** Callon‡ was probably one of the earliest Sculptors of that of Ægina who attained reputation, but there is great difficulty in coming to any conclusion as to the exact time at which he lived; and as we merely find a wooden statue of Minerva, mentioned by Pausanias as his work, and an observation in another author on the dryness of his style, his history does not appear very important. **B. C. 500 to B. C. 400.** The Æginetan artists of the greatest celebrity at a later date, were Glaucias and Onatas, the son of Micon; **Glaucias, Onatas.** the former§ was employed by Gelon, King of Syracuse, to make a chariot and four horses, which he dedicated in the Altis, or Sacred Grove, at Olympia, upon having gained the prize in the chariot-race. Onatas and Calamis afterwards worked for Dinomenes, the son of Hiero, who succeeded Gelon. The former of these Sculptors appears to have enjoyed a very high reputation, and Pausanias supplies us with a copious catalogue of his works. Amongst those more particularly noticed, was a statue of Apollo, in brass, of colossal dimensions, at Pergamus; a Ceres, which he made for the inhabitants of Phigalia; and a number of works which were at Olympia. Associated with Onatas is Calliteles his scholar, and probably his son; but the ancient writers do not furnish us with any account of works executed by him independently of Onatas, whom he is said to have assisted in making a statue of Mercury carrying a ram, which was dedicated at Olympia. **Grecia Phidian.** The Sculpture of the Æginetan School of this time had much in its character that was grand and imposing, and a careful observer will discover in the large masses of the muscles, and the bold divisions of the parts, the preparatory step to that perfection which the Art soon after attained.

Consequences of the Persian invasion. An event of the highest importance to Greece, and which tended in no slight degree to aid the progress of Sculpture, happened about this time; this was the celebrated expedition of Xerxes, which, by its failure, discovered to the Athenians the wealth of Asia, while it exposed the weakness of the invaders. It was a custom in Greece to dedicate a tenth of all spoils gained in battle to the service of the Immortal Gods: and a tenth of that obtained from the Persians was appropriated to this high service. Temples were erected and embellished far surpassing in beauty and magnificence those which had been demolished; and happily for the advancement of Art, the opportunities this application of wealth afforded for its improvement, were met by a greater quantity of talent in the respective professions of Architecture and Sculpture than had ever before appeared. This ample employment, and the high object to which their works were destined, to honour the Gods and commemorate the glory of their Country, excited a spirit of honourable emulation in the artists which called forth all their powers, and led to that perfection in Art which even at this remote period we contemplate with the highest admiration.

II. Phidian period. II. The Sculptors contemporary with, or who immediately followed, the period last under consideration, were Hegias, Ageladas, Phidias, Pythagoras, Myron, Polycletus, Alcamenes, and others; and we are, therefore, fast approaching the time when Sculpture reached its maturity. Information of considerable value and interest at this stage of our inquiry is afforded by the ancient writers, some of whom have traced, as far as their own observation of monuments enabled them to do so, the chain of improvement in style in Art, from the School which has been denominated Æginetan to that of Phidias, and it may not be amiss to take a general survey of their classification of the most striking peculiarities of the Sculptors of the respective times. Callon, of Ægina, lived in all probability between 560 and 500 years before Christ: his works, with those of Egesias, are characterised as being hard, approaching very nearly to that distinguished as the Tuscan or Etruscan manner;* Calamis, who succeeded him, was less rigid, and the style of Myron, who followed next, still more softened. Cicero alludes to the same variations in style, bringing us down in like manner to one of the contemporaries of Phidias; the statues of Canachus, he observes, are rigid and hard, not resembling the truth of Nature; those of Calamis also are hard, but less so than those of Canachus; even Myron did not succeed in imitating Nature correctly, yet he surpassed Canachus, and his works may be considered very beautiful; Polycletus, however, was still more fortunate, and his productions are pronounced

---

* They were discovered, in the year 1812, near Paulizza, supposed to have been the ancient Town of Phigalia, in Arcadia, by Messrs. Cockerell, Foster, the Baron Haller, and M. Linckh.

† Paus. *Arcad.* c. 14.

‡ Paus. lib. ii. There was more than one Sculptor of this name.

§ Ibid. lib. vi.

lpture. to be perfect.* The History of the Art is thus, it will be observed, carried out of the Æginetan into a more polished School, to which therefore our attention will now be more particularly directed; the principal artists who effected the change in the style of Sculpture having been mentioned above, it remains now to notice them individually, as some observations on their respective manner will lead to the better understanding of the excellence of Phidias. We must first take notice of a Sculptor of Rhegium, whose works have been frequently referred to, and who appears to have had very just claims to the distinguished rank he held amongst the artists of antiquity. Some of the productions in brass of the earliest practitioners of that colony, executed at a time when that material was hardly known for the purposes

agoras. of Sculpture, have already been noticed, and Pythagoras, the subject of our immediate attention, seems to have supported the credit of the School of which Learchus (who was perhaps the founder at Rhegium) and others were such distinguished members. From the difficulty which exists in making the execution of the productions of Pythagoras correspond with the times at which we find the name mentioned, it has been supposed, and with great apparent reason, that there was more than one Sculptor of Rhegium so called. The chief of the name was a scholar of Clearchus, (also of Rhegium,) or more correctly speaking, perhaps, of the School of Clearchus. An improved taste in execution seems now to have been introduced, and more attention than usual was paid to expression; a statue by Pythagoras of a wounded man is recorded, in which the expression of anguish was so admirably defined that the spectators were affected by it, and seemed to share with the figure the pain he was supposed to be suffering. Pythagoras, too, is particularly noticed as being the first who represented the veins† and nerves in his statues; he was also more careful in the execution of the hair than his predecessors.

n. Myron, of Eleutheræ, or of Athens, and the scholar of Ageladas, is the next Sculptor of celebrity who claims our notice. Pliny‡ gives him the preference in some respects even to Polycletus, and says that he introduced a greater variety in his Art than those who preceded him; but he observes at the same time, that he was not successful in expressing the feelings or passions of the mind, nor did he make any improvement in the manner of treating the hair, which was stiff and formal, as in the times of the rudest Art; his style was, in all probability, hard and minute, but he must still be considered one of those Sculptors by whose assistance the Art

V. was brought to excellence. We possess a very interesting specimen of this master's manner in a statue in the British Museum of a *Discobolus*, or Quoit-thrower, generally believed to be a copy of the famous statue by Myron, so minutely described by Lucian and Quinctilian;§ and though there is considerable dryness of manner in this work, it nevertheless possesses qualities which claim for the Sculptor a higher character than Pliny's account of him would alone have justified us in awarding him. The great excellence of Myron seems to have been shown in his productions in brass, in which he was the rival of the famous Polycletus; and we are told that Myron used the bronze or brass of Delos, while Polycletus employed that of Ægina for his works.* Grecian Phidian.

There appear to have been at least three Sculptors called Polycletus, but there is so much confusion on this point in the authors who have mentioned them, that it is almost impossible to distinguish between them; it is evident, however, that two were called *Argivi*; Pliny, indeed, calls the most celebrated *Sicyonius*, but as he is the only writer who gives him that title, it has been thought probable that both Sicyonian and Argive may have been correctly applied to the same artist, *Sicyonius* as a native of Sicyon, and *Argivus* also from his having been admitted to the rights of citizenship at Argos, where he studied and executed many of his most important works. He appears to have been an artist of very high celebrity, and, according to History, was remarkable for the great care and attention with which he finished his productions; indeed, he was the author of a statue so perfect in its proportions that it was called by common consent the *Canon*, and referred to as the "Rule of Art."† Polycletus seems, from the criticisms which have reached our time, to have been deficient in that variety which is so essential to the accomplishment of an artist. Some further particulars respecting this Sculptor will be found in the BIOGRAPHY OF THE EARLY SCULPTORS OF GREECE. Polycletus.

Hegias, or Hegesias, for it is presumed the same person is meant, and that the name is only varied by the corruption of ancient texts, was classed, as has been noticed above, amongst those artists whose style was hard and dry. Hegias.

Of Ageladas, we have no information which will tend to illustrate this part of our subject, and a mere list of his numerous works, with the conjectures of antiquaries respecting the time at which they were executed, must be considered as belonging to the History of the artist individually, rather than that of Sculpture generally; the circumstance of the greatest interest connected with Ageladas is, that he was the master of Phidias, Polycletus, and Myron, three of the brightest names in the Annals of Art. Ageladas.

It must be admitted that the Sculptors in the Æginetan class of Art immediately prior to this time, laid the foundation of that fine style which Phidias brought to perfection; yet the suddenness of its consummation has given the Sculpture of his School a character that may almost lay claim to originality, particularly when it is recollected that even some of his contemporaries are noticed for still clinging with partiality to the dryness of style and peculiarities of execution of the Æginetans. Phidias, the son of Charmidas, was a native of Athens,‡ and was born about the LXXIIId Olympiad, or 484 years before Christ. Of his early life and studies but little is known, though it is said he at first studied the Art of Painting; the circumstance of two of his family having been Painters may have led him to amuse Phidias. B. C. 484.

‡ Pausanias gives the inscription on the statue of the Olympian Jupiter, declaring it to be the work of Phidias, the Athenian, the son of Charmidas. Φειδίας Χαρμίδου υἱὸς Ἀθηναῖος μ' ἐποίησε: and see Strabo, &c.

himself in that branch of the Arts, but the authority for his having followed it, as a profession, is so slight that no great dependence can be placed on it, and it is probable that, if he did at any time employ himself in it, he soon relinquished it, and dedicated himself entirely to that Art in which he was destined to become so distinguished. His masters, we are told, were Hippias and Ageladas: of the former but little is known;* the latter enjoyed a high reputation, and executed many works of importance. Circumstances were particularly favourable for the display of the talents of Phidias; he had the advantage of living in Athens during the enlightened administration of Pericles; and, being highly esteemed by that distinguished statesman, was consulted in all works that were undertaken for the embellishment of the city.† Plutarch, speaking of the magnificent edifices erected during his government, says, "These structures, stately as they were in magnitude, and inimitable for their graceful forms and elegance, (every artist being ambitious that the excellence of the workmanship should equal the beauty of the design,) were yet more wonderful for the expedition with which they were accomplished."—"It was Phidias who had the direction of these works, although great Architects and skilful artificers were employed in erecting them."‡ The works for which Phidas has been most celebrated were his Statue of the Olympian Jupiter, at Elis, and that of Minerva, in the Parthenon at Athens. It will not be necessary here to enter into a minute description of these works, as, in the BIOGRAPHY OF THE EARLY SCULPTORS OF GREECE, a sufficiently accurate account of them has been supplied; and the reader who desires further information on the subject is referred to Pausanias, Pliny, Strabo, and other authors of antiquity who have been particular in their descriptions of the productions of Phidias. They were of colossal dimensions, and composed of ivory and gold. The statue of Jupiter was represented seated on his throne, and it seems to have been the object of the Sculptor to exhibit him, as far as was consistent, as a local Deity. He was to be placed in a magnificent Temple erected in the Sacred Grove, close to the spot where the most important of the Games of Greece were celebrated, and surrounded by the statues and votive offerings of the victors; Phidias, therefore, made him the presiding Deity of the place, the judge of the Games, and dispenser of victory; he was not armed with the thunderbolt, nor was he surrounded by any of the more majestic attributes which would have distinguished him as the King or Father of Gods and men; but his brows were encircled with a wreath of olive, the reward of the successful competitors, and in his hand he supported a statue of Victory. We purposely abstain from any minute description of this work for the reasons before stated; but we are induced to mention a tradition connected with it, which becomes interesting from its exhibiting the importance which the enlightened Greeks attached to productions of this high character. Phidias, after the completion of his work, is said to have besought the God, in whose honour the statue was erected, to favour him with some intimation whether it was pleasing to him; immediately a flash of lightning struck the pavement before him: this was at once hailed as a proof of the satisfaction of the Deity; and in commemoration of the event a brazen vase or urn was placed on the spot, which Pausanias says was existing in his time.* The statue of Minerva was standing, and fully armed; its height we are told was twenty-six cubits,† and the gold employed on it is said to have weighed forty talents.‡ Phidias executed several statues of Minerva, his Country's protecting Goddess, and the patroness of Art and Science; we find eight or nine recorded as having been made for different places, either in gold and ivory, or brass, and one, which was for the Platæans, (and placed in the Temple of Minerva Areia,) was of wood, gilt, excepting the face, hands, and feet, which were of the white marble of Pentelicus. Phidias has been called the Sculptor of the Gods,§ from the grand and sublime character which he invariably threw into his works, and from the particular excellence he displayed in his two great productions, the Jupiter and Minerva; but his genius was not limited, and though his chief power seems to have been in works of the highest and most dignified class of Art, yet it was not only in statues of a severe character that he employed his talent, for we find amongst his works various statues of Venus, Mercury, and Apollo, as well as of an Amazon, which latter was executed in competition with other highly esteemed artists of his time. Our readers, who desire to become more fully acquainted with this great Sculptor's life, are referred to Müller's learned disquisition, *De Phidia Vitâ*, where also will be found some valuable information on the probable dates of the execution of his masterpieces, the colossal Jupiter, and the statues of Minerva.

Marbles from the Parthenon.

Unfortunately, no remains of his greater works have reached our times; but we are enabled in some measure to estimate the power of this artist from those productions which have been spared to us forming the decoration of the Parthenon. The Sculptures of the pediments, the metopes, and portions of the frize which form so valuable a part of our collection of Greek Sculpture in England, are convincing proofs that the encomiums of the Ancients were not accorded without reason. There can be no doubt that these were works of Phidias and his scholars; and in vain shall we look for specimens which, generally speaking, bear more unequivocally the distinguishing marks of the master mind and hand; or which exhibit finer examples of that grand style of which Phidias has been justly esteemed the founder.|| The qualities for which these works claim our admiration will be found to consist principally in their truth to Nature: but it was not Nature copied servilely, and without selection, but viewed under particular feelings, and with a strict and careful examination of what was fit and beautiful; and thus was that combination produced

---

* He is mentioned by one writer only, Dio Chrysost. *Or.* lv.

† It is remarkable that there is no Statue of Pericles by Phidias, nor do we find any mention in the Works of the Ancients of his having ever executed any portrait of his patron, if we except that introduced in the shield of the Minerva of the Parthenon, and which was of course only in *basso rilievo*.

‡ Plut. *in Vit. Pericles*.

* Paus. lib. v. c. 11. We have no positive information respecting the height of this statue, but Strabo informs us that, if it had stood up, it would have been higher than the roof of the Temple, and he makes a very just observation that the statue was therefore disproportioned to the building.

† Plin. *Nat. Hist.* lib. xxxvi. c. 5.

‡ Thucydides.

§ Quinctilian, lib. xii. c. 10.

|| All these Sculptures are not, it is true, executed with the same correctness of detail, but these inequalities are to be attributed to the greater or less degree of talent in the inferior workmen whom it was necessary to employ in getting such extensive compositions executed.

Grecian Phidias

which has in after-times been called *Ideal Beauty*. That no works contained this before the time of Phidias may be judged by many monuments remaining to this day; that the productions of his School possessed this quality in an eminent degree the Elgin[*] collection of Marbles sufficiently testify. The statue of the Ilyssus or River God, the Theseus, the Neptune, and the draped groups, mutilated as they are, have a grandeur, simplicity, and truth to Nature in them that strike the commonest observer; it requires no teaching to understand that the attitudes are perfectly easy, that the balance of the parts is just, and that the general character is natural. These are qualities in imitative Art which every person who observes Nature at all is able to appreciate, and to do which no initiation into the arcana, or details, is requisite. Nor is it in the naked figures only that this excellence is exhibited; his draperies are treated with the greatest skill and attention; they are plentiful and rich in their effect, and yet so arranged as to show the action and form of the limbs beneath, exhibiting (as has been well observed of this great Sculptor) with the greatest art the greatest simplicity. Our observations on Phidias have been purposely condensed as much as possible; the History of himself and of many of his works, the time of their execution, and the circumstances under which they were produced, offer subjects for a very extended Treatise; but, for obvious reasons, we must not enter upon details which would lead us beyond the limits to which the History of the Art, and not of the artists, should confine us.

yselo-
ntine
lpture.

Although Phidias exercised his skill as a Sculptor in all the materials which were in general use for the purposes of his Art, gold, ivory, brass, marble, and even wood; yet his productions in the former, a mixture of gold and ivory, (*Chryselephantine* Sculpture, as it is generally termed,) appear to have been the most highly esteemed, both from the extensive scale on which he used such rich materials, and from the great importance of the works to which he applied them. We have deferred entering into any description of this branch of the practice of the Art till the Age of Phidias, as it must be considered to have attained its perfection at or about the time in which he lived. Its adoption for works in Sculpture may be traced back to a period considerably earlier, as, for instance, in works existing in the *Heræum*, or Temple of Juno, at Olympia, and in other places described by Pausanias, to which this general reference will be sufficient; but none of the Sculptors who preceded Phidias appear to have employed it on so large a scale as he did.

tic

Chryselephantine Sculpture is a branch of what the Ancients called *Toreutic* Art; which term, it is presumed, was intended to express the uniting of metals with other materials; the phrase has caused much discussion, and almost all the modern commentators and writers on Art have considered the subject with attention; but each has explained the term according to his own conception, and unfortunately a very great difference of opinion still exists as to its precise meaning. We cannot attempt to give the reasons which have influenced their conclusions, but we venture to explain the term generally, applying it to Sculpture, whether in *basso rilievo* or the round, in which a variety of materials, always including metal of some description, were used. Pliny pays a high compliment to Polycletus in speaking of the Toreutic Art, as it was practised by him and Phidias, and says, that Polycletus brought it to perfection;[*] but this may be understood as applying merely to some mechanical improvements, either in polishing or fastening the pieces together; as the great work of Polycletus, his Juno, was executed subsequently to the Olympian Jupiter of Phidias; and he, therefore, had the opportunity of seeing where any variations in these respects could be made with advantage. The statue of Phidias, we are informed, required repair very soon after his death, but we do not hear that the great work of Polycletus was subject to the accidents which affected the Jupiter, and which he avoided, probably, from the experience he gained by Phidias having made the first essay on a large scale; viewed in this light the passage in Pliny becomes at once intelligible.

It is somewhat difficult to understand how the Greeks of this time, who appear to have felt the value of simplicity in Art so thoroughly, should have executed and admired works composed of materials, which, it is natural to suppose, would injure, if not destroy the effect of the more intellectual part of them, if we may be allowed that term, applying it to expression and fine form; but we know that the great statue of Jupiter was not only composed of gold and ivory, but that it was also richly painted, and ornamented throughout in the most elaborate manner. We certainly have no means of judging what was the precise effect of such varied materials employed on a large scale; at first it seems to militate against the pure taste which we fancy pervaded all the productions of the Greek artists, and yet, when we find Phidias himself adopting it, it will look like presumption to question its propriety. The accounts, too, of those writers who had the opportunity of seeing these works in their most perfect state, convey an idea that nothing could be more magnificent and imposing; that they were not merely gorgeous to the sight, but there was that in them which seemed to add to the dignity of Religion.[†] A few observations on the means which the Ancients are supposed to have adopted for executing colossal works in these combined materials, may not be irrelevant; our notice of it must be very general, but to those who desire to enter more minutely into the subject, the valuable Work of M. Quatremère de Quincy *sur le Jupiter Olympien*, is recommended; in which the history of Chryseliphantine Sculpture is particularly considered, and traced from its earliest introduction to the period at which it appears to have been brought to perfection; and a list of the artists who were most distinguished in it at any time, and of all the most celebrated works, is supplied, as well as a variety of highly interesting details of the manner of employing it.

Mode of executing Chryselephantine work.

The first step appears to have been to make a model of the full size of the work proposed to be executed; this being completed, a rough copy or general resemblance of the model was made in wood, to answer the purpose of a nucleus, or centre, to which the ivory was to be attached. This model does not appear to have been solid, for within it were the irons and necessary supports for the safe fixing of the whole to the pedestal, and also for the security of the parts, as head, arms,

---

[*] So called from their having been brought from Athens to this Country by the Earl of Elgin, of whom they were afterwards purchased by Parliament.

[*] *Hic consummâsse hanc scientiam judicatur, et Toreuticen sic erudisse ut Phidias aperuisse.* Plin. lib. xxxiv. c. 8.

[†] As Quinctil. lib. xii. c. 10. observes of the Olympian Jupiter.

&c.; it is also probable that it was requisite to have the means of getting within the work, for the purpose of taking care of it, and repairing it, in case any of the parts or pieces of the ivory should start from their places. The wooden model, or groundwork, being completed, the surface was produced by closely fitting small pieces or plates of ivory upon the wood by means of pins and cement; whether the ivory was worked and finished to a scale before it was attached to the nucleus or under model, or afterwards, (being merely generally prepared in point of form,) is left to conjecture; but the latter appears the most probable, as well as the easiest and surest mode of proceeding. In the Olympian Jupiter, indeed, Phidias appears to have worked the ivory in pieces in his study. Pausanias[*] says, near to Altis is an edifice which is called the workshop of Phidias; and he adds, it was there that this artist worked each of the parts of the Jupiter; still this working in pieces may mean general form, for it is unlikely that each should have been made perfect first, and then fastened to the model or centre. The ivory part of the work being completed, the attachment of the drapery and ornaments in gold or other metal, either cast or beaten out, offered no difficulty. Ivory was found to be particularly subject to the influence of the atmosphere, being equally affected by excessive dryness, or by too great humidity, which would also act considerably on the wood used in the construction of the work, causing expansion or contraction to the injury of the joints; the preservation, therefore, of these works required considerable attention, and Pausanias alludes to the means adopted for this purpose, when he speaks of the principal Chryselephantine works in Greece. The Olympian Jupiter was surrounded by a ledge of black Parian marble,[†] to contain oil; this was to preserve the ivory damp, and at the same time to prevent too great a degree of moisture from rising to it, the Altis being marshy ground. The charge of taking care of this celebrated work, we should observe, was intrusted to the descendants of Phidias, under the title of *Phædruntai*,[‡] who were always obliged to sacrifice to Minerva Ergane before they commenced their functions; and we are informed that this office was in the same family down to the time of Hadrian. Pausanias acquaints us also with the manner in which the Minerva of the Parthenon was preserved, the situation of the Acropolis of Athens being dry and unfavourable to the ivory. It is unnecessary to enumerate them here; but particulars in confirmation of the Ancients having paid the greatest attention to the safety of such works, are furnished by Pliny, Pausanias, and other writers, in speaking of the Minerva of Pellene, the Diana of Ephesus, and other statues composed of these materials.

Agoracritus. Of Agoracritus, the favourite scholar of Phidias, a full and interesting account will be found in the BIOGRAPHY of Artists before referred to.

Alcamenes. Alcamenes was one of the most distinguished artists of this School, and was considered by some to be second only to Phidias; one author, indeed, alluding to the progress of the Arts, does not hesitate to class Alcamenes with Phidias himself, saying, that what was wanting in Polycletus was given to Phidias and Alcamenes;[§] and there is a tradition that Alcamenes had the honour to contend with Phidias in executing a work for the Athenians.[*] Two of the productions of Alcamenes are particularly noticed for their excellence; one was a statue of a Pentathlus, the other of a Venus, called "of the gardens."[†] Phidias is said to have given Alcamenes the advantage of his assistance in this latter work. Besides Agoracritus and Alcamenes, we find Colotes, or Colotas, Pæonius, and others, who assisted Phidias in his great works, (having accompanied him to Elis,) and who in all probability were also his scholars; the accounts, however, which we have of them are not of sufficient importance to induce us to enter into their history.

III. After this period, a gradual change took place; Sculpture, freed from the dry manner which characterised the works of the Æginetan artists, attained its perfection in the grand or sublime style under Phidias and his School; but it appears there was still some severity in treatment remaining, which the Sculptors of the succeeding Age exerted themselves to remove. The Art may have lost something of its energy by the introduction of the flowing and graceful style, but the high commendation universally bestowed on Praxiteles and those who effected the change to which we allude, are sufficient to stamp their characters as artists of extraordinary merit. Praxiteles of Cnidus has rendered himself famous for his productions both in brass and marble; and we find that his choice of subjects corresponded generally with the soft, elegant style of Art he is said to have practised; they were for the most part female figures or youths, and he is believed to be the first Sculptor who ventured to make a statue of Venus entirely naked. Millingen,[‡] on this subject, says, all the statues of female Divinities were anciently draped, and that Praxiteles was the first who represented Venus naked; such an innovation was considered extremely indecorous, but excused on account of the beauty of the performance; subsequent artists wishing to reconcile a mode of representation, so favourable to the purposes of Art, with the rules of decorum, adopted the form of drapery seen in the Venus of Capua and Melos,[§] namely, a mantle covering the lower part of the body, and falling to the ground; the statues of Venus which, in imitation of that of Cnidus, are found in a state of nudity, are almost always to be referred to a low period. Praxiteles is mostly celebrated for the perfection to which he brought his works in marble, and the Ancients all agree in the encomiums bestowed upon him for his superiority in this respect; he is also noticed for the truth of expression in his works, and two in particular are recorded as masterpieces; one was of a matron weeping, the other of an entirely opposite character, namely, a courtezan, who was represented with her features lighted up with joy; the latter was said to be a portrait of his favourite Phryne. In proof of the high estimation in which the works of Praxiteles were held by the Ancients, it will be sufficient to mention an anecdote respecting the celebrated naked Venus in marble at Cnidus. Nicomedes, King of Bythynia, offered

to liquidate an immense debt under which the Cnidians were labouring, if they would allow him to have this statue; his countrymen, however, were not tempted by the liberality of the offer, but chose rather to submit to their existing pecuniary difficulties, than to part with a work the possession of which was sufficient to render their city illustrious.

The next name of importance, as the head of a School, is that of Lysippus. He was a native of Sicyon, and his reputation was not inferior to that of any of the great men who preceded him; he was the favourite Sculptor of Alexander the Great, and the only artist who was permitted to make statues of him;[*] according to some he executed a series of portraits of this Prince, commencing from his childhood up to his maturer years. Lysippus appears to have worked exclusively in brass, and, according to Pliny, he executed no less than six hundred and ten works; amongst them a colossal statue, which he erected at Tarentum, is particularly noticed. He is said to have made some important improvements in Sculpture, being particularly commended for the attention he paid to the execution or finish of his works; he made the heads of his figures smaller than his predecessors, and introduced a proportion that was more graceful; he appears also to have got rid of a certain degree of squareness still remaining in the style of some of the Sculptors, and to have given a roundness of form not attempted by the preceding Schools. He professed, however, notwithstanding he was so attentive to his finishing, to study effect, rather than to copy details and the minutiæ of forms, at least the remarkable expression he used respecting his practice leads to that conclusion; he is reported to have observed of other artists, that they made men as they really were, he as they appeared to be;[†] which can only mean that he preferred breadth and freedom of parts, such as Nature, viewed generally, exhibits, to the representation of details which, too often, when they are too closely attended to, destroy the unity and breadth of a work. This observation, which would imply a superiority in the style of Lysippus, may appear too bold when the great names of his precursors are considered; but however difficult it may be to explain in writing the peculiarities which characterise style in Art, and which, it must be remembered, often depend upon very slight distinctions, the difference does exist, and will be easily comprehended by those who will examine and compare works, whether Coins or Sculpture, on a more extended scale, of different Ages and Schools. A Sculptor of very high celebrity must not be omitted, who is presumed to have lived about the time of Lysippus; this is Scopas, to whom the celebrated group of Niobe and her children is attributed; these statues are at Florence, in the Gallery of the Grand Duke of Tuscany.[‡]

Lysippus left several scholars, three of whom, his sons Laippus, or Daippus, Bedas, and Euthycrates, are mentioned amongst the most eminent artists who succeeded him; of these the last held the most distinguished rank, according to the account of Pliny. There is a peculiarity, however, remarked in his practice which deserves notice here, as it is an additional confirmation of what has before been observed with respect to adherence to the old style; it is said, that Euthycrates imitated the firmness[*] in his father's works, rather than the elegance for which they were esteemed, preferring, in fact, a certain austereness of character, to the more voluptuous and pleasing manner of execution which Lysippus had adopted.

Euthycrates.

School of Lysippus.

Chares the Lindian, who made the celebrated Colossus at Rhodes, which was ranked among the wonders of the world, was a scholar of Lysippus; as was Tisicrates, a Sculptor of Sicyon, who followed so closely in the steps of his master, that it was often questioned whether works were by Lysippus or his scholar. Pliny may be consulted on the number of Sculptors who were formed in the School of Lysippus, and to whom many works of first-rate merit, still existing, have been attributed by subsequent writers; whether justly or not must at present be a matter of conjecture, but the appropriation is a proof of the estimation in which the artists of this School have been held.[†]

School of Rhodes.

Our observations on the Schools of Sculpture in Greece now draw to a conclusion, the most important features in each, as far as they are illustrative of the progress of the Art, having been considered; before taking leave, however, of the subject, we must make honourable mention of the Rhodians, amongst whom the Arts were particularly protected and studied. The importance of Rhodes was on many accounts considerable, but it especially claims a place here, as some very fine specimens of Sculpture emanated from its School. The Sculptors of the Laocoon, Agesander, Polydorus, and Athenodorus, and of the group of Dirce, commonly called the *Toro Farnese*, Apollonius and Tauriscus, as well as of the famous Colossus, were Rhodians; and it is almost incredible that from this little island, not more than forty miles long and fifteen broad, the Roman conqueror brought away three thousand statues; but we shall the more readily believe this, when we recollect that the force and enterprise of these islanders were sufficient to vanquish the navy commanded by Hannibal. We shall not dwell at any length on the Sculpture of Sicily, which must, in fact, be considered Grecian. Some of the medals of this Country are particularly fine, and are well worthy the attention of the admirers of Art.

Plate IV. Fig. 3.

IV. Decline.

IV. The name, or rather the School of Lysippus, seems to conclude the History of Greek Sculpture up to its perfection; those who followed but imitated what had gone before them, or, if they invented, their works were of an inferior description; it is true many names still occur of great respectability in the Art, but there was neither that genius nor originality in the style or conception of their productions, which claim for them a place

---

[*] Pliny, lib. vii. c. 37, says that Alexander issued an order that no artist but Apelles should paint him, Pyrgoteles engrave gems of him, or Lysippus make statues in brass of him. *Edixit ne quis ipsum alius quam Apelles pingeret, quam Pyrgoteles sculperet, quam Lysippus ex ære duceret.* It is remarkable that no mention is here made of marble statues of Alexander.

[†] Pliny, *Nat. Hist.* lib. xxxiv. c. 8.

[‡] There is reason for thinking that the greater part of the statues composing this group are but copies from the original works. We possess in England a head of Niobe, similar in action and expression, but preferable for its style and execution, to that of the statue at Florence, and as we know there are repetitions of some of the figures, our doubts on the genuine antiquity of the statues in the Grand Duke's Gallery are not without foundation. For the above head, *vid. Select Specimens of Sculpture.* Dilettanti, vol. i.

[*] *Ante omnes Euthycratem; quanquam is constantiam patris potius æmulatus quàm elegantiam*, &c. Plin. lib. xxxiv. c. 8.

[†] We possess a fine specimen of the School of Lysippus, perhaps a work of the great master himself, in a small bronze statue of Hercules, in the British Museum.

amongst those who aided the developement and perfection of Sculpture. In our progress through the History of the Art we have taken occasion to mention the principal men who were distinguished as heads of Schools, and it is therefore unnecessary to add a list of all those Sculptors whose names have been handed down to us. The degree of patronage extended to the Arts would, of course, add considerably to the number of artists, as the excellence or celebrity of a master would increase the followers of the favourite style of the time. The enumeration, however, of these is not essential; for, as has before been observed, the object is not to give a History of the artists, but of the Art, and they have only been mentioned when absolutely necessary for the illustration of particular points. It is certain that a much more detailed account might with advantage have been given of the Sculptors, as well as of their productions, but this would necessarily have extended this Essay beyond its proposed length, and would have led to the introduction of matter not strictly belonging to our present subject.

Consequences of the death of Alexander the Great.

By the conquests of Philip of Macedon, and those of his son Alexander the Great, it is but natural to believe, that the light of Grecian Science, Literature, and Art were becoming generally diffused over Countries which had long been in a state of comparative darkness; but not all the advantages which might have resulted from these successes, and might have compensated in some measure for the miseries attendant upon the victor's progress, were suffered to be realized. The death of Alexander opened a field for discord and contention which operated fatally on the durability of the extensive dominion he had attempted to establish, and as fatally on the progress of the Arts in Greece. The Generals of that Prince, thinking only of their own aggrandizement, and removing the legitimate heirs to his vast possessions, divided them amongst themselves as separate Kingdoms, and were soon involved in foreign and domestic broils, the consequence of ambition, usurpation, and tyranny. The Arts continued to flourish for some short time under the most powerful of the successors of Alexander; in Syria they were protected by the Seleucidæ, in Egypt under the first Ptolemies, and at Pergamus by Attalus and his son Eumenes; but they were rapidly declining, and in the wars of this period, not only the sacred treasures were pillaged, but the edifices which contained them were subverted and destroyed, and the statues broken and melted. The artists had the mortification of seeing the finest monuments of genius purposely defaced, and they felt that their own efforts to gain distinction were crushed; the production of works in the higher departments of Art began to be discouraged, and the Sculptors found that their only employment was in portrait statues of those who happened to be in possession of sovereign power; a miserable application of their talents in times of change and violence, as the artist could have but little expectation that his work would last beyond the reign of its archetype.

Gradi Decli

About the CLVth Olympiad, Pliny says the Arts in Greece recovered partially from a state of inertness in which they had remained from the CXXth; but the artists, he observed, were very inferior to those who had preceded them,* and it appears that this was but a last effort, a feeble glimmering, before their final extinction in Greece. This restoration took place probably rather earlier than the time mentioned by Pliny; and between the CXLVth and CLth Olympiad, we find the names of several Sculptors of merit. To this time many antiquaries have referred the celebrated authors of the statue of the Hermaphrodite, and of the mutilated trunk, known as the *Torso* of the Belvidere, which bears the Sculptor's name, Apollonius, the son of Nestor. Of Glycon, whose name appears on the statue of the Hercules,* and of Agasias, the author of the Fighting Warrior, (or Gladiator, as it is generally called,) nothing is known, their names not being mentioned by any author of antiquity; these statues have however been attributed to about this period. In the CLVIIth Olympiad the last blow was given to the power and hopes of the Greeks, by Lucius Mummius, who had been sent by the Roman Senate against the Achæans. He engaged the Greek army near Corinth, the principal city of the famous Achæan League, and having entirely defeated and routed it, the city was immediately given over to destruction, and sacked; and the Romans carried from this seat of the Arts, as well as from other cities equally celebrated, all the fine productions in Sculpture and Painting which had been accumulated for Ages; and Rome became filled with the most splendid monuments of Grecian taste and genius.

Transfer o works of Art to Rome.

Athens, which for various reasons had been the chief and favourite asylum of the artists of Greece, had undergone considerable changes of fortune from the time of Pericles, under whom she may be considered to have arrived at the zenith of her glory. The reverses which affected her political importance, and from which she never recovered, did not, however, affect the cultivation of Literature and the Fine Arts, for which she was celebrated long after her influence in affairs of state was at an end. But after the death of Alexander, we find her struggling in vain to preserve even this ascendency, and she was continually subjected to humiliations and oppressions from his successors, and at last fell into the hands of the all-conquering Romans, and had to bow her neck to the cruel and unrelenting Sylla. On the breaking out of the Civil war between Pompey and Cæsar, Athens sided with the former; but she, happily, felt no additional yoke from the success of Cæsar, who, instead of visiting with vengeance a city whose inhabitants had declared themselves inimical to him, and were the supporters of his rival, treated them with clemency, and, with a fine allusion to their illustrious ancestors, declared, "that he would spare the living for the sake of the dead." The war between Brutus and Cassius, and Augustus and Antony, soon followed, and upon the success of Augustus, and the establishment of the Roman Empire, the Greek artists sought and found an asylum in Rome, where, however, the practice of Sculpture became, in a short time, widely different from that which had distinguished it in its own favourite land. It will be proper, however, to take a general view of the state of Art in the Roman Empire from the earliest accounts of it, to show what had been done in it, and by what accident it became a pursuit of any importance or value with the conquerors of the World; for it will be found that considerable collections of statues in marble and metal, as well as of pictures, were made in Rome, some time before the Art and artists emigrated

* Commonly called the *Farnese Hercules*; it is now in the Museum at Naples.

pture. from Greece into Italy as an asylum, when they were frightened and driven from their own Country.

Roman Sculpture.

For many years after the establishment of the Romans as a nation, they were too much harassed, at home and abroad, to think of the more elegant pursuits of Society; the History of Sculpture, therefore, amongst them, does not assume any importance till a comparatively late period. The city itself, like its inhabitants, was in the beginning rude and unadorned, and a nation of rough soldiers was not likely to admit the influence or value of the politer Arts, which they could only look upon as the care of an effeminate people. Their first public monuments were trophies; the trunk of a tree, stripped of its branches, was dressed up with the arms of the conquered, and exhibited to public view; and although we read of works in Sculpture of an early date, there can be little doubt that they were the productions of their more enlightened neighbours the Etruscans. It is not very easy to determine at what time the Romans themselves began to think the Arts of Design worthy their attention. Mention is made of equestrian statues erected in Rome in honour of M. F. Camillus and Q. Mænius, after their victories over the B. C. 300. Latins, above three hundred years before the Christian Era; and about the same period, Fabius, a man of noble family, who dedicated himself to the Arts, and acquired the surname of *Pictor*, distinguished himself by painting subjects in the Temple of the Goddess of Health; about this time too a bronze statue of Apollo was erected in the Capitol, out of the spoils of the Samnites. rcellus. After the taking of Syracuse, Marcellus sent works of Art from Sicily; and it is also said, that the first Greek artist who had visited Rome was sent there at this period. The increasing power and successes of the Romans now enabled them to collect various specimens of Art which they sent in great numbers to Rome, but it cannot be said that the possession of the beautiful works which fell into their hands, caused at this time any great improvement in the general taste of the people; the fact is, cities and temples were ransacked and plundered to enrich the treasury of Rome, or to swell the triumph of a general, and works of Art were merely looked upon as spoil;—the feelings, therefore, which the finest display of Art excited amongst the people, were far from any likely to generate a love for refinement, and the quieter pursuits of civilization. It is to be remembered also, that the spirit of the Government was rather opposed than favourable to the encouragement of the Arts; for the grandeur and importance of the Nation being dependent on its military prowess, it was of consequence not to cherish any feeling or taste which could tend to soften the character of the citizens, or lead them to prefer a life of tranquillity to one of continual exertion and danger. Consequently it appears, in more than one instance, that those who dedicated themselves to such pursuits were ridiculed;* and it was not till about eighty-six years before Christ, that any disposition in their favour can be said to have discovered itself in Rome. Sylla had sacked Athens and demolished some of the principal Roman. monuments and Temples of Delphi, Epidaurus, and Elis, but he had also sent a great proportion of the spoil to Rome, and it would seem that the possession of the fine productions of Greece generated by degrees a feeling in the conquerors propitious to the advancement of Art in their own Country. The taste, once admitted, soon became a passion, and Verres particularly is celebrated for the avidity he showed in collecting all the most valuable monuments of Sculpture and Painting in Sicily. At this time (when Rome was becoming the asylum of those artists who could no longer live in Greece) flourished Pasiteles, a Sculptor of no mean ability, Arcesilas, Strongylion, celebrated particularly for his Amazon *Eucnemis*, or "with the beautiful legs," and his three Muses, Olympiosthenes, Evander, and others. The successes of Julius Cæsar Julius Cæsar. enabled him to add considerably to the collection of fine works of Art which were in Rome; in his more private condition he had always manifested a strong feeling for the elegant Arts, and had made valuable collections of statues, gems, &c.; when his power became fully established, his patronage of them became more extended, and he embellished not only Rome, but many cities of Gaul, Spain, Greece, and Asia Minor.

Augustus encouraged artists, and took the greatest Augustus. possible interest in their works; he had all the finest specimens of Art collected together in Rome, and placed them in the public places and streets of the city; he is also said to have erected statues in honour of those persons who had distinguished themselves by any important actions, or had otherwise deserved well of their Country. The fine statue called Germanicus, which is now in the Museum of the Louvre, is considered to be of this period. The example set by Augustus was followed by most of the rich in Rome, and as forming collections of Statues and Paintings became a passion amongst the higher classes, no expense was spared to gratify it. Pliny enumerates many of the works which were executed under the Emperor's superintendence, and various productions in Sculpture and Painting, with which the public places, Temples, &c. were decorated. Agrippa appears to have Agrippa. been one of the most munificent and public-spirited individuals of the Augustan Age, and he spent vast sums in erecting useful and ornamental edifices in and about Rome. Before other works, the Pantheon stands preeminent, and still calls forth the admiration of posterity as one of the finest examples of Architecture remaining to us. Diogenes, a Sculptor, an Athenian by birth, was employed by Agrippa to enrich this Temple; Pliny notices some statues of Caryatides by him. There were several artists of high reputation living during the Age of Augustus; the Architect Vitruvius, whose valuable writings have reached our times, is eminent amongst them; Dioscorides, Agathopus, Epitynchanus, Pythias, Posidonius, celebrated engravers on stones and sculptors or chasers in metal, may also be placed at this date, whose works are highly spoken of by Pliny: some of these have fortunately been preserved, by which posterity is enabled to judge of the ability of the artists who executed them. The works, however, of this period which claim the attention of the student and connoisseur, are principally portraits, in which great merit will be discovered; the difference between them and the productions of the best Greek Schools will be found to consist in certain peculiarities of execution. There

---

* Val. Max. says of Fabius Pictor, *risu et contumeliâ erat.*

is, indeed, much to admire in the style of many of them; great attention seems to have been paid to the individual character of the person represented, and this without producing the poverty or littleness which too frequently offends the taste in works of this description.

The Toro Farnese.

The Laocoon.

The Cupid and Psyche.

Tiberius.

The group generally known as the *Toro Farnese*, to which allusion has been made in a former part of this Essay, has been attributed by some antiquaries to this period, or, at any rate, to the time of some of the early Roman Emperors. It will occupy too much space here to enter into a question which has already occasioned much discussion; Winckelman considered it early Greek, that is, before the time of Lysippus. This fine work, which has lately been removed from the gardens of the Villa Reale, at Naples, to the Museum there, has suffered very much from accident, and, unfortunately, the restorations which have been made are very inferior, both in style and execution, to the original work. The same date (the Augustan Age) has been given to the group of Laocoon and his sons; the manner in which Pliny speaks of it having, amongst other reasons, given occasion to some to think it was not ancient in his time. It must be observed, that this writer says it was formed out of one block of marble; a mistake which is evident to all who have examined this exquisite work, in which the joints of the various pieces are very perceptible. The Age of Lysippus also has been given as another probable time at which this group was executed, but the reasons adduced by the different antiquaries who have considered this subject in favour of the later date appear sufficiently well founded to claim the preference. One of the most beautiful and interesting groups of antiquity, "the Cupid and Psyche," at present in the Museum of the Capitol at Rome, is not noticed at all by Pliny; Flaxman considered that his silence might have been owing to his classing this as a modern work unentitled to notice, because it was not the production of any of those great masters who were looked on as the standards of excellence in his time; a reason which probably led him to pass over several other works which occupy a distinguished and well-deserved place in our estimation. A circumstance is related, which occurred during the reign of Tiberius, showing that the Roman people were not a little jealous of the fine works, which the liberality of individuals had erected or dedicated for the decoration of the city. Tiberius admired a celebrated statue, by Lysippus, representing an athlete anointing his limbs, and, desirous of possessing it, he had it removed from the Baths of Agrippa, in which it stood, (and to which the Public had access,) to his own Palace: this excited the indignation of the people, who refused to allow the Emperor to deprive them of it, and their dissatisfaction was so great, that it had nearly occasioned a revolt in the city. Tiberius, alarmed at the violent expression of public feeling, was obliged to relinquish his object; he ordered the favourite statue to be replaced in its original situation, and the people were pacified.

Caligula.

Caligula collected works of Art from Greece, but was influenced rather by a desire to gratify his own wretched ambition, than by any wish to possess them as beautiful works of Art, or interesting memorials of an enlightened people; he ordered the heads of the Gods and of illustrious men to be struck from their statues, and his own portrait to be introduced in their places. It is recorded that this Emperor wished to transport the celebrated statue of the Olympian Jupiter to Rome, but the design was abandoned on the representations of the Architects, who declared it would be destroyed in any attempt to remove it.

Nero.

The Apollo Belvidere, and the Fighting Gladiator. Plate IV. Fig. 2.

Claudius and Nero followed; the latter, notwithstanding what had already been taken from it, obtained no fewer than five hundred bronze statues from the Temple of Apollo, at Delphi, the greater part of which were employed in the decoration of his celebrated Golden Palace. Amongst the ruins of a Villa, or Palace, supposed to have belonged to Nero, at Antium, two of the most esteemed works of antiquity which have reached our times were discovered, namely, the Apollo of the Belvidere, and the Warrior of Agasias, commonly called the "Fighting Gladiator." The names of Menodorus* and Zenodorus, Sculptors, are distinguished during this period: the first was an Athenian, and is alluded to by Pliny for his skill in representing armed men, athletes, and huntsmen. Zenodorus executed many important works, but he is particularly mentioned as having made a colossal statue of Nero. This artist was practising Sculpture in Cisalpine Gaul, when Nero sent for him to Rome, but it is not known of what place he was a native.

The reigns of Galba, Otho, and Vitellius were too short and disturbed to give those Emperors an opportunity, even if they had the inclination, to protect the Arts; though, it is said, that Otho appropriated a considerable sum of money for the completion of Nero's Golden Palace. Busts of these three Emperors are extremely rare.

To this period, or soon after their time, are to be attributed the greater part of those works in Sculpture which are composed of different coloured marbles; productions in which the value or richness of the material was preferred to the merit or excellence of the design or execution—a sure indication of the existence of a false and bad taste, which was leading to the extinction of really fine Art.

Trajan.

Nothing further occurs worth noticing in the History of the Art till the time of Trajan, and the reign of that Emperor, of Hadrian, and the Antonines, may be considered the golden Age of Sculpture in Rome, though it is probable that the Art was but little practised by native artists even at this time. The arch at Ancona, and the column still existing in the Forum of Trajan at Rome, are monuments of the taste of the Emperor and the skill of the artists who were living during his reign. It is said that a custom prevailed at this time of putting Roman names on ancient Greek statues; it is not very easy to divine the object of this species of forgery, unless it were done with the hope of giving posterity a higher impression of the talent of the artists than they felt their own works were likely to create.

Hadrian.

In Hadrian, the Arts found a magnificent protector, and they maintained their excellence undiminished; he restored many of the old Temples, erected others, and amongst other important undertakings, completed the Temple of the Olympian Jupiter, at Athens, which had remained unfinished since the time of Pisistratus; he decorated it with a variety of works, and a statue of colossal dimensions of the Emperor himself was placed in it. In Italy, he built his celebrated Villa, and embellished it with all the finest works he could find of

---

* There were, probably, two Sculptors of this name; *vid.* Paus. and Plin. for their works.

Sculpture.

and took Rome; in the year 456, Odoacer gave the city up to pillage; Genseric, King of the Vandals, almost rendered it a desert; and, in 545, the Goths, under Totila, again attacked it with brutal fury, and fired the city, which continued burning for several days. We are told that in this siege the Romans, having retired into the Mausoleum of Hadrian, (the present Castle of St. Angelo,) threw down the statues which decorated it, on their enemies under the walls.

In the year 479, a fire at Constantinople occasioned the destruction of an immense number of statues and other valuable works of Art collected in the Palace of the Lausi.

Justinian.

The Arts were again protected by Justinian, and this Emperor had several monuments of importance executed, amongst others a statue of himself, which was placed on a column decorated with *bassi rilievi*: the magnificent Church of Sancta Sophia, at Constantinople, was also erected during the reign of this Prince.

Constans, Emperor of the East, in the year 661, driven from his Capital by the imprecations of his people, visited Rome, which he despoiled, during the few days he remained in it, of its most valuable possessions in Art; these were removed by his orders to Syracuse, where he proposed to establish himself, and where he concluded his pilgrimage of disgrace and rapine. Wars, seditions, Political and Religious divisions, now fully occupied the public time and attention both in the Eastern and Western World, and gave no leisure for the protection of the Arts; on the contrary more frequently led to the destruction of those few monuments which remained. The successes of the Saracen Caliphs carried them into Sicily, and thus the objects collected there fell into the hands of new masters. The fury of the Iconoclasts and the conquests of Barbarians, tended still further to forward the work of destruction; occasionally, individuals appeared who were disposed to protect the remains of antiquity, and, as was the case with Charlemagne, and afterwards with Theodoric, to stop the ravages which were consequent upon the successes of their Barbarian followers: but their influence, honourable to themselves, was quite inadequate to effect their purpose, or to save the Arts, which were now hastening rapidly towards their final extinction. We still watch with interest the existence of some of the *chef-d'œuvres* of Sculpture preserved, amidst all the confusion and difficulties of the time, in Constantinople, to which remote corner of Europe the Roman name was at length reduced, the Empire of the West being now entirely at an end; but when Constantinople was taken by Baldwin, even these few remains were doomed to destruction, and the statues in metal were melted down and converted into money;* amongst them were a magnificent Juno, by Lysippus, a colossal Hercules, a statue of Helen, and a variety of other works, the productions of the most flourishing time, and most celebrated Sculptors of ancient Greece. We have purposely hastened over this portion of our account, for it is difficult and unsatisfactory to trace the further History of the Art, when each step we take but assures us of the ruin and devastation around us, and leads us in fact into darkness. The monuments of the Romans are very numerous, and have been of great assistance both in illustrating the writings of the Historians, and in making us acquainted with the manners and customs of that people; but, for obvious reasons, the History of their Sculpture has not the same claims on our interest or attention which we are disposed to give to that of Greece, and our observations on it have, therefore, been as compressed as possible. The History of ancient Sculpture may be considered to cease at this part of our Essay; in the next stage of our inquiry we shall commence that of Modern Sculpture.

A. D. 1204.

We have endeavoured in Plates I., II., III., IV., and V. to illustrate the progress of Sculpture from the earliest period to the time of Hadrian. Plates IV. and V. contain specimens from Myron, the contemporary of Phidias, about 500 B. C., down to the IId century B. C.: the best illustrations of the School of Phidias will be found in the British Museum. No certain date can be assigned to the Fighting Gladiator, the Laocoon, or the Group of Dirce in the above Plates, but of their School there can be no doubt.

Revival of Sculpture.

Though it is difficult to trace, in the specimens of rude Sculpture and bad Painting of the darker Ages, any resemblance to the works of a former period, it would still appear that the embers of the Arts of Design had been kept alive by the Monks of the Greek and Latin Churches, and were again kindled into a flame by the Italians, as soon as they found themselves in a state of comparative ease and security. It is true that from the Age of Constans to the XIIIth century, the productions of the early practitioners exhibit but uncouth representations of the same subjects, insomuch that it is almost impossible to decide with exactness on the time of their execution; indeed, it is probable that most of these were local and accidental efforts of uncultivated Barbarism, for which there was no general demand, but which gratified ignorant individuals or corporations, chiefly Ecclesiastical; and to this circumstance may be traced the uncouth decorations of some very old Churches and Tombs. In the illuminated MSS., executed in the richer Convents, a style of design was soon adopted, which depended on neat drawing and careful finishing, and became the business of ingenious and literary Monks when there was no other demand for Painting. The *orefici* (gold-workers) in Pisa and Florence, had, however, some encouragement in ornamental work, on a small scale, in gold and silver; but there was no demand for Sculpture in large masses of less costly materials; and the characteristic of their Art would naturally be minuteness, stiffness, and timidity of design. From the Bodies of artists in these trades the first successful efforts of Painting and Sculpture seem to have arisen; but it is easy to see in the predecessors and contemporaries of Giotto and Cimabue, that their Paintings on board are little more than enlarged imitations of illuminations on paper and vellum.

The discovery of oil-painting gave to artists the means of increasing the depths of their shadows, and, consequently the roundness and relief of their Pictures; it led them gradually to abandon the meagre style of the enlarged illuminators, and to approach that of Lionardo da Vinci, who may be considered the greatest master in the early manner. In its progress it was influential on Sculpture; and as both Arts were often exercised by the same individuals, it will be easily seen that in the composition of the bronze reliefs on the gates of the Bap-

---

* Nicetus Choniates.

tistery, at Florence, (as well as in other works,) both Pisano and Ghiberti have adopted the design and arrangement peculiar to the sister Art, rather than the imitation of the antique models. This transfer of picturesque effect to Sculpture, gave a different character to the revived Art to that which it possessed in ancient times, and it unhappily became the source of much defect and corruptness of style; though it must be confessed that, in the hands of men of genius, it occasionally produced beauties of its own, which it is impossible not to admire in spite of the deviations from pure classical taste. This alliance with Painting is the grand characteristic of the works of the *Cinque Cento* artists and their successors. Among the Ancients, Sculpture seems almost to have given the laws of design and composition to Painting; their knowledge of perspective was limited, their power of representing shaded distances feeble, and their Pictures, in consequence, were treated much like *bassi rilievi* coloured. At the revival of Art, Painting soon became possessed of powers beyond the reach, but not beyond the emulation, of Sculpture, and it was vainly endeavoured to produce that, in marble, which can only please, and, indeed, can only be effected by colour; the hair, the draperies, the attempted gradations of perspective, in the works of all this School, bear witness to its failure. These observations have carried us further than we intended, but it is impossible, perhaps, to develope the actual nature of the progress of Sculpture during this period, without adverting to the contemporary progress of Painting, by which it was, to a certain extent, both guided and misled. To resume the history of the Art. In the beginning of the XIIIth century, Nicolo Pisano appeared; he was, as his name denotes, a native of Pisa, and is said to have improved his genius and feeling for his Art by the contemplation and study of some recently discovered ancient sarcophagi, &c., still existing in his native City.* Many of his works are preserved in different parts of Italy, and are evidence of the native power of his mind in general composition and feeling. Amongst the most remarkable are the pulpits of the Baptistery at Pisa, and of the Duomo of Siena, and particularly a semicircular *basso rilievo* of "the taking down from the Cross" over one of the entrances to the Duomo of Lucca. Besides these, Nicolo executed the principal part, and probably designed the whole, of the marble *alti* and *bassi rilievi* which decorate the front of the Cathedral of Orvieto: they consist of illustrations of the Old and New Testament, arranged in compartments; the figures in these are frequently ill-proportioned, the heads large, and deficient in expression or character, but the compositions are for the most part good, the draperies well understood and executed, and in the female figures and angels, particularly, there is a simplicity, grace, and feeling, which have rarely been surpassed. Nicolo lived to a great age, and was succeeded by his son Giovanni di Pisa, Arnolfo of Florence, and other scholars. In the year 1330, Andrea Pisano, who was settled in Florence, executed one of the bronze gates of the Baptistery in that city, a work which deserves attention for the beauty and simplicity of feeling it exhibits, though it is certainly deficient in the more mechanical excellences of Sculpture. With Andrea Pisano, was contemporary Andrea Orcagna, an artist of ability, who executed a variety of works, the greater part of which are still to be found in Florence. Luca della Robbia died in 1442; he has left several specimens of Sculpture. This Sculptor is well known as the inventor and only possessor of the Art of covering models of terra cotta with a beautiful and peculiar varnish, which renders them as hard as stone; he is supposed never to have disclosed this secret to any person, but it is said he committed it to writing, and enclosed it in some one of his models; whether this was the case can only be known by the destruction of his work. Amongst his productions are some of great beauty, both in feeling and composition.

Modern.

Luca della Robbia.

Ghiberti.

Donatello.

The next names which occur in the annals of modern Sculpture are those of Lorenzo Ghiberti and of Donato di Betto Bardi, better known as Donatello. The celebrated bronze gates of the Baptistery at Florence by Ghiberti have insured for that artist a lasting fame with posterity: this work consists of a series of *bassi rilievi* in the panels of the gates, illustrative of subjects of Scripture, and they contain passages of beauty, of feeling, and of expression, which far surpass any thing of the sort produced by his predecessors in the revival of the Arts, and have not been often excelled in the works of more advanced times. Donatello, one of the most deservedly celebrated of the early artists of Italy, was a scholar of Lorenzo di Bicci; he was born in Florence in the year 1383. The works of Donatello appear to have been highly prized during the lifetime of the artist, and though his principal employment was in his native city, we find specimens of his talent in many towns of the North of Italy. His most celebrated works are still to be seen at Florence; the two statues which are most noticed are those of St. George and St. Mark at Or San Michele: there is a simplicity of action and grandeur of expression in the former of these, which reminds the spectator strongly of the fierce and nervous manner characterising the works of the succeeding Age. The statue of St. Mark is distinguished by Michael Angiolo's celebrated exclamation, *Marco, pèrche non mi parli?* In the Museum at Florence are some very curious *bassi rilievi* by Donatello in marble: they represent groups of children dancing, composed with great skill; they are executed in very low relief, and the back-ground is covered with gold-leaf, put on in round pieces, each about the size of a guinea. At Padua are some specimens of *basso rilievo* of this Sculptor, which, making allowance always for the early time at which they were executed, well deserve the attention of the admirers of Art. It is probable that the somewhat exaggerated treatment which is observable in the works of Donatello, as well as those of Ghiberti, arose from a desire to avoid the dryness of their predecessors; and this will account for some peculiarities in the forced bendings of the wrists, fingers, and other articulations in their figures. The contemplation of the works of these two Sculptors, who made such rapid strides in Art, cannot fail to afford the highest satisfaction to all who feel an interest in watching the advancement of the refined pursuits of the human mind.

Anecdote of Donatello.

An anecdote is related by Vasari of Donatello and his friend Brunelleschi, who was afterwards the most celebrated Architect of his Age, which will not be read without interest in this place: we extract it from the valuable and well-known Work by Mr. Ottley on the *Italian School of Design.* "Donatello had recently made for the Church of S. Croce, at Florence, a crucifix carved in wood with extraordinary care; and proud of

---

* They are preserved in the Campo Santo at Pisa.

his performance, showed it to his intimate friend Filippo Brunelleschi, in order to have his opinion; when Filippo, who, from the previous description of Donatello, had been prepared to expect a work of much greater excellence, did not wholly suppress a smile. This did not escape the notice of Donatello, and he conjured his visitor by all the ties of friendship to declare to him his real sentiments. Brunelleschi, who possessed great frankness of character, replied, 'that the figure he had placed upon the cross appeared that of a day-labourer, rather than a proper representation of Jesus Christ, whose person was of the greatest possible beauty, and who was in all respects the most perfect man that was ever born.' Donatello, already disappointed of the praise he had anticipated, could not brook the unexpected severity of this remark. 'It is easier to criticise than to execute,' he retorted; 'do you take a piece of wood, and make a better crucifix.' Brunelleschi said no more; but upon his return home, secretly went to work, and after the labour of several months, he finished a crucifix in the most perfect manner. This done, he invited Donatello one day, as if accidentally, to dine with him, and he having accepted the invitation, the two friends walked together towards the house of Brunelleschi, till they came to the old market-place, where the latter purchased various eatables, and giving them to Donatello, requested him to go on with them to the house, where he would join him presently. Donatello, therefore, having reached the apartment of his friend upon the ground-floor, had his attention immediately arrested by the crucifix of Brunelleschi, which that artist had taken care to place in an advantageous light; and standing before it, he became so absorbed in the contemplation of its superlative merits, as entirely to forget the provisions committed to his charge; for opening by degrees the hands which supported his apron, down came the eggs, cheese, and other things, upon the floor. Notwithstanding which, he still continued in the attitude of one overcome with admiration, until the arrival of Brunelleschi, who, laughing, asked him how they were to dine, now that he had spoiled every thing? 'I,' answered Donatello, 'have had quite dinner enough for this day. You, perhaps, may dine with better appetite. To you, I confess, belongs the power of carving the figure of Christ; to me, that of representing day-labourers.'"

Giovanni Pisano the Second.

Verrochio.

Rustici.

Donatello lived to a great age, and left numerous scholars; one of them, Giovanni di Pisa, was the author of a large *basso rilievo* in terra cotta, now in a chapel in the Church of the Eremitani at Padua: it represents the Madonna and infant Christ, and on each side of her are three figures of Saints. This work has some of the faults of the time, but it is an extraordinary production, and deserves attention for the simplicity and breadth of its composition, as well as for its execution; it is remarkable, too, for the very flat style of its relief, but it has all the breadth and effect which that mode of treatment insures, and which, united with elegance of form, calls forth our admiration in the celebrated frize of the Parthenon. Passing over names of less importance, though worthy of distinction if our limits would admit of it, we proceed to Andrea Verrochio, particularly celebrated as the master of Lionardo da Vinci and of Pietro Perugino, the master of Raffaelle. Verrochio was at first a painter, but it is said that Lionardo, when a lad, being desired to paint an angel in an altar-piece on which his master was employed, the performance of the scholar proved so superior to the rest of the work, that Verrochio, indignant at and jealous of being surpassed by a stripling, renounced the palette, and devoted himself to the sister Art. Some of the works of this artist are to be seen at Florence; particularly a group of two figures, Christ and St. Thomas, in Or San Michele, and some *bassi rilievi* in the Museum. Rustici, who studied under Verrochio, and subsequently under Lionardo da Vinci, was a native of Florence; this artist was invited into France by Francis I., where he died in 1550: amongst his works are several of classical subjects which have considerable merit.

XVth and XVIth cen- turies.

The situation and political circumstances of Italy at this time are peculiarly striking and deserve attention; for the XVth and beginning of the XVIth centuries comprehend a period of the greatest interest in the modern History of Science and the Fine Arts. The extraordinary talents of the Medici had raised that Family to the highest honours at Florence; and Lorenzo, who well merited the distinguished title he obtained of "The Magnificent," added to the lustre of his condition, by attaching to his Court the most ingenious and learned men of the Age. Rome, too, was governed by Pontiffs who, uniting magnificence with fine taste, extended their powerful protection to the Arts. Julius II., who assumed the tiara in 1503, gave princely encouragement to the great artists of his Age; he was succeeded by Leo X. and Clement VII., who, descended from the Family of Medici, felt an interest in the elegant Arts similar to that which had rendered Florence so famous: the names of these munificent patrons of genius and talent are identified with all that is valuable in Art, Science, and Literature.

Michael giolo Bu roti.

The powerful genius of Michael Angiolo Buonaroti gave a new impetus to Art, and placed that extraordinary man at once in the distinguished station which he still continues to occupy, and which no artist of his own or a later Age has been able to attain. Baudinelli, the Ammanati, Rustici, the Monte Lupi, Sansovino, Benvenuto Cellini, Giovanni di Bologna, Francavilla, who were all either living in his time, or formed out of his School, and have left great names, were but minor stars in the horizon in which he shone, and still shines, resplendent. Michael Angiolo Buonaroti was born of a noble family in Florence, in the year 1474, and at an early age became the scholar of Ghirlandajo, one of the most eminent painters of the time. Lorenzo de' Medici had established an Academy in his Gardens, and the genius of Michael Angiolo did not escape the notice of that Prince, who immediately gave him apartments in his palace, and otherwise honoured him with marks of particular favour. It will hardly be thought necessary to particularize the productions of an artist so well known as Michael Angiolo; but as our object is to illustrate the History of Sculpture, it will not be improper to point out some of his most celebrated works in this Art, for the purpose of comparing the peculiarities of his style with other monuments of his own Age, or of those artists who preceded him. Till this time, the works of the artists, since the revival of the Arts, were meagre and little in their details, though considerable feeling and talent were occasionally displayed in their conception, invention, and composition. Extraordinary genius, like that which distinguished Ghiberti and Donatello, occasionally broke through the dryness of the prevailing practice in some degree, but it was left to the gifted Florentine to effect that total revolution in style which has stamped the Art of his Age with a character peculiarly its own, which has been happily termed "*di Michel Agnol' la terribile via.*" The merits of Michael Angiolo have been too frequently insisted upon to need any detailed consideration here; we shall content ourselves therefore with pointing out to our readers the most striking of his excellences, noticing afterwards in what he appears most deficient as a Sculptor. For this purpose it will not be necessary to notice his works in the order in which they were executed; we shall begin therefore with the well-known monuments in the Chapel of the Medici at Florence, in memory of Giuliano and Lorenzo, (not "*il magnifico*,") two members of that family. The statue of the latter is most remarkable for its character and expression: Lorenzo is represented seated and wrapt in thought; he leans his face on one hand, which partially covers the chin and mouth; the rest of the figure is in perfect repose, and throughout the whole there is the air of deep meditation. It is impossible to look at this statue without being forcibly struck with the *mind* that pervades it. For deep and intense feeling it is certainly one of the finest works extant.[*] The lower part of this monument consists of two statues intended to represent Morning and Evening, which form a strong contrast to the dignity and simplicity of the figure above them; they are grandly conceived and boldly executed, but there is a violence of action in them which is completely at variance with the repose of the pensive statue of Lorenzo, and which seems to have been adopted rather for the purpose of exhibiting anatomical knowledge and manual skill, than of adding to the real interest of the design. The monument of Giuliano is composed on the same principle; the two figures beneath the principal statue are those of Day and Night, and although they bear the stamp of the master hand, they want all that quiet which is not only essential to the beauty of Sculpture, but which seems to belong particularly to the subject on which they are employed. The statue of Moses in the Church of S. Pietro in Vincoli, in Rome, is one of the most celebrated works in Sculpture of Michael Angiolo, and is a grand effort of skill. The admiration which this statue excites is caused chiefly by the principles of composition which are employed in it; no small parts nor acute angles distract the attention, but quantity and large masses are preserved throughout; in the general expression there is vast energy, but it is sufficiently tempered to preserve that repose which is essential to dignity. This work requires to be studied with attention to be understood; its merits will then be found to compensate for minor faults, which the *manner* of Michael Angiolo threw more or less into most of the productions of his chisel or pencil. The statue of Christ, in the Minerva Church at Rome, has less of the violence of this master than most of his works; but, although it has excellences of a high class, it is by no means one of his finest efforts; it displays great learning and skill in execution, but it wants that dignity and refinement of form and expression which should characterise the representation of the Saviour of the World. An allegorical *basso rilievo* preserved in the Vatican, (and of which there are casts,) is an interesting monument of Michael Angiolo's knowledge of the human form; it is more remarkable for this than for any other quality; the composition being too complicated to render it unexceptionable as a work of Sculpture. The statue of David, in the Piazza del Gran Duca, at Florence, was executed under very unfavourable circumstances, Michael Angiolo having been employed to finish it when the block of marble had already been worked upon by an inferior artist, and considered spoiled; but the powerful hand of the master is visible, and few can look upon this work without being struck with the grand air it has as a whole, and particularly with the turn and expression of the head and throat. The statue of Bacchus is admirable for its expression of inebriety, and for the execution, but it wants purity of taste, and the beautiful form which the Ancients always considered proper to the young and joyous God. The group in marble of the Madonna and Child in the Chapel of the Medici at Florence, the Pietà in St. Peter's at Rome, and the unfinished group of the Body of Christ supported by Nicodemus, the Madonna, and Mary Magdalen, are compositions of the highest merit, abounding in pathos, and many excellences of execution: the dead Christ in the Pietà is particularly worthy attention; the tranquillity and perfect repose of death is finely portrayed throughout this figure, and, with some exceptions to the head, and articulations of the joints, it is free from the *manner*, as it is called, which is generally so conspicuous in Michael Angiolo's Sculpture. We would notice, too, a work which we possess in England by this great master, abounding in grace and feeling; it is a circular *basso riliero* in marble, consisting of three figures finely composed, representing the Virgin, the Infant Saviour, and St. John, and which, though unfinished, is a beautiful and highly valuable example of the artist.[*]

In contemplating the works of Michael Angiolo, the spectator is so completely absorbed in admiration of the invention, vigour and energy of mind, and vast knowledge of form and anatomy displayed in them, that he hardly allows himself to think they can be wanting in any other qualities of Art. But it is an undeniable fact that Michael Angiolo's Sculpture does not afford that high satisfaction which works of ancient, and some even of modern times occasion; and we are naturally led to inquire the cause of this, in an artist whose reputation stands so high, and the productions of whose pencil still fearlessly defy competition. Sculpture, to be perfect, must be practised on certain principles, and, without them, whatever other qualities it may possess, it has not the power to please, nor to make any lasting impression on the mind. The chief of these essential properties is simplicity. This it is which gives a charm the productions of Greece, and to the best works of a later Age, and it is to the absence of this, that we must attribute the little effect produced by the generality of modern works; amongst them by many of those by Michael Angiolo. All who have seen it remember with feelings of satisfaction his "*thinking*" statue of Lorenzo de Medici; it comes home to every heart; it is Nature, but in character and expression dignified by the highest power of Imagination. Few recollect more of the statues of Morning, Evening, Day, and Night, than their attitudes; the affections and feelings have little or nothing in common with them, and their want of simplicity dis-

---

[*] It has been well and justly observed of this statue, "There is no resemblance to the antique, but it rivals the best excellences of the Ancients in expression with repose and dignity; *such effects are produced by the study of real life contemplated by genius and imagination.*"

[*] This work was purchased in Rome by the late Sir George Beaumont, Bart., and bequeathed by him to the Royal Academy, where it is now preserved.

tracts rather than interests the attention. It has been our duty in these few observations to consider the Sculpture of Michael Angiolo with reference to its merits compared with that of the Ancients; for he made gigantic strides which placed him, beyond comparison, far above any of his contemporaries. We have only had to consider him as a Sculptor, but in giving him the distinguished rank his high and extraordinary merits claim for him, it has been thought necessary to notice what his Sculpture wanted to place it on a level with the finest productions in that Art.

In the Chigi Chapel in the Church of S. Maria del Popolo, at Rome, is a group in marble of Jonas with the sea monster, which is believed to be a production of the time which we are now considering. It is a work of great beauty, and it is to be regretted that its situation is such as to preclude the possibility of viewing it to advantage: **Lorenzetto.** it is said to be the production of Lorenzetto, but if the tradition may be believed, Raffaelle d'Urbino furnished the design for it, and even made the model from which the Sculptor afterwards executed the marble. **Beggarelli of Modena.** About this time also lived Beggarelli of Modena, famous for his models in clay; concerning whom a remarkable expression of Michael Angiolo is recorded; he exclaimed, on seeing some of this artist's works, "If this clay could but become marble, woe to the antique statues." **Sansovino.** Tatti, better known as Sansovino, appeared at this time; several of his productions, statues, and *bassi relievi*, in marble and bronze, are preserved at Venice and Padua, and although they want simplicity, they display considerable talent; his scholars were numerous, and some of them, particularly Danese Cattaneo, Ammanati, Lombardi, and Vittoria, distinguished themselves by the success with which they practised their Art. **Baccio Bandinelli. Plate VII.** Baccio Bandinelli was a native of Florence, and takes a high rank amongst the artists of this Age; he was the scholar of Rustici, the intimate friend of Leonardo da Vinci, a connection from which Bandinelli must have derived great advantage. His style was very bold, his general designing vigorous, and his works display considerable knowledge of form; but his drawing is too free, and abounds in the *mannerism* which characterises the Art of this time. Several works in Sculpture by Bandinelli exist in Florence, which, though they do not place him on a level with Michael Angiolo, to whom he was always opposed, attest the skill of the artist. Amongst his most highly esteemed productions may be reckoned a number of figures in compartments, in very low *rilievo*, which decorate the base of the screen round the high altar in the Duomo of Florence; a *basso rilievo* in marble on a pedestal which stands in the Place of S. Lorenzo, also at Florence; which though in many respects open to criticism, has high claims to distinction, and may be considered a fair illustration of the Art of the Age. He made a portrait of himself in the statue of Nicodemus supporting Christ; (a group in marble, the size of Nature, for his own monument in the church of the Annunziata at Florence;) and in the Palazzo Vecchio are statues of Adam and Eve with the Tree and Serpent between them: the former of these works is superior to the last mentioned, but both are inferior to those before noticed. Baccio Bandinelli, either from his lofty pretensions, or the jealousy of his disposition, of which many instances are mentioned by Vasari, appears to have been exceedingly unpopular during his lifetime, and his works were severely satirized by his contemporaries; the sting of these remarks has however passed away, and his works remain to claim for him the distinction to which his merits as an artist entitle him. **Benven Cellini. Plate VII.** Benvenuto Cellini has a double claim upon posterity as a Sculptor and a writer. The estimation in which his smaller works were held, is attested by their numbers, and the high prices he obtained for them; most of these, from the value of the materials in which they were executed, gold, silver, and precious stones, have disappeared in the disturbances that have agitated Italy; but some of his larger works remain, and his Perseus, in the Loggia of the Piazza del Gran Duca, at Florence, particularly claims attention for the general conception of the subject, and the knowledge it displays. Faults no doubt may be found in it, but this work places Cellini amongst the most distinguished artists of his Age. His Life, written by himself, is one of the most curious histories of the manners of the XVIth century which we possess; he also wrote on casting in metal. **Properti da Rosi.** Propertia da Rossi, of Bologna, executed amongst other works some statues for the façade of the Church of S. Petronio, at Bologna; she also painted well, and was a good engraver. Propertia, it is said, became enamoured of a young artist who did not make a suitable return to her love, and the disappointment threw her into a languishing disorder which brought her to her grave; her last production was a *basso rilievo* in marble, preserved at Bologna, representing the history of Joseph and the wife of Potiphar, in which the object of her love was represented as Joseph, and in the other figure she portrayed herself. She is said to have been one of the most beautiful as well as accomplished women of her time, and died in the flower of her age.* **Guglielm della Por Sebastia del Piom** Guglielmo della Porta, the friend of Michael Angiolo and of Sebastian del Piombo, is celebrated for his restorations, particularly of the legs of the Farnese Hercules, and for two recumbent statues, one of Prudence, the other of Justice, forming part of the monument of Paul III. in St. Peter's at Rome. The latter figure has parts of considerable beauty, and is a valuable specimen of Art of that period; reminding the spectator strongly of the style of Michael Angiolo. Since Della Porta's time, this statue has been partially covered with bronze drapery.

The quality for which the Sculptors at the end of the XVIth and beginning of the XVIIth centuries are remarkable is, extreme facility of execution, which led them to lose sight altogether of repose and simplicity; the works of that time exhibit very great merit in many respects, but they abound with affectation and exaggeration; the first owing to a mistaken notion of grace, the other to a desire of showing science in the anatomy of their figures. **Gio di Bolog Plate** The works of Giovanni di Bologna, a native of Douai, are a remarkable illustration of this state of the Art; they are full of imagination and fire, and are executed with astonishing boldness and ability; his diligence as well as his skill is attested in the vast number of works which he has left in marble and bronze. The famous bronze statue of Mercury by him, in the Gallery at Florence, is conceived in the true spirit of Poetry, and is deservedly admired as one of the most elegant productions of modern Art; the form is light, and the action graceful; the only fault in this otherwise beautiful work is, that the muscles are rather too round for the character of the Messenger of the Gods. The celebrated marble group in the Loggia, at

---

* Vasari. She died in 1530.

Florence, called the Rape of the Sabines, affords further illustration of what we have said respecting the style of Art of this time; as a specimen of invention it is full of fire and expression, but the composition partakes too much of the *corkscrew* form, and is extravagant; it is impossible, however, not to admire the courage as well as ability of the artist who ventured to execute so daring a work. Other statues and several *bassi rilievi* exhibit in like manner the power of mind and hand, but at the same time the defects of style, of Giovanni di Bologna. Unfortunately the imitators of his "manner" were numerous. The beautiful and simple figure of S. Cecilia in the Church of the Convent dedicated to that Saint in Rome, would place its author Stefano Maderno in the very highest rank, if he had not forfeited his claim to the distinction by the production of later works in which all the finer qualities of Art are lost sight of. This statue was executed when he was very young, probably before his taste had become corrupted, and its excellence arises from its simplicity and general truth to Nature. It is said, that when the coffin, in which the Virgin Saint was deposited after her martyrdom, was discovered, her body was found undecayed, and lying in the position in which Stefano Maderno, by order of Clement VIII., has here represented it.* This will account for the superiority of this work over others of the same artist; prevented by the circumstances from introducing any of the prevailing bad taste of the time, he has, by making Nature his model, produced a work which excites the sympathy and engages the suffrages of all who see it.

ano
lerno.

te VII

One of the most extraordinary artists of the XVIIth century, and one whose practice tended more than any thing not only to check but to subvert all good taste in Sculpture, was Bernini. He was born at Naples, and at a very early age gave indications of talent in the Fine Arts; a head in marble is still preserved which he is said to have executed at nine or ten years of age. It is quite surprising, that, with so many fine works of antiquity before them, the admirers of Art should have so extensively patronised a Sculptor who set all the principles of true taste completely at defiance, and whose influence was so great that no Art was protected which was not conformable to that which he had established. Under him the distinctive bounds of the different classes of Art were trampled down; Sculptors were busied in imitating the works of the pencil, and Architects in seeking to introduce into their compositions the curved line of beauty. It would, indeed, be difficult to conceive two styles more directly opposed to each other than that which characterised the Sculpture of this Age, and that of the great artists of antiquity. In the one, simplicity was the pervading principle and expression united with fine form; in the other the eye is offended by strained actions, uncommon arrangement in composition, and draperies flying and frittered away. Undercutting, perforations, and all the other mere mechanical difficulties of the Art were also resorted to, to catch the attention and create surprise; thus the means were mistaken for the end, and the artists were content to rest their claim to distinction on the poor foundation of their ingenuity as handicraftsmen. A few artists may be selected from this large class, possessing qualities which raise them some little above their contemporaries, but in these the great principle which should pervade all Sculpture is lost sight of, and the picturesque is everywhere substituted for simplicity; indeed the *alti* and *bassi rilievi* of the best of the artists of this time are but bad pictures done in marble, on no part of which can the eye rest with satisfaction. The works of Bernini are too well known to require particular notice; we shall content ourselves, therefore, with mentioning a few of the most celebrated, to illustrate our observations on the merits and defects of this artist. Two of his best, and they were two of his earliest productions, are in the Cascino of the Villa Borghese, at Rome; *viz.* the Apollo and Daphne, and David, (said to be a portrait of himself,) preparing to throw the stone at Goliath. These figures display great feeling for the respective subjects, and equal skill in the execution, and only want good taste to entitle them to a very high rank in Sculpture. The statue of S. Bibiana, the fountain in the Piazza Navona, the four Doctors of the Church supporting the chair of St. Peter, are all characteristic works of this artist. In St. Peter's, also, are the monuments of Urban VIII. and of Alexander VII., which surpass all his other productions in bad taste. A group, intended to represent the ecstasy of S. Teresa, in the Church of La Vittoria, in Rome, has merits of execution, but it is difficult, amidst the flutter and confusion of the drapery, to discover either the figure of the Saint, or the subject of the work. Bernini lived during nine Pontificates: no artist ever had greater patronage, and few greater talents, had they been properly applied; but the variety of his pursuits, and his inordinate love of picturesque effect, ruined the progress of Sculpture, and we are compelled to admit, that it would have been better for that Art if Bernini had never lived. In proof of the versatility of his talents, mention is made of a theatrical entertainment which had been given in Rome by him, for which he built the theatre, painted the scenes, cast the statues, constructed the engines, wrote the comedy, and composed the music. We could easily extend our observations on this extraordinary man, but our object, that of illustrating the History of Sculpture, is sufficiently answered by noticing a few of the leading Sculptors, and making some observations at the same time on the peculiarities which mark their practice, and the improvement or decline of the Art.

nini.

Plate VII.

Algardi.

Contemporary with Bernini was Alessandro Algardi, of Bologna, whose principal work, a large *basso rilievo*, in marble, of Attila driven from Rome by the apparition of St. Peter and St. Paul, is well known. This work is above 30 feet high, and 18 feet wide, and forms an altar-piece in St. Peter's Church. The observations which apply to the works of Bernini are equally applicable to those of Algardi, who, if he did not servilely copy the faults of the first-named Sculptor, was equally distant with him from the purity of the antique; in the *basso rilievo* alluded to, an attempt is made to obtain distance and picturesque effect by a variety of planes, and difference in the degrees of relief of the figures. The consequence is inevitable in Sculpture: it is a mass of confusion. Considerable intelligence is shown in parts of the composition, as well as in the execution of the work, but a principle of bad taste pervades the whole, which is not compensated by any other qualities. In short,

---

* Venuti says, *nella positura medesima che si vede la sua statua scolpita.* The inscription under the statue is, *En tibi sanctissimæ virginis Ceciliæ imaginem quam ipse integram in sepulchro jacentem vidi, eandem tibi prorsus eodem corporis situ hoc marmore expressi.*

Il Fiammingo.

Mocchi.

Plate VII.

the Art instead of rising was now fast falling to decay; the very facility of execution, which should have been the means of carrying it to a second perfection, equal to the best times of Greek Sculpture, only hurried it to its ruin, and to the artists of the XVIIth century we must, in a great degree, attribute the disgrace of its downfal. One Sculptor, however, who lived at this period, deserves to be distinctly mentioned, inasmuch as he did not suffer himself to be carried away by the prevailing false taste, with similar facility to that with which the generality of artists bowed to its influence; this was Fr. de Quesnoy, commonly called Il Fiammingo, a native of Brussels, who, although his taste was far from correct, has left a few works which secure him a respectable name with posterity. His statues of Sta. Susanna, and of St. Andrew, at Rome, in St. Peter's Church, as well as his *bassi rilievi* of children, have passages of great merit, and claim the attention of all admirers of Art. Francesco Mocchi executed two statues in the Duomo of Orvieto, representing the Annunciation; they are not grouped together but are distinct figures. The angel has been much overrated, the boldness of the conception and execution having excited greater admiration than the general merits of the work warrant. The figure is supported on a cloud, which rests on the pedestal. The Virgin is gently shrinking and starting back; the intention is good, but the figure is short and heavy, and has none of that beauty of form proper to the subject. But little advantage will be gained by enumerating the works of the Rusconi and others of the same School, which only tend to illustrate the further decline of Sculpture. The minute and laborious works of San Martino and Corradini, in the Church of St. Severo, at Naples, representing the dead body of Christ covered with drapery, Modesty veiled, and a figure of Deceit within a net, attest the patience of their respective authors, and remain monuments of their bad taste. The same may be said, with few exceptions, of the works of the Bonazzi, Tagliapietra, Toretti, and Morlaiter, at Venice, and an infinity of other Sculptors, who deluged the different cities of Italy with absurd productions of their misplaced ingenuity.

Sculpture in France.

This was the state of Art in the XVIIIth century; and the taste which pervaded Italy was the prevailing taste in other Countries in which Sculpture was practised, the artists of Italy being almost exclusively employed to execute whatever works were required; or if native artists were anywhere thought worthy of confidence, they were for the most part scholars or followers of some distinguished or fashionable Italian practitioner. That this was the case in France will be evident on examining most of the Sculpture produced there from the time of Francis I.; the epoch from which the practice of the Art, and of its assuming any importance in that Country, is generally dated; and at which time Italian artists, Lionardo da Vinci, Primaticcio, Benvenuto Cellini, Rustici, and others were invited into that Country. The French Sculptors who arose out of this encouragement of Art, exerted themselves, it is true, with industry and success, and several have left distinguished names and valuable specimens of their abilities. A History of the French School of Sculpture* will not afford any additional information on the general History of Art, but from their most celebrated names we gladly select such as Puget and Girardon.

In England.

Henry III.

Edward I.

Edward III.

Henry VII.

Charles I.

We possess some very early specimens of Sculpture in England. Those who returned from the Crusades made attempts to imitate the Arts and magnificence of the Countries they had visited, and introduced some richness of decoration into the Architecture of their time; but no Sculpture in figures is deserving of particular notice till the reign of Henry III., when efforts were made in that Art not unworthy our attention even at the present day. In the year 1242, the Cathedral of Wells was finished under the care and superintendence of Bishop Joceline. This was about the time of the birth of Cimabue, the restorer of Painting in Italy, and the work was in progress at the same time that Niccolo Pisano, one of the earliest Sculptors after the revival of the Arts, was exercising his profession in his own Country. The circumstance is remarkable, and the late lamented Professor of Sculpture in our Royal Academy adduces strong arguments for believing the execution of the *bassi rilievi* and statues which decorate this structure to have been by native artists.* These Sculptures, consisting of subjects from the Scriptures, and some statues, larger than life, of our early Kings and Queens, exhibit much grace, beauty, and simplicity, and, making allowance always for the time at which they were executed, are well worthy the attention of the curious. The richly decorated crosses erected by Edward I., in those places wherein the body of Queen Eleanor rested, (and of which three are still remaining,) were most probably by Italian artists; but under Edward III. it seems that our own Countrymen were capable of exercising the Art. To use the words of Flaxman, "it is a gratification to know that the principal Sculptors and Painters employed by Edward III. in his Collegiate Church, (St. Stephen's,) now the House of Commons, were Englishmen;" and he gives us the names of Michael the Sculptor, Master Walter, John of Sonnington, John of Carlisle, and Roger of Winchester, Painters. Passing on to the reign of Henry VII., we find that Torregiano, an Italian artist of some celebrity, was much employed in England in the beautiful Chapel built in Westminster Abbey; but it is thought that much of the Sculpture of this period was by native artists. It will be sufficient to refer the curious reader to some of the statues that decorate the above Chapel, which are well worthy attention for the beautiful and simple arrangement of their draperies. From the reign of Henry VIII. to that of Charles I. Sculpture seems to have been much neglected; indeed works of Art were wantonly and purposely destroyed; but from the wrecks that remain it appears that from the year 1200 down to Henry VII., we have works in Sculpture, not only executed in England, but certainly in many very important instances by Englishmen. In Charles's time we meet with the names of Christmas and Stone, Englishmen. The principal works in Sculpture after this period were by foreigners, and we find that Cibber, Scheemacker, Roubiliac, and others of their School, had all the employment in Art. Their productions are well known, and a particular account of them

---

* The French (though a great improvement has taken place) were soon led away by a desire to display nice and curious execution; the Sculptors above named were their purest artists. For the *ne plus ultra* of bad taste we need only mention Pigal's extraordinary works, particularly the Tomb of Marshal Saxe, at Strasburg, executed in 1776. The Sculpture of other European Countries, Spain, Germany, &c., affords no information on the History of the Art, and we therefore omit them.

* *Vide* Flaxman's *Lectures on Sculpture.*

would be both unnecessary and out of place. This was the state of Art in England till the middle of the last century, when, under the protection and auspices of George III., Sculpture and the sister Arts rose into notice, and were practised by native artists with honour to themselves and to their Country.

The Count Cicognara, in his valuable Work on Sculpture, considers that the epoch of a revolution in taste in Italy was the reign of Charles III. of Naples; of Popes Clement XIII., Benedict XIV., and of Leopold, Grand Duke of Tuscany. Besides these Princes, Cardinal Albani, justly called the Hadrian of his Age, attached the literati and best artists of the day to him, and his Palace was the resort of genius, taste, and learning. He formed a collection of the finest remains of antiquity, well calculated to remodel the taste, and excite the emulation of the artists of the time. To this princely taste of the Cardinal the World is indebted also for the learned labours of a distinguished antiquary, for under the immediate protection of the Prelate, Winckelman wrote his *History of the Arts of Design.* The Clementine Museum at the Vatican received important additions under Pius VI., after whom it was called Pio-Clementino; and the greatest activity prevailed at his accession throughout the Roman States to secure whatever fine works in Sculpture were discovered, forming a remarkable contrast to the carelessness which existed on these subjects a few years before. Amongst the Sculptors of that period were Cavaceppi, Penna, and a few others; the influence of the Bernini School had ceased, and as the false principles of its practice were discovered, the want of a just style was felt, and, in point of fact, Sculpture in the hands of the above artists will be found to have made considerable approach to purity, and to have acquired much of its lost character.

The honour, however, of giving a new direction to Taste, and of establishing this Art on true principles, is certainly due to Flaxman and Canova; and the works of Banks may also be cited as valuable specimens of improvement. In the Theseus of Canova, one of his best and earliest works, we recognise the long lost purity of form, and a decided devotion to the simplicity of the antique; in the designs of Flaxman, in like manner, simplicity, grace, and expression resume their influence in the place of long-established affectation and distortion. The simple taste of which the earlier works of Canova gave promise, it must be allowed, is occasionally less conspicuous in some of the later productions of this master: exceptions will also be made to Flaxman, in whose works execution will be found a very secondary object compared with design; but the works of these distinguished artists are before the World, and their merits have been too often discussed to render it necessary here to enlarge upon them; besides, a critical examination of them would be quite out of place, our object, that of tracing the History of Sculpture down to our own times, being fulfilled. The influence of these second restorers of Sculpture, as they may justly be called, on the Art of their day is acknowledged, and though distinct Schools have arisen out of those which they formed, to them must be attributed the merit of having at least directed the attention of artists and the admirers of Art to that which is really excellent.

Mechanism of Sculpture

The mechanical process of Sculpture is now so generally known, that it seems hardly necessary to notice it here, but as it may be considered to form a part of our subject, we shall conclude by a short explanation of the manner of proceeding. The Sculptor having invented or conceived his subject, proceeds from a small sketch, drawn on paper or modelled in clay or wax, to build up his statue or group, for which purpose a general nucleus or skeleton is first formed of wood or iron; to this, small crosses are generally attached, in order to make the clay adhere to it; the figure is then built up in clay, of which different sorts are used, according to the fancy of artists; the figures, even if they are intended to be draped, should always be first carefully modelled naked, and the drapery should be added afterwards. In modelling *alto* or *basso rilievo*, a plane or ground (generally of clay) is prepared, upon which the Sculptor draws his proposed design; the clay is then placed upon this, the outline of the figures being carefully preserved by attending to the drawing already made upon the surface. The model being completed, and kept moist, a mould of plaster of Paris is made upon it, which when dry (or *set*) is removed, and the model is destroyed; the mould being oiled, is then filled up with fresh plaster, which is prevented from adhering too firmly by the oily substance with which it has been saturated; the mould is then broken off, and a cast of the model is produced entire. The next process is copying it in marble; for this purpose two stones of the same size, each having a scale in front, are prepared; the model is placed upon one of these, the block of marble on the other; a movable instrument or beam is applied to the scale of the model, and a needle branching from it, and capable of being extended and withdrawn at pleasure by means of screws and ball and socket joints, is made to touch the particular part of the model intended to be copied;* this is carefully removed to the corresponding number on the scale on which the rude block is fixed, and the marble is cut away till the needle reaches as far into the block as it had been fixed at upon the model; this process is repeated till the whole is copied, the joints on which the needle works being so constructed that it can be carried round to any part of the work. The statue being thus rudely blocked out, or pointed, as it is technically termed, is delivered over to a carver, who copies the minute parts of the work, and by degrees, with chisels and files, brings it to a surface, ready to receive the finishing strokes of the Sculptor.

---

* The construction of these instruments for pointing is not always the same, but the principle upon which they act is exactly similar.

PAINTING.

HISTORY OF THE ART.

HISTORY OF ANCIENT ART.

Origin of Painting.

To renew that inqufry of the over-curious, as to the country wherein the Art of Painting was first invented, is nearly as absurd as to raise a question with regard to the persons who may have originated the Art of dressing skins or cooking meat, or introduced any of the commonest occupations of life; so natural is imitative Art to man, and so common is it to find some efforts in this line even among the rudest people, and those who are the farthest removed from the chance of intercourse one with another. We shall only observe, then, generally, that the extreme antiquity of this Art is fully shown, when it is admitted as a fact, that the use of representation by outlines, imitating the external forms of things, preceded the use of arbitrary and conventional signs amongst Mankind. Hieroglyphics were used before Letters, and the Art of Drawing is therefore undoubtedly prior to that of Writing; and we might fairly substitute this simple statement for the more common and fabulous part of its History. Of the fact we have proof enough in the painted and engraven monuments of Egypt, Persia, and India, as well as in the stained leather of the savages of the Ohio and the Mississipi, who relate a battle by figures of men fallen and falling, just after the same fashion. Very forcibly indeed are these ancient and primitive, and necessary habits of the human race brought before our eyes, in the accounts we daily receive of those uncivilized nations, among whom we view Man as a social animal during the time that the state of society is in its infancy.

Raphael Mengs remarks with great truth, that it might have happened that the Art of design was invented at the same time in Greece, Egypt, and in Tuscany, or that some of these people, of whom Historians speak as inventors, did themselves receive the Art from others who practised it before their day; but, after what has been observed above, this is of little consequence. We must consider, therefore, the stories related by ancient authors, as to the invention of the Arts of Painting and Statuary, not as relating actually to the first discoverer, but to that person of whose successful efforts the earliest tradition has been preserved,—to the improver, rather than the originator. Such was Gyges, a native of Lydia, who, as Pliny informs us, was a teacher of the Art of Painting amongst his countrymen in Asia Minor; and by whom the practice was afterwards carried into Italy by a colony from those parts, known under the name of the *Hetrusci* or Tuscans. Of the degree of skill possessed by these Hetrurians, some writers have asserted, that specimens may yet be seen in the painted figures discovered in the tomb of an ancient monarch, on the site of *Clusium*, and in some similar relics at Arezzo and Viterbo.

School of the Ancients.

In a like view must we regard the stories of the love-sick girl tracing the shadow of her suitor's profile on the wall, by the light of a lamp, or of the shepherds marking with their crooks the outline of their shadows, projected by the sunshine upon the sand. Such, too, are the claims usually put forward on the part of the Egyptians to the invention of the Art of design; that people probably were inventors, as many other people were so; but only among themselves, and for themselves. And no doubt there were attempts made by other countries as well as these, and perhaps at as early a date: we certainly read of Pictures being in use amongst the inhabitants of the land of Canaan, at the time that the Israelites took possession of it; the words in our translation of the Bible, in which Moses addresses the Israelites, are these, "destroy all their Pictures, and destroy all their molten images.' *Exod.* xxxiii. 52. And whether borrowed from Egypt or otherwise, it is clear that the Art of design was not unknown amongst the Jews themselves, either as Statuaries or Painters: for we read of the image of a calf set up by them in Dan; and we read in the prophet Ezekiel, of the "form of creeping things," &c. "portrayed upon the wall." *Ezekiel*, viii. 10.

All that is here mentioned under the name of Picture or Painting was probably no more than a simple delineation of form, the interior of which was occasionally filled up with colour; such as the earliest specimens of Egyptian Art present to our view; the capacity of executing such matters in such sort, being, as we have said, natural to Man as an imitative animal.

Its prog

The further developement of the Art of Painting, of that, indeed, which alone gives it a title to the name of Art, has been to a certain extent detailed to us by the ancient writers of Natural or Civil History. And the successive degrees of improvement which were achieved in these early days, afford to our contemplation a curious analysis of the nature of those ideas relative to Painting, which in the present more advanced state of our knowledge appear so simple in themselves, and to need so little elucidation. In our HISTORICAL and BIOGRAPHICAL DIVISION, we have already stated a few particulars relative to some of the Early Painters of Greece, (vol. ix. p. 404.) Without repeating what has there been said, we shall here notice the several steps by which they appear to have advanced the Art of Painting. One of the first instances of the progress of this Art is shown in the attempt to give a greater durability to the colours than had hitherto been attained. *Polygnotus*, (the elder of that name,) an Athenian, is said to have been the first who subjected his works to the action of fire for this purpose: but it is uncertain whether it was the encaustic method, the mode of Painting in enamel, which he invented; or, whether it was simply that he first adopted the use of wax with his colours, which of course could not be applied without some degree of heat; or it may be, that he merely invented the style of delineating by means of burning the surface

Use o by Po gnotu

of wood with hot irons, producing something similar to that which we now know under the name of *poker drawings*. Polygnotus lived about the XIVth century before our Saviour.

ochro- ic style, Chiaro- uro.

The next step in Art was made, as we are told, by the Greeks, who invented what is called the Monochromatic style or the use of a single colour, or that which we now describe under the title of Painting in *chiaro-oscuro*. It might be black and white that was made use of for this purpose, or a brown or a gray colour, or indeed any other, so long as the difference of the parts was marked only by the intensity or strength of the respective shades of colour, not by a variety of colours. It may seem singular at first sight, that the use of many colours should have preceded the simple use of one colour only: but when we regard the nature of the means by which an effect is to be produced, we must instantly recognise the proof of a greater progress in Art having been made in this case than the former; for to paint trees as green, or sky as blue, is one of the easiest and most obvious of the efforts of imitation, but to distinguish them by degree of shade alone, or, which is the same thing, by the intensity of the colour, when one only is employed, requires no small degree of knowledge and skill: it is, in fact, the power of giving relief to one body beyond another, and representing on one even plane surface the appearance of a variety of objects or parts which stand out or recede one from the other.

son why was not first e of the

We have an account given us by Cheselden, of a young man originally born blind, and afterwards receiving his sight from the operation of couching, at a time when his judgment was sufficiently advanced to give an account of his observations; namely, at the age of thirteen years. He says, "we thought he soon knew what Pictures represented, which were shown to him, but we found afterwards we were mistaken; for about *two months after* he was couched, he *discovered* at once they represented *solid bodies*, when to that time he considered them only as *parti-coloured* planes, or *surfaces diversified* with *variety of paint;* but even then he was no less surprised, expecting the Pictures would feel like the things they represented, and was amazed when he found those parts, which by their light and shadow appeared now round and uneven, felt only flat like the rest; and asked which was the lying sense, feeling or seeing?" (Smith's *Optics*, 1, 5, p. 43.) This story makes us acquainted with the progress of the human mind in these particulars. The distinctions of colour were natural, they seemed, from the first, familiar to the patient's comprehension, or at least were acknowledged as soon as perceived: but that an apparent variety of prominence and recess should result from adopting a variety of shade, was by no means an idea so soon to be acquired. His mind had not made the necessary observations on the appearance of objects in Nature to enable him to comprehend this fact; and hence it seemed to him quite easy to distinguish the object by different colours, but he required an explanation with respect to their distinction by means of light and shade. It is difficult for us in these days to recur even in imagination to the thoughts and ideas of an unenlightened mind; but we may learn much from this story. Thus, it is clear that the Painters in *chiaro-oscuro* showed greater skill than the Painters in various simple colours: it was indeed, perhaps, the most important discovery yet made by the artist; and we may add, that it was only the application of this same principle of the monochromatic style to a number of colours so combined together, that afterwards introduced the most perfect and beautiful of all the artificial processes with which the Art of design is acquainted. All the exquisite delight that is to be derived from variety of light, shade, and tint, flowed from the developement of this single principle of the monochromatic style.

School of the Ancients.

The next invention of which we find notice, regarded skill in Drawing, with respect to the attitude and posture of animate figures; and as former Painters had made all their figures stiff, alike, and upright in their lines, he was a great improver who first ventured to represent them with their heads looking upwards or downwards, or sideways, (the *catagrapha* of the ancient writers;) in short, who represented them in any way except that which was the most inefficient representation of the original, and yet the easiest to accomplish. The honour of this improvement is attributed to *Cimon of Cleone;* who also, with similar boldness of mind, ventured to make a fresh innovation in established practices, by marking out the muscles and veins of the human body, and the folds of garments.

Cimon of Cleone diversifies attitudes.

Phidias.

We next hear of *Phidias*, a person most celebrated indeed as a Sculptor, but who also exercised the sister Art of Painting: he flourished about the IVth century before the era of Christ. He is stated by Pliny to have painted a *Medusa's head* at Athens with wonderful skill. Of other artists of this date we may mention the name of *Mycon*, also an Athenian born, and, like Phidias, a Sculptor as well as Painter. He is celebrated for his preparation of a famous black pigment out of some part of the vine, (*trigynon*,) and seems to have turned much of his attention to the *matériel* of the Art; he is said also to have been the first person that made use of Attic ochre as a colouring substance in his Pictures.

Mycon.

Apollodorus

Apollodorus of Athens also possessed skill in both these lines of Art. It is recorded of him, that he was so fastidious as to destroy his finished works, and was in the practice of breaking them up, (whatsoever might have been the pains and cost expended,) if they did not correspond in the end to the conception which he had formed in his mind. The expression of Pliny with regard to him, that he was the first whose Painting fixed and absorbed the attention of the spectator, leads us to form a high idea of the improvements which he effected in this Art; and this idea is strengthened by the fact of his being noted as first showing the method of discriminating with delicacy the various gradation of shades in Painting. He seems also to have noticed that the colours of objects were to be preserved even in those parts which were darkened in shade, and hence he obtained among his countrymen the name of the Shade-Painter. It must be added, that this merit, asserted of Apollodorus by Plutarch, is attributed by Quinctilian to Parrhasius.

Parrhasius.

Parrhasius was a native of Ephesus who flourished about the same time, and a person who certainly greatly added to the advancement of the Art. He is universally praised for the attention which he paid to the symmetry of the human figure in Drawing, for his attempts to give an improved expression to the countenance, to form the curls of hair with grace, and carefully to finish the extremities of the hands and feet. But of all the great names among the Painters of antiquity, none, perhaps, are more celebrated than that of *Zeuxis*,

Zeuxis.

a native of Heraclea, one of those artists who came to Athens at the call of Pericles, and subsequently acquired great wealth by the practice of his profession. He it was that painted *The Venus* at Crotona, from a selection of the several beauties of all the fairest virgins of that city; and he it was that maintained the noted contest with Parrhasius, to which we have adverted elsewhere. Some of his designs, such as figures on vases and vessels of pottery, seem to have been collected and preserved with great care by the connoisseurs of ancient Rome.

Aristides. *Aristides of Thebes* is reported by Pliny to have been the first Painter who represented the various emotions of the mind, in the delineation of the human countenance. He depicted passion and sentiment with great success; but his works are said to have been harsh and unpleasant in their tone of colouring. We presume that he limited himself to the province of History; for the subjects ascribed to him are chiefly such as the following, *Bacchus and Ariadne, The Sacking of a Town*, and *A Battle between the Greeks and Persians.* We are furnished too, by the same author, with some clue to the pecuniary value at which the labours of an artist were commonly estimated; since in the last-named Picture, which contained one hundred figures, Aristides received ten minæ for each; the purchaser being Mnason the Tyrant of Elis. Attalus of Phrygia also purchased one of the Pictures of this artist at the price of one hundred talents; and when Greece fell under the arms of Rome, such was the rage of amateurship, that the price of six thousand sesterces at a public sale for a Picture was offered by the same King Attalus, and refused. Attalus, too, who seems to have been a great collector, went so far as to offer sixty talents for a Picture by Nicias of Athens; but here also unsuccessfully, for the Painter gave it to his Country.

Pamphilus. We may mention here, as relative to this part of our subject, the name of *Pamphilus of Macedon*, the master of Apelles, whose terms for instruction were so high, that those who complied with them must have entertained a vast reverence for Art. He received no less than a talent for ten years of tutorage, or, as the passage has sometimes been explained, a talent for each year as far as ten. It was by the influence of this same Pamphilus, that the law was first passed at Sicyon (where his School was held) which afterwards was adopted throughout Greece, That all boys born of free parents should be taught the Art of design; and to prove their admiration for it, the study was interdicted to slaves.

Apelles The story of *Apelles*, the Painter of Alexander the Great, is well known. He fell in love with Campaspe while painting her Portrait, and received her as a gift at the hand of that truly munificent monarch. It was Apelles too who once making a visit to a brother artist, to whom he was personally unknown, and finding that he was absent from home, left a sketch of a head in the hands of the domestic. Upon the return of Protogenes the sketch was shown to him, and he cried out, as it were intuitively, it must be Apelles himself, for no other mortal could have made this design. The most noted works of Apelles were an allegorical Picture of *Calumny, Alexander bearing a Thunderbolt, Venus rising out of the Sea, The Procession of Megabyzus, The Priest of Diana at Ephesus, Clytus arming for Battle, Menander King of Caria, Ancæus the Argonaut*, &c., besides which, during his visit to Rome, he painted a *Castor and Pollux*, a figure of *War* with her hands bound behind her, *Alexander the Great* in a triumphal chariot, a figure of *Victory*, &c. Sandrart makes mention of a specimen of ancient Painting, preserved in the Academy of St. Luke at Rome, which was certainly of Grecian origin, and generally considered as the work of Apelles. He has given an engraving of it in the *Academia Artis Pictoriæ*, lib. i. c. iv. p. 75. The improvement in the Art, for which Apelles is most celebrated, is the varnish with which he used to cover his Pictures, on which we shall presently have occasion to insert a remark by Sir J. Reynolds.

Protogenes of Rhodes will be readily recognised by the reader of History, as the Painter who succeeded in making the representation of foam at the mouth of a horse, by dashing his sponge in a lucky fit of passion upon his Painting. It was his Picture of *Temperance* which forced from the mouth of his rival Apelles that extravagant compliment, that it was a work worthy of being carried to Heaven by the Graces. Protogenes also painted the beautiful *Cydippe, A Satyr named Jalysus, Tlepolemus son of Hercules and Antiocke, Philiscus (the Tragedian) in meditation, King Antigonus, Athleta the mother of Aristotle the Philosopher*, and *A Sea-piece.* With his name we may close our account of Grecian Painters, as the Art seems to have declined greatly after his time, which, though he long survived that conqueror, we may call the Age of Alexander the Great.

As to the Romans, and the skill which they acquired in the Art of design, we know that no great taste for the Arts, either of Painting or Sculpture, was visible amongst them before the time of the capture of Corinth; and that almost every specimen which they possessed, even as late as the time of the Empire, was either imported from Greece, or the work of Greek artists settled at Rome. There was, indeed, one *Pacuvius of Brundusium*, a nephew of Ennius the Poet, who practised Painting; and we learn that one of the *Fabii*, who was living in the IIId century before our Christian era, made great proficiency in the Art, and painted with his own hand the walls of the Temple of the Goddess of Health and this work was preserved even in the days of Pliny. We gather, indeed, amidst the profusion of praise lavished on him by Cicero, that he was remarkable for the variety of his attainments, and in point of taste ranked far higher than most of his countrymen. An account is given us of a Picture, representing the battle in which he overcame the Carthaginians and Hiero King of Sicily, having been placed in the *Curia Hostilia*, by Marcus Valerius Messala, in U. C. 409. Lucius Hostilius Mancinus also, who first made an inroad into Carthage, exposed a Picture of that assault in the *Forum*, and used to seat himself there to explain it to the People. L. Scipio moreover put up in the Capitol a tablet to commemorate his conquest in Asia: we have no reason however to imagine that these monuments possessed any great merit as works of Art. We have the testimony of Virgil to show, that, even in his more civilized Age, these peaceful Arts were not held in much honour by the Roman People. Nevertheless, in a later day, the Art of drawing seems to have been taught to the youth of both sexes, and we find upon record the names of many females who attained a considerable degree of skill; Martia, the daughter of Varro, is mentioned in particular for her excellence in this line.

Protogenes. Roman School. Pacuvius. Fabius.

inters of
e Au-
stan Age.
dius.

Several Painters were resident at Rome during the reigns of Augustus and Tiberius. Of these, *Ludius* is celebrated for the taste and skill with which he decorated, with Painting in stucco, several apartments in the houses of wealthy individuals; and, as far as we can collect from Pliny, to him the Romans were chiefly indebted for the fanciful and grotesque taste with which these ornamental works were conceived. Many specimens of this description are to be seen at Pompeii, as also in the public Baths at Rome; and we know that from these Raffael, in after days, drew the ideas upon which his *arabesque* or *cinquicento* style was founded. Augustus seems to have been a considerable amateur; it was at his command that Apelles was employed in Painting at Rome. Some Pictures by Nicias also were placed in the Temples, and in the more conspicuous parts of the *Forum*, both by Augustus and Tiberius. Of the former we must presume, that he entered into the pursuit of the Art with all the enthusiasm of a private collector and *virtuoso;* for we are informed, that the curious sketch which Apelles left as a memento at the house of Protogenes, (as above related,) was purchased for the Imperial Palace. The Emperors Nero and Hadrian were not merely amateurs, but possessed considerable practical skill in Painting, and the latter in Sculpture also:

lern
iting
pared.

Thus we have briefly noticed the gradual developement of the Art of Painting, from the days of its earliest invention to the period of the decline of that, as well as of every other Art, under the Roman Emperors. We have yet, however, to speak of the degree of excellence that it had at one time attained. With regard to the testimonies given by authors who were the contemporaries of some of the above-named artists, they can be considered only as speaking of their relative merit, that is, of each individual as compared with others of his day, or, at the most, with those who had preceded him; and of course their expressions furnish no criterion by which we can ascertain the degree of merit they might claim, when put in competition with the works of the modern School. But we have some specimens of ancient Art open to our inspection, it will be said, and we may form our judgment upon them; still, however, there is this difficulty, that we do not know the repute in which the artists who executed them were held in their day. If, for example, the Pictures in the Museum at Portici, taken from the excavations at Pompeii and Herculaneum, are to be regarded as specimens of the best powers of the ancient artists, (though it seems hardly fair to expect so much in the embellishments of a remote country town,) we can at once pronounce a decisive opinion on the subject. They are certainly very inferior to the productions of modern skill, with regard both to colour and general effect; but it must be admitted that they have, at least some of the best of them, a purity and elegance of design such as none but the most eminent and most illustrious of the modern School have ever attained. The very elegant figure commonly known under the name of *The Dancing Girl of Herculaneum*, is an example of the best taste. *The Nereid riding on a Sea Monster*, (*Antich. di Ercolano*, ii. 46,) the two sitting female figures in the Picture representing the *Sale of Cupids*, (ibid. 38,) *The visit of Juno and Minerva to Venus*, (ibid. 11,) *Ascanius and the Nine Nymphs*, (ibid. 3, tav. 13,) *The Europa* wrought in Mosaic, in the Barberini Palace, and the *Apollo giving a chaplet to a Poet*, taken from the Baths of Titus, are specimens which may be said to be of the very first merit in point of design; certainly nothing better than the three first-named has been produced in after times, unless by Raffael or Corregio. It is well known, that, at the time of their discovery, certain ancient frescoes were actually attributed by some virtuosi at Rome (strangers to their history) to those very masters. (See quotation in Turnbull, *On Ancient Painting*, p. 4.) Raphael Mengs, too, expressly says, that he thinks the design of the Ancients was much superior to that of the Moderns; "because among the ancient Paintings that I have seen, many are as well designed as the best of Raphael, notwithstanding they were done at Rome when the Grecian taste was a little vanished." R. Mengs, p. v. ch. iii. As another instance of beauty of design, we may mention the figure of the Girl playing on the harp in the *Nozze Aldobrandini*, as they are called, the most valuable of all the specimens of ancient Painting that have been yet discovered; it has been frequently made use of by N. Poussin in his compositions, as those who are acquainted with his works will allow. Not only the figure of the Harp-player, but many others in that piece, possess inimitable ease and grace of attitude. In short, we may declare that in these figures we recognise all that charm and power of the Art of design, which the excellence displayed by the Ancients in the sister Art of Sculpture might have led us to expect in their Paintings. To this, however, we must limit our encomiums upon the Ancient School.

Defect of colouring

It is evident from the still remaining bright colours, scarlet, yellow, &c., which are seen on the walls of the apartments at Pompeii, that the colouring matter in general, as used by the Ancients, has lost little or nothing of its original freshness and vigour. Yet there is no science discoverable in their principles of colouring, as applied to their better Pictures; no richness of tint, no fulness of colour is attempted to be displayed; they have the harmony arising from universal meagreness and lowness of tone, but that is all. It is fair to add, perhaps, that real excellence in that line was scarcely attainable, until the invention of Oil Painting furnished newer and more promising methods of producing picturesque effect.

Oils unknown.

As to the secret of Oil Painting, we are sure they were not in possession of it, from the story related on the subject of the Picture of *Bacchus and Ariadne* by Aristides the Theban; for this Picture was carried to Rome and placed in the Temple of Ceres, and M. Junius the Prætor having ordered it to be cleaned, previous to the commencement of the *Ludi Apollinares*, all its beauty was destroyed by the application of water.

Opinion of Sir Joshua Reynolds on ancient colouring.

Sir Joshua Reynolds, in his comment on Dufresnoy's *Art of Painting*, makes the following remarks on the state of ancient Art, which are worthy of notice as coming from so great a master. "What disposes me to think higher of this colouring than any remains of ancient Painting will warrant, is the account which Pliny gives of the mode of operation used by Apelles; that over his finished Pictures he spread a transparent, liquid-like ink, of which the effect was to give brilliancy, and at the same time to lower the too great glare of the colour. '*Quod absolutâ operâ atramento illinebat ita tenui, ut id ipsum repercussu claritates colorum excitaret; et cum ratione magnâ, ne colorum claritas oculorum aciem offenderet.*' This passage, though it may possibly perplex the Critics, is a true and an artist-like description of the effect of glazing or scumbling; such as was practised by Titian and the rest of the Venetian Painters. This custom, or mode of operation, implies at least a true taste of that in which the excellence of colouring consists; which does not proceed from *fine* colours, but *true* colours; from breaking down to a deep-toned brightness those fine colours which would otherwise appear too raw. Perhaps the manner in which Corregio practised the art of glazing was still more like that of Apelles, which was only perceptible to those who looked close to the Picture, *ad manum intuenti demum appareret;* whereas in Titian, and still more in Bassano, and others his imitators, it was apparent on the slightest inspection. Artists who may not approve of glazing, must still acknowledge that this practice is not that of ignorance."

Examined.

Perhaps it is hardly fair to argue in favour of the general state of the Art, as Sir Joshua has done here, from a practice which Pliny states to have been a secret of Apelles alone, and known to no other artist; and there may, after all, be nothing more meant by the passage, than that he used a thin, transparent liquor, which he spread over the surface of his Paintings, in order to give them that depth of colour and general appearance of harmony, which such a process would naturally impart to a piece of dry colouring. Carlo Dati, indeed, in his Treatise *Della Pittura Antica*, translates the word *atramentum*, with a reference to this very passage of Pliny, simply as varnish; and it is obvious, that the use of a simple varnish would produce all that effect which Pliny describes; it would unite the clearness of the colours, as well as destroy their hardness. A varnish, indeed, which gave greater transparency than had ever been produced by the *encaustic* style of working.

Judgment of ancient Painters founded upon ancient criticism.

But we may assume, fairly, from the state of criticism exhibited in the writings of Philostratus, Pliny, or Quinctilian, or indeed any of the best informed ancient writers, that no great power was possessed by any of their Painters in the more artificial parts of the study. Unless we consider this passage of Pliny in the way in which Reynolds does, (which seems rather an overstrained interpretation,) there is nothing in any of their remarks which would lead us to suppose, that the delicacies and higher refinements of the Art were at that time known. Nothing can be more unartist-like than the general ideas expressed by these writers, and nothing less profound than their observations. They labour, like modern Commentators on the Classics, to display their own ideas rather than to illustrate the ideas of the author on whom they are employed, and present us with conceptions which could have originated only with themselves. The very course and line of their critical remarks is faulty; and as they were, no doubt, persons the best informed of their day, we must presume their ignorance was the natural result of the real imperfection of the state of the Art.

The works of Winkelmann, *On Ancient Painting*, and Junius, *De Picturâ Veterum*, are too well known to need mention here. In Turnbull, *On Ancient Painting*, much matter and several plates are given, illustrative of the imperfection of the Ancients in this department.

HISTORY OF MODERN ART.

Derived from Greece.

As in ancient times the Italians drew all their stores of Art from Greece, so we find even as late as the XIth and XIIth centuries, which are times comparatively modern, that all the best Painters came from that country. There are, indeed, some specimens of the works of native artists of that period still in existence, such as the Paintings in the Crypt of the Cathedral at Aquileia, at St. Primerano, at Fiesole, and in St. Brigio at Orvieto; but, still, the chief artists of any *repute* (for we cannot say *skill*) were natives of Greece, who were almost invariably employed not only in Painting, but in Sculpture and Architecture,—in short, in all that passes under the name of the *Arts of design*. Whether in these times there were not some examples of native talent in Italy, has been made a matter indeed of question; some perhaps there were; but the point in debate is of very little moment: greater admiration is due to the production of excellent works, than of those the merit of which lies only in their antiquity; and here the case is clear, the modern Italians owe none of that skill and power which distinguished the Age of the revival of the Art to any foreign quarter, but they drew it wholly from the resources of native genius, and from exertions both excited and rewarded by themselves. The Greek artists, it is true, were driven in abundance to Italy, as the Mahometan power began to encroach upon the countries wherein they had lived, and they brought with them the mechanism of their Art: but this is all that can be said; the first Painters whose names deserve a place in History were Italians born.

Cimabue and Giot

First we must mention the names of *Cimabue* and *Giotto*, both Tuscans, who probably studied under the Greek artists, but enlarged the principles of Art, and carried on their labours with a new and bolder aim than their masters; and having succeeded in forming a new style, travelled throughout many parts of Italy, and disseminated their knowledge in every direction, laying the foundation of that fame which the several Italian Schools in time acquired. Cimabue died in 1300, Giotto in 1336.

Cemete Pisa.

Towards the close of the XIIIth century the then powerful Republic of Pisa designed a splendid cemetery, in which were to be entombed the most illustrious of her citizens. It was named the *Campo Santo*. The superstitions of the day led them to import earth from the Holy Land for the reception of the dead, and a spacious cloister was raised around this sacred ground, in decorating the walls of which the most distinguished artists of Italy were employed. First *Giotto* and *Buffalmacco* commenced this work, then the two *Orgagni*, *Laurati*, *Simon Memmi*, *Antonio Veneziano*, and *Spinello;* and in the following century we find the works of *Bennozzo Gozzoli* added to the number. This last displayed great originality of mind; and the grace and expression of his figures, which were designed after a manner hitherto unknown, show him to have been the greatest regenerator of the modern Art of design. These Paintings, which were all executed in stucco, are yet remaining in the *Campo Santo*, though they may be better known to the world by the engravings of Lasinio, an artist of Pisa, which possess considerable interest, from the proof they give of the comparatively advanced state of Art in Italy, at a time when its inhabitants were

Chapel, as works of the pencil; and the *Pietà* in St. Peter's, and the Monument of Pope Julius in St. Pietro in Vincoli, in sculpture, sufficiently attest the powers of this wonderful man.

"The figures of M. Angelo are less Classical and studied in their form than those of Raffael, and though filled with equal, or perhaps sometimes superior force of expression, are yet more natural. Nevertheless, to call them purely natural, would be to give a poor idea of his excellence; it is seldom in Nature that we see personages who move as his figures seem to do: there is a species of internal intelligence exhibited by their external attitude, that few persons in common life appear to possess, and there is a degree of impressiveness in their air, that arrests and fearfully rivets the attention." (James's *Italian Schools*, p. 111.)

His pupils.

As to specimens of his style in Painting, there are few works in existence beyond those above mentioned which can be authenticated as genuine; but in the works of his best pupils and imitators, such as *Pellegrino Tibaldi*, *Sebastian del Piombo*, and *Daniel di Volterra*, we may trace the elements of what the Italians justly name *il grande gusto*. Michael Angelo is said to have furnished the design of the *Taking down the Body of our Saviour from the Cross*, which was painted by Daniel di Volterra for the Church of the Trinità di Monte at Rome; the engraving of which by Dorigny may be quoted as a specimen with which the Tramontanes are generally familiar; while we have, in the invaluable Picture by Sebastian del Piombo, in our National Gallery, a still more tangible illustration of the force of conception, and dignity of manner, inherited by the pupils of this great master.

Bartolomeo di S. Marco. Andrea del Sarto.

We are not, however, to suppose that he was the only Painter of eminence at that day at Florence; we have mentioned the name of Da Vinci, and we may also add those of two other Painters, scarcely inferior to him, *Fra. Bartolomeo di S. Marco*, and *Andrea Vannuchi*, called, from his father's profession of tailor, *Andrea del Sarto:* both of whom had Schools of Painting, and numerous followers, at Florence. Of the former, there are but few specimens in England which can give a fair idea of the noble simplicity of his composition. They are formed of few figures, seldom more than three, and mostly of a size larger than Nature.

Andrea del Sarto added another grace to the Florentine manner; his works partake, indeed, in every way, of what is called greatness in point of style, but it is combined with a certain suavity and gracefulness, which infinitely heightens the pleasure we receive in their contemplation. As far as he was an imitator of the manner of M. Angelo, he will be observed to have caught the feeling which that master showed in some of his earlier works in marble; that of the *Pietà*, for instance, in St. Peter's at Rome, or that more subdued conception of the beauty of form, which may be discovered in the Picture of the *Creation of Eve*, in the ceiling of the Sistine Chapel, and in some other of the compartments. His mind was naturally averse to that terrible sublimity of ideal Nature, with which, in later years, the mind of Michael Angelo seems to have been absorbed. The finest Painting of Andrea del Sarto is the *Madonna del Sacco*, as it is called, in the cloister of the Annunziato at Florence, an engraving of which is published by Volpato. We have a few Paintings of this master in England; but those who have seen only his early Pictures can form no conception of the greater talents which were developed by him in his works in fresco.

Florentine School.

XVIth century.

Towards the middle of the XVIth century there arose among the Florentine artists a style which was rather imitative of the more unessential peculiarities of Michael Angelo, than of his dignity and force; there is a certain heaviness, and empty ambitiousness of design, in the works of his scholars and imitators in general, but still we trace the remains of that noble spirit with which this great man inspired the Florentine artists. Of these we may make mention of *Giorgio Vasari*, the Historian of the Florentine School, who was much employed by the Pope at Rome, as well as by the House of Medici at Florence; *Lazzaro Vasari*, his brother; *Marcello Venusti*, who also settled at Rome; *Rossi*, or (as he was called from the name of his patron) *Rossi dei Salviati; Marco da Pino*, who lived chiefly at Sienna; *Jacopo Carucci*, (*alias Pontormo*,) of whom Michael Angelo is said to have prognosticated greater talents than he ever lived to display; *Rhidolfo Ghirlandaio*, descendant of the master of Michael Angelo; and *Pierino del Vaga*, a native Tuscan, who became the pupil of Raffael. We see the remains of Michael Angelo's style kept up, though in a still lower state of degradation, in the works of the pupils of these men, such as were *Angiolo Bronzino*, *Jacopo del Conte*, *Alessandro Allori*, *Zuccaro*, &c.

With regard to colouring, we cannot trace many symptoms of improvement until the days of *Cigoli* and *Pagani*, about the end of the XVIth century. Cigoli was a Poet as well as a Painter and Musician, and certainly succeeded in introducing a greater softness of manner, and higher brilliancy of colouring, than the Florentines had hitherto been accustomed to see. We may say, indeed, that this taste accorded better with the feelings of the Age in regard to these matters, at a time when the *bouquet*-like Paintings of Baroccio were generally rising into fashion throughout Italy. It was then that colouring, not expression, became the chief object of the Artist.

Carlo Dolce

Great skill with regard to the management of colour appears in the works of another master of that day, namely, *Carlo Dolce*, who attained high reputation, and had, like other great artists, his scholars and imitators. There was now no longer a demand for large Paintings as formerly in fresco, by means of which the Heroic style of Painting, if it may be so called, had been created and fostered from its birth; they were easel Pictures that were chiefly sought after by the wealthy. Yet *Franciscbini*, *Jacopo Empoli*, *Giovanni di S. Giovanni*, who belong to this period, are respectable names even among the Painters of large works, or *opere di machina*, as they are called.

XVIIth century.

Pietro d Cortona

Cipri

Acad Flore

After the middle of the XVIIth century a rich and harmonious style of colouring, and the more pleasing graces of Art, were brought more and more into fashion. *Pietro da Cortona*, who came to Florence from that city, which gives him his name, was engaged in the decoration of the Pitti Palace; and this public employment alone was enough to give currency to the style which he introduced at Florence. Of succeeding Florentines, none attained more celebrity than *Gio. Bat. Cipriani*, a name well known in England, both by his Pictures and the engravings made after them; elegance and beauty are their chief characteristics, and we see nothing of the original greatness of manner that once so proudly distinguished this School. The present Academy of Florence offers no remarkable distinctions of style and manner; but its professors are fully equal to those of Rome or Bologna, or Venice, and conceive their designs in that dramatic fashion which may be said now to be common in all parts of Europe. A very interesting Historical collection of Pictures, illustrating the different masters of Florence, and all the glories of their line, is preserved in their establishment in that city.

Roman School.

Raffael.
