METEOROLOGY.

INTRODUCTORY OBSERVATIONS.

Introductory observations.

(1.) The condition of Man is so intimately connected with the various phenomena of the atmosphere, that he may, without impropriety, be regarded as a Meteorologist by nature. In all the varied circumstances of his state, whether as a wild and uncultivated savage, exposed to the fury and inclemency of the weather, or in the first stages of his civilization, when he has discovered some feeble means by which he can shelter himself from the descending torrent and the scorching energy of the sun; or when, as a shepherd and agriculturist, his interest leads him to watch with more anxiety the varying aspect of the sky, or as a mariner to connect the agitations of the ocean with the terrible force of the sweeping wind, he finds much of his happiness, and, at times, even his safety and existence, identified with the mighty and changeful character of the great fluid ocean, in which it has pleased the Almighty to place him.

Intimate connection of Meteorology with the condition of Man.

Difficult to trace the steps of its early History.

(2.) It would be difficult to trace the probable steps by which Man, during a long succession of Ages, has arrived at his present limited knowledge of atmospherical phenomena. The great causes which impeded the general march of Physical Science, necessarily exercised their influence on this branch as on others; and when we consider the peculiarly intricate conditions connected with every atmospherical problem; the large advances that must be made in many capital portions of knowledge, before one successful step can be made in this; the subtile nature of the medium which is the subject of investigation; its singular relations to moisture; the changes it undergoes with every alteration of temperature; in one region influenced by the full power of a vertical sun, and in another chilled by the frozen masses of the Polar zones; altering its circumstances on lofty hills, and again assuming new conditions in valleys; the islands of the West receiving the air that a few hours before lingered over the countries of the East; the warm breath of the South softening the rigours of the colder regions of the North; the vapour rising from the bosom of the Atlantic, dropping richness and fertility on the verdant shores of Britain; all these, and a thousand more complicated inquiries, beset the investigator at the very threshold of Meteorology, stimulating him to ardent investigation, and inspiring him with wholesome caution.

Causes which have retarded its advancement.

Connected with many of the most interesting branches of knowledge.

(3.) Meteorology, therefore, is not an insulated department of knowledge, detached from every other, but is intimately related to many of its most important branches. With Chemistry, for example, it stands connected in a highly interesting manner, and is blended with almost every page of its splendid History. The Chemical constitution of the atmosphere, must at all times have been an interesting object of research; and in later days, when this beautiful branch of inquiry has assumed so perfect a form, and unravelled so many of the hidden mysteries of Nature, its relations to Meteorology have been contemplated with redoubled interest. With the properties of Heat, and with the distribution of temperature over the varied and unequal surface of the globe, Meteorology necessarily holds an intimate connection. The principles are singularly curious which mark the gradations of climate, and disclose the interesting system of changes by which the atmospheric currents are produced; and a fertile and instructive branch of inquiry is opened by tracing, amidst the apparent uncertainty which characterises these diversified operations, something like the existence of laws; and by endeavouring to embody, in general analytical forms, representative values for them. It is thus that the Meteorologist has been enabled to obtain at the level of the sea, an approximative value of the temperature of his place of observation; and it is some evidence that a few successful steps, at least, have been made in the inquiry, when the mean temperature of a place can thus be obtained, sometimes within the fraction of a degree. Connected also with the same inquiry, is the consideration of the laws which mark the gradations of temperature, as we ascend above the Earth. There are approximative laws which the ingenuity of the

Gradations of temperature as we ascend above the Earth.

Plane of perpetual frost.

Vicissitudes of this great plane.

Scientific Meteorologist has reached, which connect the temperature of the loftier regions of the air with that of strata more accessible to Man; and in following up the gradual system of changes which mark the decrements of Heat, to the point at which water congeals, he has been enabled to fix in every latitude the limits of perpetual frost in the air; tracing it to its greatest point of elevation between the tropics, following it as it descends in the temperate regions, until it sinks to its lowest possible level in the frigid zones. In tracing also the varying altitudes of this magnificent plane during the uncertain vicissitudes of the seasons; marking its ascent during the tide of summer, and its descent when chilled by the blasts of winter; its Northern portion rising, when by the increments of the solar declination the temperature of Europe and Asia are augmented; or its Southern portion falling, as corresponding regions of the globe lose a part of the sun's vivifying power,—the subject has become connected with many other departments of the Natural Sciences, with the Geographical distribution of plants, for example, and has given to Meteorology another claim to high and attentive consideration.

Radiant Heat.

Solar radiation.

Terrestrial radiation.

(4.) With all the inquiries connected with radiant Heat, the subject of Meteorology is also most intimately connected. The atmosphere is influenced in different forms by the innumerable objects of the material world, each having a radiating power of its own, and all exercising an influence on the air. To trace in their fullest extent all the conditions connected with solar radiation, it became necessary for the Meteorologist to measure its effects in different latitudes; to follow its changing influence through the different months of the year; to estimate its progress during the several hours of the day; to trace its power on the varied tribes of vegetation; and to discover, under all its diversified circumstances, its maximum force. In like manner, in order to trace the laws which regulate terrestrial radiation, the Meteorologist has found the extent of its power in different latitudes; compared its influence upon plains and mountains, and measured its effects in the several months. All these inquiries have much extended the labours of the Meteorologist, and opened to him most fertile and instructive fields.

Density of the air.

Incessant fluctuations.

Applications of the Barometer to Physical Geography.

Refinements which have been introduced into Barometrical measurements.

Atmospheric tides.

Their remarkable uniformity in the torrid zone.

Discoverable also in the temperate zone.

(5.) While, by the agency of the Thermometer, these interesting phenomena have been disclosed, the Barometer has unfolded the most singular relations respecting the density of the air. The early cultivators of Meteorology must have almost despaired of being able to trace any thing like uniformity, amidst the incessant fluctuations which the Barometer displayed. Influenced, apparently, by a multitude of capricious causes, it must have seemed as if no clue existed by which any resemblance to a law could be detected; yet later observers, employing instruments of a more perfect construction, and extending their observations over a longer period of time, have arrived at many important conclusions of the greatest interest to Meteorology, and to the Physical Sciences in general. One of the most useful of these, is that equality of pressure which the mean altitude of the Barometer, at the level of the sea, has in every latitude disclosed, and which, as a standard in so many interesting Physical investigations, is of very great importance. In the applications of this instrument, also, to many important objects connected with Physical Geography; in making us better acquainted, for example, with the varied irregularities existing on the surface of the globe; determining the altitudes of the loftiest mountains, fixing the elevations of the sources of rivers, and of the positions of cities which the enterprise of Man has reared, in many situations far above the level of the sea; and making known, in all its minutest forms, the exact conditions of the terrestrial surface, an interest of the most important kind is given to this application of the resources of Meteorology. The refinements, also, which have been introduced into Barometrical measurements, by the employment of corrections; for the influence of capillary attraction, and the accession of the minutest atoms of moisture; the varied shapes which the ingenuity of the analyst has given to the formulæ of computation, all impart deep interest to this important branch of Meteorology. But it is from the delicate and uniform changes which the atmospheric tides display, that the Barometer becomes most important. In the torrid zone, these remarkable oscillations are disclosed with such admirable uniformity, that the Meteorologist contemplates the horary changes of the mercurial column, with a part of the certainty which marks the anticipations of the Astronomer. And even in the more varying regions of the temperate zone, where the changes from heat to cold are most capricious, and where the winds, ever changing, seem to impress the character of perpetual uncertainty on every thing connected with the Barometer, the Meteorologist has been enabled to detect an analogous system of changes.

Various relations of aqueous vapour to Meteorology

(6.) The state in which aqueous vapour exists in the atmosphere is also another important branch of Meteorology, and has been the object of much anxious inquiry. It is connected with all the interesting relations of the Hygrometer; with the series of laws regulating the force, the weight, and the expansion of vapour; the discovery of the term at which precipitation takes place from an alteration of temperature; the rate of evaporation under different temperatures and with different velocities of the wind; the consideration of the alteration of volume which air undergoes from Heat, and from the accession of vapour; its alterations of density, and the changes of its Specific Gravity in different states of saturation.

Dew.

(7.) The subject of dew likewise unfolds to the inquiring Meteorologist very interesting properties. No other investigation developes in a more perfect manner the singular relations of radiant Heat, and the laws by which caloric is communicated from one body to another. The vegetable world in particular opens a fertile and most interesting train of observation. Of the different grasses, each draws from the atmosphere during the night a supply of dew to recruit its energies, dependent on its form and its peculiar radiating power. Every flower has a force of radiation of its own, subject to changes during the day and the night; and the deposition of moisture on it is regulated by the peculiar law which this radiating power obeys; and this power will itself be influenced by the aspect which the flower presents to the sky, unfolding to the contemplative mind the most beautiful examples of creative wisdom.

Rain, hail, snow.

(8.) With the phenomena of rain, its primary formation, and the principles which regulate its descent; the formation of hail, the consideration of the laws that occasionally impart to it its beautiful crystalline forms; the still more delicate creation of snow, and the investigation of the endless groups to which particular conditions of temperature, and the peculiar circumstances attendant on the vapour actually existing in the air give birth, it is needless to say how closely Meteorology is connected.

Clouds, haloes, coronæ, &c.

(9.) The formation and classification of clouds, the varied and incessant changes which they present; the laws which regulate their suspension, and their gradual and sometimes sudden destruction by rain, belong all to this branch of Meteorological inquiry. So also the consideration of the laws which appear to influence the formation of haloes, coronæ, parhelia, &c. all of which owe their origin to the presence of aqueous particles existing in the air, place Meteorology in a most interesting relation to Light.

Electrical phenomena.

Aurora Borealis.

(10.) With all the phenomena of Electricity, the Meteorologist has claimed an intimate connection, ever since Franklin identified lightning with the ordinary electric fluid. The first conception of the thunder rod, was one replete with magnificence. To draw down silently from a cloud the matter, which, if discharged, would hurl destruction upon thousands, and destroy the finest monuments of Art, is an operation which seems to impart to the feeble hand of Man, a portion of the power of the Supreme. The beautiful phenomena of the Aurora Borealis, illuminating by their splendour those unexplored regions of Nature, which are covered at all times with a hoary desolation; their occasional descent into the temperate zones of the Earth; and the influence which their changeful coruscations is said to exercise in particular cases on the Magnetic needle, have identified in an especial manner the Science of Electricity with that of Meteorology.

Winds.

Sea and land breezes.

(11.) The general theory of winds, and their many modifications, opens also another interesting and instructive field of Meteorological inquiry. To trace the sources which produce those tremendous hurricanes and storms, that spread desolation over the fairest prospects of Nature, and which communicate likewise to the ocean its awful character and power; to consider the causes also of local winds; to account for the economy of Nature, in providing for the inhabitants of the tropical regions the refreshing interchanges of sea and land breezes; and for the existence of those periodical winds, which in some of the regions of the Earth perform, for definite periods, with the most exact uniformity, their stated and particular courses; facilitating the objects of navigation, and impressing a character of uniformity on the latitudes in which they abound; these, and many other inquiries of an analogous kind, awaken in an uncommon degree the attention of the Meteorologist.

Natural History. Indications of animals.

(12.) The cultivation of Meteorology is connected also, in an especial manner, with many of the departments of Natural History. With the habits of particular animals it is intimately identified, the sagacious observer being enabled to anticipate many atmospheric changes from an attentive observation of them. The common Swallow has always been considered as a weather-guide; and not only may the approach of rain be expected when she dips her wings in the stream, but even the gradations of climate may be marked by her approach. The voice of the solitary Crow, the clamours of the Pintado, and the activity of Ants, are all indications of coming rain; and by the mariner, the approach of the stormy Peterel, seeking for shelter under the wake of his vessel, is regarded as the harbinger of a storm. So that of the Fulmar to land, is a sign to the inhabitants of St. Kilda, that the West wind is very distant from them.

Meteorology useful in Practical Astronomy.

(13.) With the most exalted branch of Physical knowledge, Astronomy, the Science of Meteorology stands in many interesting relations. In determining the exact situation of a celestial object, the conditions of the internal and external temperatures require constant observation; nor must the movements of the Barometer be neglected, when the delicate problem of the Astronomical refractions is to be applied. Meteorology has indeed furnished to the latter many of its most important elements.

Figure and extent of the atmosphere.

(14.) In the inquiries also connected with the figure and extent of the atmosphere, the most beautiful applications of the law of gravitation have been made. The Mathematician, in considering the figures of the atmospheres of the Planets, is necessarily led, in a peculiar degree, to notice the volume of air surrounding the sphere which he inhabits. Its spheroidal form has called into action the most profound theories of analysis; and the Meteorologist rejoices to find, that the great laws which Newton delivered respecting the system of the World, meet with some of their most interesting applications in that atmosphere, whose incessant mutations it is his constant object to watch and record.

These different relations of Meteorology display the importance and value of the inquiry.

(15.) In this rapid sketch of the relations of Meteorology to some of the leading departments of Physical Science, an attractive picture is exhibited of the importance and value of the inquiry. The Meteorologist, while he is engaged, either for his amusement or instruction, in tracing some of the steps of the great system of atmospheric changes; in recording the incessant fluctuations of the Barometer, marking the vicissitudes of temperature, or estimating the force and influence of aqueous vapour, is thus preparing, sometimes unconsciously, materials for perfecting many of the other Sciences. While his primary object is, perhaps, to arrive at some of the elements connected with the great problem of climate, he is aiding the Astronomer in forming his catalogues of the stars. The inquiry therefore is not only valuable in itself, but is rendered doubly so by the relations which it bears to so many of the other Sciences.

Present condition of Meteorology

(16.) The condition of Meteorology at the present moment is one of very great interest. Much has been attained, and much, very much, remains to be done. The chief wants appear to be improvement in the instruments of observation, and *unity* amongst the observers. To copy the example of the most perfect of the Physical Sciences, Astronomy, it may be remarked, that that splendid department of knowledge has advanced to its present perfection, by the improvements that have been gradually imparted to its instruments of observation, and to the cautious and accurate deductions that have been drawn from their successful employment. In like manner must Meteorology advance, if similar methods be adopted. It is true that the elements connected with the inquiries of this Science are much more uncertain and variable; but *an extension of the field of observation*, both as regards *space* and *time*, must surmount many of them. The successive improvements of the Telescope have revealed to the Astronomer unnumbered clusters of stars; and the Micrometer, advancing from year to year in improvement, has enabled him to measure, with unhoped-for accuracy, the minutest intervals of space. So must an improved construction of the Barometer and other instruments employed in

Meteorological observations, guided by a more cautious spirit of induction, lead, in process of time, to like satisfactory results. When we reflect on the general condition of Physical Science, at the time when Bacon laid down the rules according to which Philosophical inquiries ought to be prosecuted, and contrast it with its condition now; how by the steady application of his inductive precepts many of its branches, which were characterised by uncertainty and doubt, have been reduced to comparative certainty and order; it is not too much to expect, that Meteorology, although still surrounded with so much difficulty and error, will hereafter attain its proper rank in the scale of the Sciences. The indefatigable recorder of atmospheric changes will then no longer be classed with the mere empiric. A survey of the past History of Physical knowledge will lead us to consider this conviction as neither romantic nor unnatural.

Sources of error which the Meteorologist has to avoid.

His objects.

General theories specious and seductive.

(17.) The great error which the cultivator of Meteorology has to avoid, is that tendency, which has more or less existed in different stages of its History, to a premature generalization departing from the narrow and cautious path which Bacon laid down. To accomplish an analysis of all the complicated phenomena of the atmosphere into simple and original principles, ought to be the aim and object of the Philosopher, and it is one well worthy of his lofty ambition and hope. But to proceed with success, "it is necessary to ascertain facts before we begin to reason, and to avoid generalizing in any instance, till we have completely secured the ground which we have gained. Such a caution, which is necessary in all the Sciences, is, in a more peculiar manner, necessary here, where the very facts from which all our inferences must be drawn, are to be ascertained only by the most patient attention."[*] There is something specious and seductive in all attempts at generalization; and it seems as if the mind, from the influence of improper habits, rather clung to the consideration of general principles, than to those severe and rigorous modes of observation, which the pure principles of the Inductive Logic require. But the History of knowledge is filled with the most melancholy proofs of the absolute futility of all attempts of the kind; and notwithstanding the splendour and success that have resulted from the application of the legitimate rules of Philosophy as laid down by Bacon, we yet find a strong tendency to violate them. It seems as if the mind delighted in hanging every thing on a single point, and adopting some principle as an infallible rule, to make the whole framework of Nature bend to its dictates. "It required nothing less," says an eminent Philosopher,[†] "than the united splendour of the discoveries brought to light by the new Chemical School, to tear the minds of men from the pursuit of a simple and primary element; a pursuit renewed in every Age with an indefatigable perseverance, and always renewed in vain;" and the History of Meteorology is filled with like impotent attempts. But checked as its growth has been by the application of mistaken rules, it must yet advance with success, if the principles of the Inductive Logic be rigorously applied to it. In all the other Sciences,[‡] the progress of discovery has been gradual, from the less general to the more general laws of Nature; and it would be singular, indeed, if, in so complicated an inquiry as Meteorology, one which labours under so many disadvantages peculiar to itself, a step should, all at once, be made to a single principle comprehending all the particular phenomena which we know. The Meteorologist must be content, like the cultivators of all the other departments of Natural Science, to advance by careful induction; to interrogate Nature under all her forms, and not to abandon the subject in despair, if her responses be not immediate.

Helps which Meteorology may derive from popular observations of phenomena.

Examples.

More general views of the Philosopher.

(18.) There is one peculiarity, however, belonging to the Science of Meteorology, which distinguishes it in a particular degree from all the other Sciences; and that is the helps it may receive from popular observations of phenomena. Saussure has remarked,[*] that "it is humiliating to those who have been much occupied in cultivating the Science of Meteorology, to see an agriculturist or a waterman, who has neither instruments nor theory, foretell the future changes of the weather many days before they happen, with a precision, which the Philosopher, aided by all the resources of Science, would be unable to attain." But there are no just grounds for the humiliation which the Swiss Philosopher has here alluded to; for "the knowledge of the Philosopher differs from that sagacity which directs uneducated men in the business of life, not in *kind*, but in *degree*, and in the manner in which it is acquired."[†] And when we consider, that the agriculturist and the waterman are always employed in the open air, with their minds constantly occupied with an object which interests them more *immediately* than it does the Philosopher, it can be no matter of surprise that they often group together facts, which, like the instinct of animals, serve to guide them in their predictions. The local sign which directs them may be a fog which rises at a particular hour, in some peculiar locality, the appearance of a cloud on the summit of a mountain, to which their attention has been directed by many early associations, or the song or migration of certain birds. But if these limited interpreters of Nature be transported to new seats, the symbols which guided them in their own locality will no longer be efficient; and other trains of observation must be begun, to fit them for their new condition. The views of the Philosopher are much more extended and general. His aim is not to limit his conclusions to a single locality, but to develop them under their most general form; and it is then that the superiority of well-directed observations becomes manifest. If, indeed, the Scientific Meteorologist could be constantly occupied like the agriculturist and the waterman, in watching the appearances of the heavens, our knowledge of atmospheric phenomena would soon be prodigiously increased; but unable thus to employ himself, it will be the object of the genuine cultivator of Meteorology to draw from the experience of even uneducated men all the helps he is able.

(19.) In the present rage for innovation, and for

---

[*] Stewart's *Philosophy of the Mind*, vol. i. p. 400, 3d edition.

[†] De Gerando, *Hist. de Systémes*, tom. ii. p. 481, 482.

[‡] We have here applied to Meteorology what the eloquent Dugald Stewart has with so much truth said respecting the peculiar difficulties which beset the Philosophy of the Mind. Many of the reasonings of Stewart, such is their truth and generality, are as applicable to Physics as to Metaphysics.

[*] *Essais sur l'Hygrométrie*, ch. x.

[†] This beautiful and highly Philosophic maxim is taken from Stewart's *Outlines of Moral Philosophy*, p. 4, 4th edition, and is peculiarly applicable to the subject before us.

Evils to be anticipated from entirely rooting out all recollection of popular superstitions.

rooting up what are commonly called popular superstitions, much valuable information may be lost. Many of the common adages respecting the weather, have doubtless had their origin in the observance of Meteorological phenomena; and that Philosopher would but half perform his duty, who, dazzled by the splendid results which modern Science now discloses, should abandon without any examination the traditions that time has handed down. There are some phenomena of the atmosphere, which seem to have suggested to Man in different conditions of his state, ideas and forms of expression of the same common kind. In investigating these, under the dark and shadowy forms which the mutations of language have imparted to them, much important information may be disclosed; and connected as many of them are with cycles and periods of observation, they possess a very high value. Some attempt at a classification of the phenomena to which these traditions relate, would not be unproductive of advantage. Most of them have some foundation in Nature, and it is at least prudent for a Philosopher to keep them in view in the course of his inquiries.

(20.) It is thus by watching appearances, and diligently recording phenomena, generalizing observations, and disclosing in their fullest extent the grand system of signs by which Nature works, that Meteorology will advance to that perfection which its ardent cultivators desire.

Constitution of the atmosphere.

Constitution of the atmosphere.

(21.) The great volume of the atmosphere is composed of permanently elastic fluids, the whole of which are retained on the surface of the Earth by the law of gravitation. All eudiometrical processes, when skilfully performed, concur in proving that, apart from the carbonic acid and aqueous vapour which are present in atmospheric air, 100 volumes consist of 79 oxygen, and 21 nitrogen; or, including the two former ingredients, that it is constituted, at a mean temperature and pressure, of

Nitrogen gas....	77.5 by measure,	75.55 by weight.
Oxygen gas	21.0	23.32
Aqueous vapour.	1.42	1.03
Carbonic acid...	0.08	0.10
	100.00	100.00

(22.) It is the business of Chemistry to unfold the delicate processes by which these different relations are determined, and for these we refer the reader to our Essay on that Science; but we may notice here the remarkable fact, that with the exception of the aqueous vapour, the quantity of which varies with the temperature, as will be hereafter explained, the other ingredients of the atmosphere bear at all times, in every region of the globe, whether on the summits of the loftiest mountains, or at the lowest levels of the deepest valleys, the same relative proportion to each other. Thus, air from the Alps analyzed by the younger Saussure, from Spain by De Marti, from France and Egypt by Berthollet, from England and the Coast of Guinea by Davy, from the Peak of Teneriffe and from near the summit of the Andes by Humboldt, and from the still loftier elevation of 22,000 feet by Gay Lussac and Thenard, all gave results approaching as nearly as possible to each other.

This constitution the same in every region of the Earth.

(23.) It has been commonly supposed that the atmosphere must contain, diffused throughout it, minute portions of the vapours of all those substances with which it is in contact, even down to the earths and metals; and although the unknown ingredients which are occasionally mingled with the atmosphere, and which impart to it deleterious properties, are either of too subtile a nature, or present in too small a proportion, to be discovered by our imperfect instruments, yet Mr. Faraday has shown, in the *Philosophical Transactions for* 1826, that a *limit* exists to the production of vapour of any tension by bodies placed in vacuo, or in elastic media, beneath which limit they are perfectly fixed.

Mr. Faraday's discovery of a limit to vaporization.

Chemical constitution of the atmosphere.

(24.) Two views have been entertained of the nature of the union which exists among the several elastic fluids constituting the atmosphere. By the greater part of Chemists it has been considered as a Chemical compound, chiefly from the uniform nature of its composition, and from the fact that its several ingredients do not separate and arrange themselves according to their relative Specific Gravities. Mr. Dalton was the first who presented, under a distinct point of view, the remarkable theory, that of the various elastic fluids constituting the atmosphere, the particles of one have neither attractive nor repulsive power towards those of another, but that the weight or pressure, upon any one particle of any fluid mixture of this sort, arises solely from the particles of its own kind. According to this hypothesis, oxygen, azotic, and carbonic acid gases may exist together under any pressure, and at any temperature, while each of them occupies the whole space allotted for all. Each ingredient of the atmosphere, according to this view, exerts its own separate pressure in supporting the mercury of the Barometer, and performs, says Dr. Henry, the part assigned to it in the following table:

Mechanical constitution of the atmosphere.

	Inches of mercury.
The nitrogen gas exerts a pressure equivalent to	23.36
The oxygen gas	6.18
The aqueous vapour	0.44
The carbonic acid gas	0.02
	30.00

Latest views of Mr. Dalton respecting the constitution of the atmosphere.

(25.) In the *Philosophical Transactions for* 1826, Mr. Dalton has entered into an extended view of the principles by which he conceives the constitution of the atmosphere may be regulated; and to illustrate his views, he imagines two equal cylindrical tubes, A and B, to exist in contact with each other, perpendicular to the horizon, of indefinite lengths, closed at the bottom, but open at the top. Into the tube A he supposes an atmosphere of hydrogen to be introduced, equivalent to a mercurial column of 30 inches; and into the other tube B, an atmosphere of carbonic acid gas, capable also of supporting a column of 30 inches of quicksilver. Now supposing, he says, these atmospheres to remain, for an instant, of uniform density throughout the extent of each column, and that density to be the same as exists at the surface of the Earth, the altitude of the atmosphere of hydrogen would be about 66 miles, and that of the carbonic acid about 3.3 miles; these heights being to each other nearly in the ratio of 20 to 1. And if these atmospheres be afterwards expanded to their natural extent, equal elasticities of the two gases would be found to exist at altitudes, also in the ratio of 20 to 1; that is, if at two miles of elevation the atmosphere of carbonic acid supported 15 inches of mercury, that of hydrogen would support the same at 40 miles' elevation. Conceiving now these atmospheres to have acquired their perfect equilibrium, Mr. Dalton imagines numerous air-tight, horizontal partitions to be formed across the tubes, at equal intervals from the ground upwards; these intervals being either a foot or a mile, as may suit our purpose.

(26.) Supposing now a communication to be opened between each two horizontal portions of the tubes, an intermixture of the gases would follow, and finally such an equilibrium be obtained, that *one-half* of the gas existing at first in each division, would pass into the division opposite, and the other half remain in its original position. The whole weight of the gases in each entire tube would therefore be unchanged, and equivalent as before to 30 inches of mercury, half in each tube being carbonic acid, and half hydrogen gas.

(27.) In tracing the conditions of the gases as we ascend in the tubes, great differences would be found to exist, both as regards volume and weight. In the lowest division we should find equal volumes of carbonic acid and of hydrogen. At the height of two miles, one volume of the former gas would be found mixed with two of the latter; at four miles' elevation, the carbonic acid would be to the hydrogen nearly as one to four; and at 40 miles all the carbonic acid will have probably disappeared, but the hydrogen would remain of one-half its density in the primitive cell. Above the limits of the carbonic acid, wherever it may be, nothing but hydrogen gas would be found in each tube, up to the limits of the hydrogen atmosphere.

(28.) After a complete equilibrium has taken place between every two adjacent cells, Mr. Dalton conceives the horizontal divisions to be withdrawn. The descent of the upper part of the hydrogen column in each tube will be immediate, as there will be vacuities to be filled up in it. The same would take place in the column of carbonic acid, but the great body or weight of the mixed atmospheres would remain unchanged, excepting a slight condensation. The column of hydrogen in each tube would support 15 inches of mercury, and in all respects would resemble the upper half of the first column A, of hydrogen, that supported 30 inches, excepting a slight difference occasioned by distance from the earth and temperature; and the same may be said of the carbonic acid column in each tube.

(29.) But would this constitution of the mixture, Mr. Dalton asks, be permanent? Would a mixed atmosphere, which, in fact, as a whole, consisted of equal *weights* of carbonic acid and hydrogen, continue to exhibit, at the surface of the Earth, equal *volumes* only in mixture? Or, on the other hand, would not the whole be wrought up in due time into one uniform composition in all its extent, of twenty volumes of hydrogen with one of carbonic acid, as many suppose to be the nature of the Earth's atmosphere with regard to its component parts? To these questions, Mr. Dalton replies, by observing, that from what we know of the nature of mixed gases, each of the two gases would be disposed in the same manner as if the other was not present. They would be mixed in equal volumes at the Earth's surface; the carbonic acid would *rapidly* diminish in density as it ascends, terminating perhaps at 28 or 30 miles of elevation; and the hydrogen would *slowly* diminish in density, terminating perhaps at an altitude of eleven or twelve hundred miles.

(30.) In applying this doctrine to the Earth's atmosphere, supposing it to be in a quiescent state, Mr. Dalton neglects the carbonic acid and aqueous vapour, as inconsiderable in weight, and fixing the weight of the atmosphere at 30 inches of Mercury, he finds $\frac{21}{100}$ of $30 = 6.3$ inches, for the weight of the oxygenous atmosphere; and $\frac{79}{100}$ of $30 = 23.7$ inches, for the weight of the atmosphere of azote, since the weights of the respective atmospheres in this view are proportional to the *volumes* found at the surface of the Earth, and totally independent of their *Specific Gravities*. The weight of the aqueous vapour being variable, he fixes at 0.4 inches of mercury, and that of the carbonic acid at 0.03 inches.

(31.) This train of investigation has been conducted on the supposition of a *quiescent* atmosphere, or of one in a state of perfect equilibrium. How the case would be with regard to the Earth's atmosphere, such as it actually is, in a state of continual agitation, it is not easy to ascertain; and it is besides, says Mr. Dalton, rather a question to be decided by experiment and observation than by theory. Mr. Dalton, it appears, has a series of observations already made on this important subject; and he has promised to add them, as a supplement, to the paper from which these interesting extracts have been made.

Inquiries of Mr. Daniell.

Division into four parts.

(32.) The labours of Mr. Dalton, on the constitution of the atmosphere, have become the foundation of much of our knowledge in this important department of Science; and, accordingly, Mr. Daniell, the latest writer on the subject, has grounded his inquiries entirely on the principles established by the Manchester Philosopher. In his *Essays on the Constitution of the Atmosphere*, Mr. Daniell has divided his inquiries into four branches. In the first part, investigating *the habitudes of an atmosphere of perfectly dry, permanently elastic fluid, under particular conditions;* in the second, those *of an atmosphere of pure, aqueous vapour;* in the third, *the compound relations arising from a mixture of the two;* and in the fourth, *the application of such principles as the former sections of his inquiry may have disclosed, to some of the observed phenomena of the atmosphere of the earth.*

Investigation of the conditions of the first part, the temperature uniform.

(33.) In tracing the habitudes of an atmosphere of perfectly dry, permanently elastic fluid, surrounding a sphere in a state of rest, of uniform temperature in all its parts, and to the centre of which it gravitates equally, Mr. Daniell first shows that its height, density, and elasticity must be everywhere equal at equal elevations; and that the column of mercury which it would support in the Barometer, would be everywhere the same at the surface of the sphere. This is a necessary consequence of the law of Hydrostatics. The second condition is, that its density must decrease in a geometrical progression, in ascending through equal stages to its higher regions, because the density must be everywhere proportional to the superincumbent weight; and, thirdly, that its sensible heat must decrease progressively from below upwards.

The temperature to rise generally and equally in all its parts.

(34.) Mr. Daniell next supposes the temperature of the sphere to rise generally and equally in all its parts, and traces the consequent increase of elasticity, and total augmentation of height. There being no alteration in the ponderable matter of the vertical sections into which the atmosphere may be supposed to be divided, the total pressure will remain the same as before, and the Barometer at the base remain unaffected; but as a different distribution of the weight in the different horizontal sections must take place, the altitude of the mercurial column will be changed in every other situation.

Temperature to increase by equal increments from the Poles to the Equator.

(35.) Advancing a step higher in his inquiry, Mr. Daniell next imagines the temperature of the sphere round which the atmosphere is diffused, to increase by equal increments from the Poles to the Equator; and assuming zero for the temperature at the former, supposes that of the latter to be 80°. By limiting the pressure of the atmosphere to 30 inches of mercury at all parts of the surface of this sphere, the elasticity of the air must remain constant, but its Specific Gravity at the Poles will be much greater than at the Equator, and hence the atmospheric column in the Polar regions must be proportionally shorter than that in the Equatorial.

Polar and Equatorial currents.

(36.) The unequal densities of the aerial columns must produce a current from the Poles to the Equator; but as the difference of gravity becomes less as we ascend from the surface, and at a certain point is neutralized; so, on the other hand, the elasticity, which is constant at the surface, varies with the height; and the barometer stands higher, at equal elevations, in the equatorial than in the Polar column. This disproportion increasing with the elevation must, at some definite elevation, much more than compensate for the unequal density of the lower strata, and thus occasion a counter-flux from the Equator to the Poles.

(37.) These differences of gravity and elasticity may be regarded as distinct and opposite powers, their forces being measured upon the same scale. The excess of gravity may be estimated from the consideration, that the pressures of equal columns are as their Specific Gravities; and as, by Mr. Daniell's supposition, this excess of gravity is unopposed at the surface of the sphere by any excess of elasticity, so is it the exact measure of the force with which a Polar atmosphere would press upon an Equatorial, supposing the two in juxtaposition. The same excess of gravity is also the measure of the pressure which would be required at the Equator to equalize its density with that of the Poles. Could this increase of pressure actually take place, the aerial current would be reversed, and flow with the same force from the Equator to the Poles, the current being now occasioned by excess of elasticity, as it was before caused by excess of gravity.

Illustrative Table.

(38.) After assigning limits to the elevations of these currents, Mr. Daniell proceeds to estimate their velocities, and then furnishes, as in the following Table, the elasticity, Specific Gravity, and temperature of such an atmosphere, calculated upon his peculiar data, for every ten degrees of latitude, from the surface, by equal altitudes, to the height of 30,000 feet.

TABLE I.—*Numerical Values of the Elasticity, Specific Gravity, and Temperature, for every Ten Degrees of Latiude, of an Atmosphere of Dry Air surrounding a Sphere unequally heated from the Poles to the Equator, together with the Decrease of each, due to different Elevations.*

Remarks on the preceding Tables.

(40.) It may be remarked, with reference to these Tables, that a change of temperature, which equally pervades a column of air throughout its whole length, may effect an adjustment of density without disturbing the equiponderant mercurial column situated at its base; but the force of the compensating currents will be altered, and, under some circumstances, their courses even changed. An alteration of temperature, for example, in latitude 50°, will increase the force of the current from latitude 60° to 50° in its original direction, while that from 50° to 40° will be reversed: the wind, which had blown on the surface between the former parallels with a force of 0.810 inches, being increased to 2.560 inches; and that which moved between the latter parallels with a force of 1.034 inches, blowing now in the opposite directions with a force of 0.840 inches. Corresponding changes of velocity and direction ensue in the upper currents, and thus the compensation of pressure takes place.

(41.) Any cause also which tends to diminish gradually the Specific Gravity of a permanently elastic fluid column at its base, or, on the contrary, to augment its temperature at its superior limit, will affect it through its entire length; so that, if its heat be slowly increased below, its temperature must rise from one extremity to the other, and *vice versâ*. But although such a change may take place, without increasing the length of the mercurial column at its lower extremity, at all higher stations the Barometer will rise.

Effects of an increase of temperature of the upper strata of the atmosphere.

(42.) Let us next follow Mr. Daniell, when he imagines heat to be communicated to the upper strata of his atmosphere, and which, from some temporary cause, does not originate in, or extend to the lower. For this purpose, he supposes some increase of temperature at a definite altitude. The influence of the heat communicated will be felt in the superior strata, but those in the lower regions must, by the supposition, remain unchanged. The first effect which results will be an augmentation of elasticity in the upper beds of the atmosphere, which, exerting its force upon the high Equatorial current, will accelerate its velocity on one side, and diminish it on the other. The expanding air, not being laterally confined by a proportionate expansion of the neighbouring sections, will not accumulate above, but, flowing off, will cease its vertical pressure upon that column. The upper regions, therefore, will be rarefied, and become lighter, and pressing with less weight upon the lower, the Barometer will fall at the surface of the sphere, in proportion to the degree of expansion. The density of an elastic fluid being the result of its gravity acting upon its elasticity, by the reaction of these powers, any change in the vertical column must be communicated instantaneously throughout its entire length, and no inequality of density can for a moment exist.

Local accession of heat, commencing at a definite point, and gradually extending in depth.

(43.) To generalize still further, let us again imagine with Mr. Daniell, the local accession of heat, instead of pervading at once the whole of either horizontal section, to commence at some definite point, and gradually extend itself in depth. The disturbing cause will then affect the lower current, and the expanding volumes of air, not being checked by a simultaneous increase of elasticity in the adjoining columns, will rush forward with accelerated velocity, and the diminution of density occasioned by the excessive drain will be distributed throughout the column by mechanical adjustment. The fall of the Barometer would be proportionate to the extent to which the rise of temperature would reach in this progressive manner. A small increase, thus operating, will produce the same amount of depression, as if a greater expansion had been exerted in a more limited space.

(44.) In the following Table, the effect upon the Barometer is exhibited of a small partial increase of temperature, gradually extending itself throughout the aerial column, in conformity to the preceding changes.

Illustrative Table.

From latitude 40 to 30, it will be observed, that the force of the Polar current is greatly increased; while from 30 to 20, the effect is entirely reversed.

Remarks.

(46.) It may readily be imagined, continues Mr. Daniell, that irregularities thus introduced into these compensating movements, the consequence of diminished mechanical pressure, must of themselves be liable to produce changes of temperature in the atmospheric columns, foreign to the natural gradation; and that, amongst others, the atmosphere, in its upper parts, may be liable to greater depressions of heat than would result from the elevation alone. A gradual process of cooling taking place in the higher portions of a body of air, would communicate itself to the whole mass, in an analogous manner to the equal diffusion which would ensue from the slow communication of heat to the lower parts; that is to say, without producing any effect upon the Barometer at the surface of the sphere, or any irregularity in the gradation of temperature. But where the change is effected suddenly, by the admixture of a large body of cold air, a mechanical effect is produced by the increased pressure of the mass; and the equilibrium of density takes place before the adjustment of temperature. An atmosphere hence results, the heat of which decreases in a greater proportion than is due to the decrease of density; and the effect is analogous to that which arises from an irregular increase; and the Barometer must also rise to equalize the specific gravity.

(47.) It is not required here that we should point out all the means by which such changes of heat as we have alluded to may be effected, or that we should trace further the endless modifications of densities and currents which would result from their different applications. It is sufficient, says Mr. Daniell, at present, to have shown that, supposing them to arise, certain general consequences must follow.

Effects of the preceding changes upon the adjacent columns of the atmosphere.

(48.) In the preceding review of the labours of Mr. Daniell, we have found that he has contemplated the various changes that have been alluded to, with reference to the particular column of the atmosphere in which they had their origin. We shall now make our readers acquainted with his estimate of their effects upon those with which they are connected. For this purpose, we must remember, that it has been established as a principle, that the equal height of the Barometer, in every situation upon the surface of the sphere, was dependant upon the maintenance of the Equatorial and Polar currents, with a certain determinate velocity in the different parts of their courses; and that no disproportionate alteration or interruption in these could take place, without a corresponding effect upon the mercurial column. Now, upon a reference to Tables I. and II., continues Mr. Daniell, it will be found, that to keep the Barometer at 30 inches, under the parallel of 40, a current is required of the force of 0.854 inches towards the parallel of 30, counterbalanced by one in the contrary direction, of the force of 0.291 inches at the elevation of 30,000 feet; but by the unequal alteration of temperature, arising from the gradual extension of heat from one stratum of the atmosphere to another, the current at the surface will be increased to 2.07 inches, and continue with decreasing force to the height of 30,000 feet in the same direction. It is clear, therefore, that a much greater drain takes place upon this latitude, without an adequate compensating supply; and the Barometer must fall throughout the column. The atmosphere incumbent upon the parallel of 20 will be similarly affected by the same change of temperature at latitude 30. In its original state, the lower Polar current flows upon the surface with a force of 0.648 inches, and feeds this column with a supply of air. It is balanced at the height of 30,000 feet by an Equatorial current of 0.170 inches. The course of the former is now reversed, and the drain is increased in the contrary direction. A rapid fall of the Barometer must therefore ensue.

(49.) On the other hand, an increased afflux of air, beyond the usual supply, to any portion of the atmosphere, occasioned by the expansion of any of the neighbouring parts, must cause an increase of density; and the equiponderant column will of course be lengthened. It is easy to perceive, that these secondary effects must widely extend the influence of the original disturbing cause; and it is obvious, that every depression of the Barometer must be accompanied by an equivalent rise in distant parts of the elastic medium, and *vice versâ*. The local impulse, continues Mr. Daniell, extends its influence in this, as in all other fluids, by the laws of undulation. The mean pressure, at any moment of time, of all the waves upon the surface of the sphere, will be the pressure of the atmosphere at rest, and the average of a large number of oscillations at any particular spot, will approximate to the same quantity.

Effects of analogous changes in a longitudinal direction.

(50.) In the preceding inquiries we have considered the atmospheric changes to operate alone in a direction from the Equator to the Poles, or from the Poles to the Equator, as if the changes of temperature had operated entirely in parallels of latitude round the sphere. But Mr. Daniell enters also into the changes produced in a longitudinal direction from the operation of similar causes.

(51.) The atmospherical arrangements represented in Tables I. and II. resulted from the temperature of the sphere itself; but let us suppose the change referred to immediately following the last-quoted Table, to extend its influence to 10 degrees of longitude as well as to 10 degrees of latitude; is it not apparent that currents will be established at right angles to the directions of the former winds, and that they will tend to compensate the irregularity which has been introduced? The following Tables present the results of the calculation of these easterly and westerly currents.

Illustrative Tables.

Intermediate currents produced by the Polar and Equatorial currents.

(52.) The preceding forces operating, one in the direction of the meridian, and the other at right angles to it, must necessarily produce a system of intermediate currents, which will reach their destination with a Northern or Southern deflection.

Effects of an increase of temperature along an entire meridian.

(53.) There is, however, another of Mr. Daniell's views on this interesting subject, which we must not omit to notice; and that is, the increase of ten degrees of temperature which he supposes to take place along the entire range of a given meridian, and a diminution of heat of equal amount at the opposite point, all the meridians on each side being similarly affected in some ratio between the two. Mr. Daniell has computed the distribution of heat upon these two meridians, and also the two intermediate, for every ten degrees of latitude, the results of which are to be found in the next Table.

Illustrative Table.

Limit to the preceding increase of heat.

(54.) This increase of heat Mr. Daniell limits to the condition, that it takes place in so gradual a manner, as not to affect the Barometer at the bases of the different atmospheric columns. There will then be two currents established upon the surface of the sphere, in opposite directions on either side of the cold meridian towards the hotter, with a force of 1.304 inches; or rather, the body of air, which was before in motion from North to South, will now be deflected with this force to the East and West; and the whole lower atmosphere, excepting upon these lines where the effect would be null, will move from the Poles to the Equator with a greater or less bend to the East and West. If the cause producing this variation of heat be supposed to move round the sphere from East to West, then will every meridian in succession be subjected to alterations of currents from the East and West.

Effects of a communication of motion to the sphere.

(55.) Let us now suppose motion to be communicated to the sphere with an uniform velocity from West to East, that the force of gravity is equal, and for the present that centrifugal force produces no effect. Since this rotatory motion must be greatest at the Equator, and is directed Eastward, the air in its passage from the Poles, not having attained the maximum velocity, will have a relative motion Westward; and hence the motion of the wind in the Northern hemisphere will be from North-East to South-West, and in the Southern hemisphere from South-East to North-West. Whenever this apparent tendency coincides with an actual impulse in the same direction, derived from other sources, it will augment its force; and when opposed to one in a contrary direction, it will tend to neutralize it. Thus, in the supposition which has been just made, of an accession of temperature through the entire range of any meridian, the current, which we found would thence arise from the East towards that meridian, would be increased by this further mechanical impulse; while the Western current acting on the opposite side would be decreased, if not annihilated.

But as the lower Polar current would thus have a relative Westerly direction, with regard to the motion of the sphere itself, so the upper Equatorial current would have an absolute movement in the contrary direction. The particles of air, which are transported from the Polar regions to the Equator, have not time to assume the velocity of the different parallels of latitude as they reach them; and are, therefore, necessarily behind as they revolve. To other bodies, therefore, possessing that velocity, they oppose a resistance which appears to proceed from the Eastern quarter. Those, however, which are transported above from the Equator to the Poles, have an excess of absolute motion from West to East above those parts of the globe towards which they are carried. And as the heating power, which is the source of all the motions of the imaginary atmosphere, is in the sphere itself, it follows that the upper parts, which are most remote from it, will become cooled; while those which are nearer to, or in contact with it, maintain their proper temperature. As they cool they of course become specifically heavier and descend; their place being supplied by the subjacent warmer strata. Another kind of circulation becomes thus established in a direction perpendicular to the horizontal currents; and if we contemplate the motion of a single particle of air, we shall find that it maintains an angular course, in a direction compounded of these two motions. The upper Equatorial current having also a movement of rotation from West to East, greater than that of the Polar latitudes towards which it is carried, the effect must be felt by the particles in their descent from the higher to the lower stream, and the consequence will be, that the latter will be deflected from its course, the Northern current receiving a Westerly direction at the point where this influence reaches its stream with sufficient power.

We shall now proceed to the second part of Mr. Daniell's inquiry,

On the Habitudes of an Atmosphere of Pure Aqueous Vapour.

Atmosphere of vapour surrounding a sphere covered with water, of uniform temperature

(56.) This atmosphere of vapour must be first contemplated as surrounding a sphere entirely covered with water, and of uniform temperature throughout. This temperature is limited by Mr. Daniell to 32°, as in his first hypothesis of the permanently elastic fluid.

(57.) The elastic force of steam, for the different degrees of heat within the range of atmospheric temperature, has been determined with great precision by Mr. Dalton; the results of which may be seen in the Table at p. 333 of our *Essay on* HEAT. According to that Table, with a temperature of 32°, the equivalent column of mercury would be .200 inch, which would moreover be the same at every point of the spherical surface. The density of the vapour, like that of the gaseous atmosphere, must diminish in a geometrical ratio for equal elevations, and the temperature also will decline proportionally with it. The ratio, however, of its diminution will be of a different value. Mr. Daniell then traces the decrease of density and temperature in an atmosphere of aqueous vapour, of the force alluded to, at different elevations; and infers, that with such an arrangement, there would be a perfect equilibrium in the aqueous mass in all points of the sphere. Neither would precipitation or evaporation take place, but the atmosphere would remain transparent and undisturbed. Such also must be the state to which an atmosphere of vapour would tend, notwithstanding any obstacles that might be presented to oppose it. And hence also Mr. Daniell infers, that, if condensation were to take place in any part of an atmosphere so constituted, evaporation must also take place to maintain the equilibrium; and conversely, that evaporation must be accompanied by precipitation.

(58.) Should the temperature of the sphere rise gradually and uniformly over every part of its surface, the elasticity of the steam would increase without any disturbance; and obeying its own law of decrease for different elevations, it would remain perfectly transparent.

Effects of an elevation of temperature from the Poles to the Equator.

(59.) In considering again, with Mr. Daniell, the second condition, namely, that of an elevation in the temperature of the sphere from the Poles to the Equator, it may first be remarked, that a pure unmixed atmosphere of vapour could by no means render itself obedient to such a law. The elasticity of the whole would be measured by that of the lowest point; and the water would distil from the hottest to the coldest point with such a rapidity, as to occasion a strong ebullition at the former. The condensation of vapour may be effected not only by decrease of temperature, but by an increase of pressure; it is not necessary, therefore, that it should pass from the hottest to the coldest point to be precipitated, which would be a gradual process; but the elastic force, arising from an increase of density at one extremity, would instantly be felt at the other, Illustrated by Wollaston's Cryophorus.

the impression being conveyed as through a spring. Mr. Daniell illustrates this effect by the beautiful Cryophorus of Dr. Wollaston, in which the force of the vapour is so much reduced by the cold applied to one extremity of the instrument, as speedily to produce congelation at the other by the rapidity of the consequent evaporation. The rapidity of action is, however, not necessary for the present investigation; for we must imagine the passage of heat from one point to another to be so mechanically retarded, as to enable it to assume all the gradations due to the heat of the sphere. This will enable us to estimate the relative force and pressure of two of the vertical columns at different stations; and Mr. Daniell having computed the decrease of density and temperature in an atmosphere of aqueous vapour of the force of 1.00 inches, at different elevations, observes, that unlike the case of the permanently elastic fluid, both the density and elasticity will be found greatly to increase with the temperature; and that therefore the Equatorial columns must press upon the Polar columns throughout their entire length. A circulation will hence arise very different from that of the aerial currents. The vapour would flow in a mass from the Equator to the Poles; and being necessarily condensed in its course, would return from the Poles to the Equator in the form of water. Great evaporation would be constantly going on at the latter station, and condensation at every other; so that the atmosphere, excepting at the Equator, would be rendered turbid by perpetual clouds and rain. As in the case of the permanently elastic fluid, the temperature of the sphere would by this process soon become equalized, did not our hypothesis provide for its permanency: the Equatorial parts would become quickly cooled by the evaporation, and the Polar become warmed by the heat evolved during the process of condensation.

(60.) It is further worthy of attention, that the elasticity of vapour increasing nearly in a geometrical proportion for equal increments of heat, the decrease of temperature in ascending in this atmosphere will be in arithmetical proportion only; the diminution being nearly three degrees for every 5000 feet.

(61.) Upon the hypothesis of the gradation of temperature before assumed, in the case of the gaseous atmosphere, Mr. Daniell furnishes the following Table to represent the corresponding elasticity and density of the vapour at the surface of the sphere, for every ten degrees of latitude.

Illustrative Table.

The temperature of some Latitude increased to that which adjoins it.

(62.) Let us next imagine, that the temperature of any particular latitude is raised to the level of that which adjoins it. This will cause condensation to cease at that point, evaporation to commence, and the atmosphere to become transparent. The quantity of water precipitated will be proportionally increased on the other side. But if, on the contrary, the temperature of the parallel be lowered to that of the parallel next above, the precipitation will be increased, and the higher latitude be cleared of its turbid matter. The next Table represents the condition of Latitude 30 under these interesting circumstances.

Effects of Evaporation

(63.) Again, if the mechanical retardation of the flowing vapour were subject to variation, the quantity of evaporation and precipitation would be proportionate to the velocity of its passage: thus, supposing the evaporation from a given surface at a given temperature, and under a given resistance, to be three grains per minute, that quantity would be doubled with half the resistance. The changes at the surface affect the whole of the superincumbent column equally, and the temperature of the vapour follows its own particular law of decrease. But what, says Mr. Daniell, will be the consequence, if the vapour should be forced to adapt itself to a progression of temperature different from its own; and if, from some cause, the heat of the upper regions should diminish at a greater rate than is due to its natural gradation?

(64.) Let us, for instance, suppose that the heat of the water upon the surface is 80°, but that at the height of 5000 feet above the surface, a temperature exists of only 64°.4, which from that point follows the former decreasing scale. The water in such a case will have a tendency to throw off vapour of the same constituent heat as its own temperature; but the pressure above, being rendered too little by the influence of the forced degree of cold, to preserve the necessary elasticity below, the atmosphere will only possess the tension due to the lower degree; that is to say, the constituent temperature of the vapour will be only 67°.9. Evaporation must therefore ensue below, and its concomitant precipitation above. The calculation of these effects is entered in the next Table.

Illustrative Table.

Table X.—*Showing the Effect upon the Atmosphere of Vapour of a forced gradation of Temperature.*

20000	.443	55	55	"
25000	.401	52	52	"
30000	.363	49	49	"

Formation of a Cloud.

(65.) The consequence of this supposition will be, that a Cloud will be formed at the height which has been named; for the atmosphere will be forced upwards by the nascent vapour existing below, and a condensation at this point will ensue. The Cloud, however, supposing the process to be sufficiently gradual, would not extend very far below, because the water, during its precipitation, would be redissolved by the excess of heat in the lower regions, so that they might remain transparent and undisturbed. The ultimate effect would be, that the temperature would be slowly equalized, and the balance of force restored. The water, in its circulation backwards and forwards, would act as a carrier of the heat, which it would abstract from the lower parts by its evaporation, and give out to the upper by its condensation. The atmosphere would thus gradually recover its state of equilibrium and repose, the upper regions remaining clear, because the gradation is there undisturbed.

Effects of the diminution of temperature throughout an entire column.

(66.) The sudden decrease of heat need not, however, be confined to a single point; but may be supposed to continue throughout the entire column, and to adapt itself to some progression. Instead also of its being limited to a single vertical atmospheric column, it may be taken in connection with other adjacent sections. As an example, Mr. Daniell gives the annexed Table, adapted to the Equator with a temperature of 80°, and the parallel of 10°, with a temperature of 76°.8, and in which also the flow of the lateral currents is exhibited.

Illustrative Table.

Table XI.—*Showing the State of the Atmosphere occasioned by the Intermixture of Lateral Currents.*

Remarks relating to the last Table.

(67.) In the Equatorial division of the Table, the first point of condensation is supposed to take place at the height of 5000 feet, while, in the other division, it is limited to 10,000 feet; and it will be perceived, that up to the former elevation, the vapour of the first column is of much greater elasticity and density than that of the latter, and that it must consequently flow towards it with considerable force. No Cloud, however, will be formed, as before, at the point of condensation, because the supply arising from the evaporation at the surface, will be carried off in a lateral direction, or, if previously formed, would soon be dissipated by the same operation. Nor would the transparency of the parallel of 10° be affected up to this height; for the current which it would receive would, in its constituent temperature, still be below what its sensible heat would maintain. But above this line a dense Cloud would be precipitated. A counter flow of small extent towards the Equator will be established at the altitude of 10,000 feet; and above this, again, the pressure will return to the first direction. The constituent temperature of the returning current being below the temperature of the elevation, the transparency of the Equatorial column will be preserved throughout.

Case where the water is only partially diffused, the uncovered portions being dry.

(68.) The preceding hypotheses have been framed upon the assumption, that the sphere round which the aqueous atmosphere has been diffused, was covered entirely with water, from which a continual supply of vapour would flow, equivalent to every circumstance of temperature. Let us now suppose, with Mr. Daniell, that the water is only partially diffused, and that the uncovered portions are absolutely dry. Vapour, not in contact with water, is known to be affected in the same manner as the permanently elastic fluids, by variations of temperature, its volume expanding or contracting $\frac{1}{480}$th part for each degree of change above its point of precipitation, by Fahrenheit's scale. If a current, therefore, were to pass over a dry space, of a higher temperature than itself, the same changes would take place, in miniature, as we have already traced in the dry atmosphere. Its density would diminish, while its elasticity would remain the same upon the surface, and be increased at all the higher stations. In the case of vapour becoming heated in this manner, out of the contact of water, it may reach its point of deposition at a high elevation without producing any sensible Cloud; for although it would be slowly precipitated, it would be instantly restored to the elastic form by the excess of heat in the inferior strata; and no accumulation could be formed for want of a supply from the dry surface below. A slight haziness might possibly be the result.

Effects of a stream of vapour passing from a part of the sphere covered with water to a part perfectly dry.

(69.) Let us now imagine, continues Mr. Daniell, a stream of vapour, of known density, filtering its way laterally, from one part of the sphere, which is covered with water of a certain temperature, to another which is perfectly dry, but of equal or superior temperature. As the vapour arrives at the dry space, it will be rapidly diffused; and its elasticity, being no longer confined by an incumbent atmosphere of like density, will be reduced, and will assume that force which its own diffusion will enable it to maintain. Or a stream of vapour, of high elasticity, flowing into a space where there already exists an atmosphere of inferior force, will be reduced in density to that of the general mean.

Case where the surface is differently embued with moisture and variously heated.

(70.) But the surface upon which an atmosphere of any particular density rests, may be neither water, nor yet perfectly free from it; it may be earth differently embued with moisture and variously heated. A partial supply of moisture, varying in quantity in different places, but of the same degree of density, would arise, and Clouds of more or less opacity would be formed, at corresponding situations, in the planes of deposition above. Mr. Daniell has calculated the following Table to illustrate these interesting positions.

Illustrative Table.

TABLE XII.—*Showing that the Elasticity of Vapour, yielded by different Surfaces variously heated, is governed by the incumbent Atmosphere.*

(71.) This atmosphere, which is supposed to be of equal force in every part, and in which the same general temperature prevails, rests upon a surface covered with water in one part, with moist earth in another, and on a dry surface in a third. The first point of precipitation is placed, it will be perceived, at 10,000 feet. The water upon which the first part of the column rests, is of the same degree of heat as the general temperature at the surface. The force of evaporation is estimated by Mr. Daniell at 368, and the supply being equal to the force, the density of the Cloud is denoted by the same number. The moist earth upon which the second portion rests, is of the temperature of 70°, which makes the force of evaporation 507; but less steam being given off from the earth than from the water, the quantity precipitated is proportionally diminished. In the Table, Mr. Daniell has estimated it at one-fourth. The dry surface of the earth, which supports the third portion, being heated to 80°, yields no vapour; the evaporating force, which is equal to 786, is wholly unapplied, and no Cloud can therefore be maintained. The higher points of the atmosphere are subject to similar modifications. The temperature of the evaporating surface regulates the quantity of water raised in vapour, and the tension of the pre-existing atmosphere determines its elasticity.

We shall now proceed to the consideration of Mr. Daniell's third division of his inquiry, *viz.*

On the Habitudes of an Atmosphere of permanently elastic fluid, mixed with aqueous vapour.

Consideration of the case of an atmosphere of permanently elastic fluid, mixed with aqueous vapour.

(72.) The properties which each possessed in its separate state, will be retained in this connection unchanged; and the two fluids will exercise no further action upon each other, than a mechanical opposition when in motion. The particles of steam, in penetrating the interstices of the permanently elastic fluid, experience the same species of retardation, as may be supposed to exist, if they flowed through the pores of sand or cotton. When an equilibrium is attained, this mutual action ceases, and the particles of each press only upon those of their own kind. There are, therefore, continues Mr. Daniell, two principal points of view under which such a mixture may be regarded; first, that in which the particles are in a state of perfect equipoise amongst themselves; and, secondly, where they are seeking to attain an equilibrium by means of intestine motion. With respect to the first, there is no distinction between such a complete mixture, and that of two or more permanently elastic fluids; and it may be regarded like a mixture of gases, as an homogeneous fluid.

Conditions of such an atmosphere when surrounding an atmosphere of uniform density.

(73.) Let us now inquire what would be the natural condition of such an atmosphere, when surrounding a sphere of uniform temperature throughout.

The first effect of mixing known measures of gases, with vapour of different degrees of force, is to produce an increase of bulk, under an equal pressure in the permanently elastic fluid; not, however, in proportion to the measure of the vapour communicated to it, but in proportion to its elasticity. The second result is, that the Specific Gravity of the gas is diminished, but not exactly in proportion to its expansion; for while the atoms constituting the vapour are all dilated, their own weight is added to the mixture. But this weight, though increasing with the elasticity, being, in all cases, less than that of an equal bulk of common air, a decrease of density must follow. This diminution of temperature becomes greater with every increment of temperature.

Progress of vapour in a perfectly dry atmosphere.

(74.) To place all the circumstances connected with this interesting subject in a clear point of view, let us, continues Mr. Daniell, trace the progress of vapour just beginning to form in a perfectly dry atmosphere. For this purpose, let the temperature of the sphere be 77°. The first arrangement will be the same as that represented under the parallel of 10° in Table I. If we now suppose water suddenly to overflow the surface, evaporation will instantly commence. No atmosphere of vapour exists to impede its progress, and the nascent steam will merely assume such a degree of tension, as is necessary to overcome the *vis inertiæ* of the air which obstructs its motion. What this force may be, we have not, perhaps, sufficient data to determine. For the present, we must give to it an arbitrary value, and assume, that, at the temperature of 77°, and pressure of 30 inches, it amounts to .200 of an inch. The constituent heat of vapour of this elasticity is 32°, so that at the height of 13,500 feet it arrives at its point of condensation. An aqueous atmosphere of such a degree of force being now established, a resistance proportioned to this amount is made to the progress of evaporation; and the elasticity of the rising steam must in consequence be doubled. Its constituent temperature, therefore, by Table V. p. 333 of our *Essay on* HEAT, is raised to 52°, and it cannot pass the height of 7500 feet without decomposition. The resistance upon the surface now amounts to .601 inch, to overcome which, vapour at 65° must be emitted. The first point of precipitation, in ascending from the surface, would thus be fixed at about 3600 feet; and it may now further be remarked, that the diffusion of vapour does not cease at the height of 3500 feet, to which point we had first traced it, but that the mechanical obstruction is proportionably reduced, and is carried by successive stages to loftier regions, where its tenuity is so much increased, that it rapidly eludes all observation.

Points of condensation.

(75.) With regard to the various points of condensation, it is probable, continues Mr. Daniell, that, as in the atmosphere of pure steam, no cloud will be formed at any of them. The process of evaporation would be so gentle under these circumstances, that little above six grains of water would be raised per minute from a square foot of surface; so that, as the gradual precipitation of this quantity took place between the different stages, it would instantly be redissolved by the excess of heat into which it would be naturally inclined to fall. The circulation thus becomes a process of equalization, by which the temperature of the upper regions is raised: the heat which is abstracted below by evaporation is evolved by condensation, the pressure of the vapour becomes increased, and all the changes tend to that peculiar distribution of heat, which we before contemplated as the natural state of an unmixed atmosphere of steam.

Approximation to the quantity of vapour which would exist upon such an hypothesis.

(76.) The average quantity of vapour which would exist upon the hypothesis we have just assumed, while the atmosphere maintained its proper progression of temperature may be roughly approximated as follows:—A stratum, of the force of .616 inch, extends to the height of 3600 feet; another, of the force of .401 inch, reaches 3900 feet higher; a third, of only .200 inch, stretches almost as far as both the former together; making a total of 13,500 feet. The mean, therefore, to this point is nearly $\frac{.616}{4}+\frac{.401}{4}+\frac{.200}{2}=.354$ inch. For the further distance of 17,500 feet, Mr. Daniell thinks we cannot greatly err in taking .064 inch, as the mean pressure, making the average to the height of 31,000 feet, .209 inch. One-third of the atmosphere beyond this being considered free from vapour, reduces the mean to .139 inch.

Change of hypothesis to that of a sphere whose temperature increases from the Poles to the Equator.

(77.) Changing now our hypothesis of a sphere of uniform temperature, for one whose temperature increases from the Poles to the Equator, let us assume that the Barometer stands every where upon its surface at the constant height of 30 inches. The constituent temperature of the vapour, also, in the different columns of this mixed atmosphere, at the surface of the sphere, is to approach to within eleven degrees of the temperature of the several zones. The succeeding Table has been calculated by Mr. Daniell, to develope the consequent arrangements.

Specific Gravity and elasticity of the air but slightly influenced by the intermixture of the aqueous vapour.

(78.) By comparing the results contained in this Table with those recorded in Table I., it will be seen, that the Specific Gravity and elasticity of the air is but very slightly influenced by the intermixture of the aqueous vapour; so slightly, indeed, that the course and velocity of the currents, as represented in Table II., may with safety be adopted, without producing any sensible error in the investigation. Their balance also is to be that by which the Barometer is maintained at an unvarying height. It will also be remarked, that while the great aerial ocean is divided into two great strata, flowing in opposite directions from North to South, and South to North, the aqueous part, which is nearly confined to the lower current, presses in a contrary direction. The adjustment of these particulars remaining as now supposed, the compensating winds flow on in the courses which have been described, and the balance remains undisturbed.

Evaporation will affect the gradation of temperature resulting from the decreasing density of the upper parts of the atmosphere.

(79.) The admixture of vapour, hitherto considered, has not yet affected the gradation of temperature, resulting from the decreasing density of the atmosphere in its upper parts, but the process of evaporation must in time necessarily induce such an alteration. The steam, as it reaches its point of condensation, must give out its latent heat, and, during its precipitation, combining with a fresh proportion, it must again ascend, and again be evolved in the middle regions. The atoms of steam may thus be considered as carrying caloric from the surface of the sphere to the higher strata; and it is obvious how a considerable section of any one column may thus have its temperature equalized and fully saturated with aqueous particles. The currents thus become affected both by the expansive power of the vapour and of the liberated heat;—causes, the influence of which so applied, must be partial, and cannot reach the higher regions. This unequal action must produce a fall in the Barometer.

Effects on the Barometer.

(80.) Again, as, on the one hand, this effect upon the Barometer is produced by the augmentation of the quantity of aqueous vapour, so, on the other, a rapid increase of the latter may be produced by a fall in the former. The mechanical resistance of the air must of course be increased by its motion in opposition. When this is stopped, as it soon is, by any small diminution of the mercurial column, the vapour will rush forward with its whole force, retarded only by the kind of filtration which must take place through the quiescent air; and the temperature of the higher latitude being unable to support its elasticity, precipitation must follow. From the operation of these causes, the temperature of the latitude will be partially affected, the density of the air be still further reduced, and the aerial column become reversed. The course of the vapour being thus greatly accelerated, an abundant precipitation must follow.

Precipitation of moisture.

Further effects of precipitation.

(81.) The progress of the precipitated moisture, from the time when its first streaks would be found to shoot in a visible form across the atmosphere, to the period when it descends in rain upon the globe, is not without its interest. In proportion to the density of the vapour, must be the magnitude of the condensed particles. When first formed in the higher regions, the cloud would probably assume a light *cirriform* appearance, but at lower elevations, their precipitation would be more dense, and the attraction of aggregation stronger. The mass would thus gently subside to a lower station, where the density of the air would oppose a greater resistance to its descent. Here, in a higher temperature, the cloud would begin again to be dissolved, and assume a rounded and more compact form, and thus the equalization of the temperature, and the diffusion of the vapour, would be carried on from several points at once. The different beds obey the impulse of the winds, and, as they sail along, enlarge the sphere of their action, till, at length, the natural equilibrium of the atmosphere can be no further checked. Hence precipitation will increase, the strata of the clouds unite, and the air no longer be capable of buoying up their load.

Force of the aerial currents between the Poles and Equator.

(82.) In the next Table Mr. Daniell furnishes us with a view of the force of the aerial current, and the counter pressure of the vapour in a mixed atmosphere, surrounding a sphere unequally heated in the manner already set forth.

Difficulties respecting the resistance offered to the passage of the aqueous vapour by the gaseous constituents of the atmosphere.

(83.) We have already stated our difficulties, with regard to the amount of resistance which the pores of the gaseous constituents of the atmosphere offer to the passage of the vapour in motion. Experiments are wanting to elucidate this subject, but the observations of Saussure and Dalton throw some light upon the subject. The resistance here alluded to may be regarded as twofold; first, in connection with the permanently elastic fluid at rest, and secondly, with it in motion.

(84.) With regard to the state of rest, the opposition with which vapour passes through air, is in proportion to its density. Saussure concluded from his experiments, that a diminution in the density of one-third doubled the rate of evaporation.

(85.) With respect to motion, a breeze acting in opposition to the stream of vapour, must retard its progress as much as one in the same direction favours it. Much obscurity, however, envelopes this inquiry, from the vagueness of the terms employed in denoting the velocity of the air. Mr. Dalton has determined that the rate of evaporation, in a perfect calm, being denoted by 120, that of a brisk wind is 154, and of a high wind 189. The retardation of opposing currents of the same respective forces, may therefore be reckoned in proportion.

Velocity with which aqueous vapour travels.

(86.) It is impossible, in the present state of our knowledge, continues Mr. Daniell, to determine the absolute velocity with which vapour travels under any of the circumstances mentioned; but the relative rates of different parts of the same column may be approximated.* Thus, taking as an example the latitude of 30 laid down in the last Table, the current which blows in the direction of the parallel of 40 may be deemed high, and retards the motion of the vapour towards latitude 20 accordingly. At the elevation of 10,000 feet, the density of the air is reduced one-third, and the velocity is consequently doubled. To this must be added the consideration, that the opposing current, at the same elevation, declines in strength, thereby increasing the force in the still higher ratio of 189 to 154. More vapour, therefore, would probably pass at this elevation than at the surface, although its excess of elasticity is only .044 inches at the former station, and .138 inches at the latter. Whenever a deep stratum of air has had its temperature and vapour equalized, in the manner before described, it is easy to conceive that the aqueous atmosphere may travel in its upper parts with considerable velocity, in a course directly opposed to the wind at its lower. The approximation, however, has been carried a little further by Mr. Daniell. The effect of a brisk wind, in accelerating evaporation, is equal to an increase of about three-tenths of the elasticity, that of a high wind being six-tenths. The retarding influence of the Polar current, in its regular state, may therefore be apportioned to the different latitudes in Tables XIII. and XIV., as follows:

From the Poles to latitude 80 = $\frac{1}{10}$ of the elasticity, to latitude 70 = $\frac{2}{10}$, latitude 60 = $\frac{4}{10}$, latitude 50 = $\frac{6}{10}$, latitude 40 = $\frac{6}{10}$, latitude 80 = $\frac{5}{10}$, latitude 20 = $\frac{3}{10}$, latitude 10 = $\frac{2}{10}$, and from latitude 10 to the Equator $\frac{1}{10}$. The following Table will then represent the efficient force of the vapour in a lateral direction, calculated for the surface of the sphere, and for the altitude of one-third the density.

TABLE XV.—*Showing the efficient lateral force of Vapour between the Poles and Equator at the Surface of the Sphere, and at the Altitude of one-third the Density.*

This last Table, Mr. Daniell remarks, will give some idea of the retardation of force, in the vapour, occasioned by the wind, at the surface of the sphere, and also of the increase of velocity occasioned by diminished pressure in the upper regions. It is easy to understand that, whenever the aerial current coincides with the direction of the vapour, the progress of the latter is accelerated in the same proportion.

(87.) The permanency of the Barometric pressure, on the surface of the sphere, is dependent, as already remarked, upon the equal balance of the aerial currents; and its fluctuations have been traced to the destruction of this equipoise, by unequal and local expansions and condensations. One of the chief causes of these latter, Mr. Daniell attributes to the increase and decrease of the aqueous vapour, counteracting the natural progression of temperature by the caloric evolved in its condensation. But there is another cause, which must exercise a powerful influence, and to which no allusion has yet been made. It has hitherto been supposed, for the sake of simplifying the subject, that the source of heat has been in the sphere itself, and that all the regular changes of temperature emanate from its surface. This so far agrees with the condition of the atmosphere of the earth, with which it is Mr. Daniell's final object to identify his different hypotheses; for while in a transparent state, the sun's rays pass through the air without materially affecting it, and exhaust their influence upon the surface of the globe. But if the atmosphere become cloudy and opaque, the rays of heat, emanating from an externa source, are in great part absorbed before they reach the surface, and an increase of temperature and elastic vapour must take place in the middle regions. Here arises another source of partial and powerful expansion. To this also may be added the property which

Effects of cloudy an opaque st of the atmosphere on the temperat

---

* Mr. Herschel, at page 51 of the third volume of the *Transactions of the Astronomical Society*, has the following remarks:—"On the night of the 19th of April, the sky had continued perfectly cloudless, with not a breath of air stirring, and a dew so copious as to run off the telescope in streams till about half past two A. M. I had to take the transit of 25 Herculis as a settling star, which passed at 16 hours 21 minutes, (per Chron.) At 16 hours 8 minutes, one of Piazzi's stars passed, and was taken; after which I continued sweeping, the heavens continuing beautifully clear. About 5 minutes before the expected passage of 25 Herculis, I noticed a dusky cloud bank in the East; it advanced rapidly. Immediately before the transit, Arcturus was completely invisible: while yet in the act of bisecting my star, the edge of the haze was on it, and in less than three minutes from that time had extended to the Western horizon, obliterating every star by a thick uniform coating of cloud. All the time the calm remained quite undisturbed. The least supposable rapidity of propagation in this case is 300 miles an hour, in the direction of the Sun's motion; and the cause is obviously the exact attainment of a determinate temperature in the region of the atmosphere, where the cloud formed, either by radiation, or by a diminution of atmospheric pressure taking place in succession along the whole zone of sky, and as it were pursuing the point of the heavens opposed to the Sun."

the clouds possess of preventing the radiation of heat from the surface beneath them, and the greater conducting power of damp, than of dry air.

Effects of further inequalities in the surface of the sphere.

(88.) Amongst the numberless modifications of condition, to which an atmosphere of the nature we have been considering is liable, there are yet two or three to which it will be necessary shortly to refer. The surface of the sphere has hitherto been chiefly considered as perfectly plain, and either thoroughly dry or everywhere covered with water. Let us now contemplate it as covered with water to the extent of three-fourths of its surface, and the remaining fourth of dry earth, uneven and intersected by eminences; conditions which assimilate it still more closely to the actual terrestrial atmosphere. Such an intermixture of land and water must at once introduce inequalities of temperature of a different character from those which have been hitherto considered. These will arise chiefly from the greater rapidity both of heating and cooling, in the dry surface, dependent upon the peculiar constitution of the watery element. As the processes by which their impressions are communicated to the incumbent air are slow and gradual, they mostly affect the different columns in an equable manner; so that their influence upon the atmospheric currents resolves itself into the cases which have been already proposed, of total and regular expansion. With respect to the vapour, however, the case is different. The parts of the atmosphere above the dry spaces cannot remain free from its admixture, because the elasticity of the surrounding medium will soon supply the vacuum. The law of this equalization will depend upon the mechanical obstruction of the air, which is influenced also by the conditions of the wind. When once diffused over the land, it will be more subject to condensation; and the amount of precipitation must be restored from the great expanse of waters.

(89.) Finally, unevenness of surface will tend, says Mr. Daniell, to modify the atmosphere in some minor degree. Any elevation will obviously partake of the temperature due to the stratum of air into which it may rise; but the action must be reciprocal; and as the heating surface is raised to higher regions, those regions must be proportionally and unequally affected.

We shall now pass to the consideration of some of the phenomena connected with the actual atmosphere of the earth.

Figure of the Atmosphere.

Figure of the Earth's atmosphere.

(90.) The problem of the figure of the atmosphere is connected with some very refined and delicate points of analysis. Had the Earth been truly of a spherical form, and entirely at rest, every portion of the atmosphere surrounding it, would, by the action of gravity, have assumed a perfectly globular form. But any velocity of rotation imparted to the Earth, would be gradually communicated to the atmospheric strata that surround it; and the friction of these strata against each other, and against the surface of the body, would accelerate the slower motions, and retard the more rapid, till a perfect equality was established.

(91.) At its surface the atmosphere is only retained by its weight; and the form of this surface is such, that the force which results from the centrifugal and attractive forces of the body, is perpendicular to it. The atmosphere is flattened towards the Poles, and distended at its Equator; but this ellipticity has limits, and in the case where it is the greatest, the ratio of the Polar and Equatorial axes is as two to three.

Limit to the atmosphere first conceived by Kepler.

In the seventh chapter of the third Book of the *Mécanique Céleste*, Laplace has entered on the consideration of the figure of the atmospheres of the celestial bodies, with his usual generalization and skill.

On the Limits of the Atmosphere.

(92.) The existence of a definite limit to the altitude of the atmosphere was first conceived by Kepler; and he sought to determine its elevation by means of the duration of the twilight. By an ingenious and interesting process, which most writers on Astronomy explain, it is known to extend to between 40 or 50 miles above the Earth's surface, and even at that altitude it still continues to possess a density sufficient for refracting and reflecting the rays of light.

(93.) The authors* who have written, says Mr. Ivory,† on the height and figure of the atmosphere, have likewise assigned a boundary beyond which it cannot reach. But in this they have rather fixed a limit to the domain peculiarly belonging to the Earth, than reasoned upon any distinguishing properties of the atmosphere itself. If we conceive a body that circulates round the Earth by the force of gravitation, in the time of a diurnal revolution, the path which it describes will mark the limit whereat the centrifugal force arising from the rotatory motion of the Earth will just balance the opposite centripetal force. Therefore any body that participates in the rotatory motion common to all, if placed beyond the boundary we have mentioned, would continually recede from the Earth, and be eventually lost in the immensity of space; or, if placed within the same boundary, would fall to the common centre. The radius of the orbit described by the revolving body is about 25,000 miles, or something more than three diameters of the terrestrial globe. Now the air surrounding the Earth cannot reach so far, for if it did it would be continually dissipated; a supposition which is extremely improbable, since we are acquainted with no source from which a constant waste of so necessary a fluid could be supplied.

Dr. Wollaston's attempt to fix a definite limit to the atmosphere.

The first writer‡ who attempted, from Physical considerations, to fix a definite limit to the atmosphere, was Dr. Wollaston, in the *Philosophical Transactions* for 1822, who remarks in his interesting Paper, that, in attempting to estimate the probable height to which the Earth's atmosphere extends, no phenomenon caused by its refractive power in directions at which we can view it, or by reflection from vapours that are suspended in it, will enable us to determine it. From the law of its elasticity, which prevails within certain limits, we know the degrees of rarity corresponding to different elevations from the Earth's surface; and if we admit that air has been rarefied so as to sustain only $\frac{1}{100}$ of an inch Barometrical pressure, and that this measure has afforded a true estimate of its rarity, we should infer from the law, that it extends to the height of forty miles, with properties yet unimpaired by extreme rarefaction. Beyond

---

* D'Alembert, *Opus*, tom. vi. Laplace, *Mécanique Céleste*, liv. iii. ch. vii.

† *Philosophical Transactions* for 1823.

‡ Mr. Cavendish communicated to Mr. Davies Gilbert, President of the Royal Society, in the year 1808, the substance of a very interesting investigation relative to the definite limits of the atmosphere; but this appears never to have been published.

this limit we are left to conjectures founded on the supposed divisibility of Matter; and if this be infinite, so also must be the extent of our atmosphere. For, if the density be throughout as the compressing force, then must a stratum of given thickness, at every height, be compressed by a superincumbent atmosphere, bearing a constant ratio to its own weight, whatever be its distance from the Earth. But if air consist of any ultimate particles no longer divisible, then must expansion of the medium composed of them cease at that distance, where the force of gravity downwards upon a single particle is equal to the resistance arising from the repulsive force of the medium.

Observations of Mr. Faraday.

(94.) Mr. Faraday, when alluding to the admirable argument of Dr. Wollaston, observes, that on passing upwards from the Earth's surface, the air becomes more and more attenuated, in consequence of the gradually diminishing pressure of the superincumbent part, and its tension or elasticity is proportionally diminished; and when the diminution is such, that the elasticity is a force not more powerful than the attraction of gravity, a limit to the atmosphere must occur. The particles of the atmosphere there tend to separate with a certain force; but this force is not greater than the attraction of gravity, which tends to make them approach the Earth and each other; and as expansion would necessarily give rise to diminished tension, the force of gravity would then be the strongest, and, consequently, would cause contraction, until the powers were balanced as before.

Views of Dr. Wollaston extended to the atmospheres of other bodies.

(95.) Dr. Wollaston, however, has not confined his inquiries to the Earth's atmosphere; and, in extending his views to the probable existence of atmospheres round other bodies, he properly remarks, that since the law of definite proportions discovered by Chemists is the same for all kinds of Matter, whether solid, fluid, or elastic, if it can be ascertained that any one body consists of particles no longer divisible, we then can scarcely doubt that all other bodies are similarly constituted; and that we must conclude, without hesitation, that those equivalent quantities, which we have learned to appreciate by proportional numbers, do really express the relative weights of elementary atoms, the ultimate objects of Chemical research.

Absurdity of attempting to discover an atmosphere of infinite divisibility around the Moon.

(96.) In the first place, the views entertained by those, who, believing in the existence of a terrestrial atmosphere of indefinite extent, sought to discover the existence of an atmosphere of a similar kind round the lunar spheroid, may, from the reasoning of Dr. Wollaston, be proved to be utterly fallacious. For, since the density of an atmosphere of infinite divisibility at the surface of the Moon would entirely depend on her gravitating force at that point, that density could not be greater than the density of our atmosphere at the point where the Earth's attraction is equivalent to the Moon's attraction at her surface. At this height, which by a simple computation is about 5000 miles above the Earth's surface, we obviously can have no perceptible atmosphere, and, consequently, should not expect to discern an atmosphere of similar rarity around the Moon.

Approach of Venus to the Sun proving that no atmosphere of infinite divisibility surrounds the latter.

(97.) In the next place, the approach of Venus to the Sun, if the latter body were surrounded by an atmosphere of infinite divisibility, might be reasonably expected to present some degree of retardation in her apparent motion; whereas, from the very precise and accurate observations of Captain Kater, no such retardation can be perceived. If we calculate at what apparent distance from the body of the Sun his attractive energy is equal to the gravitating influence at the surface of the Earth, it is there that his power would be sufficient to accumulate (from an infinitely divisible medium filling all space) an atmosphere[*] fully equal in density to our own, and, consequently, capable of producing a refraction of more than one degree in the passage of rays obliquely through it.

(98.) By considering the mass of the Sun as 330,000 times greater than that of the Earth, the distance at which his gravitating force will be equivalent to the force of gravity at the surface of the Earth, will be $\sqrt{330,000}$, or, in other words, about 575 times the terrestrial radius; and if the radius of the Sun be 111.5 times that of the Earth, then will the distance here referred to be $\frac{575}{111.5}$, or 5.15 times the solar radius. Now the Sun's apparent semi-diameter on the day of observation (May 23d) having been $15' 49''$, it follows that $15' 49'' \times 5.15 = 1^\circ 21' 29''$ was the distance from the Sun's centre, at which his gravitating force was just equivalent to the ordinary force of gravitation at the Earth's surface.

Strong confirmation afforded by the approach of Jupiter's Satellites t Jupiter, tha the atmosphere of that planet is not one of infinite divisibility.

(99.) But the approach of Jupiter's Satellites to that Planet, instead of being retarded by refraction, is well known to be perfectly uniform, till they appear in actual contact; showing that there is not that extent of atmosphere surrounding Jupiter, which that body should attract to itself from an infinitely divisible medium filling all space. For since the mass of Jupiter is full 309 times that of the Earth, the distance at which his attraction would become equivalent to the ordinary terrestrial gravity, must be as $\sqrt{309}$, or about 17.6 times the Earth's radius. And since his diameter is nearly eleven times that of the Earth, we shall have $\frac{17.6}{11} = 1.6$ times his own radius, for the distance from his centre, at which an atmosphere, equal in density to our own, should occasion a refraction exceeding one degree. To the fourth Satellite, this distance would subtend an angle of about $3^\circ 37'$; so that an increase of density equivalent to 3½ times the density of our ordinary atmosphere, would be more than sufficient to render the fourth Satellite visible to us when behind the centre of the Planet, and, consequently, to make it appear on all sides of the Planet at the same time, or rather as a luminous ring surrounding the entire disc of the Planet.

General conclusion of Dr. W laston respecting th finite extent of the Earth's atmosphere.

(100.) Now, though with regard to the argument respecting the Solar atmosphere, some degree of doubt may be entertained in consequence of the possible effects of heat which cannot be appreciated, it is evident that no error from this source can be apprehended in regard to Jupiter; and as this Planet has certainly not its due share of an infinitely divisible atmosphere, the universal prevalence of such a medium cannot be maintained; while, on the contrary, all the phenomena accord entirely with the supposition that *the Earth's atmosphere is of finite extent, limited by the weight of*

---

[*] Such an atmosphere would, in fact, be of greater density on account of the far greater extent of the medium affected by the Solar attraction, although of extreme rarity; but the addition derived from this source, may be disregarded in the present estimate, without prejudice to the argument, which will not be found to turn upon any minute difference.

ultimate of atoms of definite magnitude no longer divisible by repulsion of their parts.

Mr. Ivory's views on the same subject.

(101.) Mr. Ivory, in a Paper in the *Philosophical Transactions* for 1823, on Astronomical Refractions, in treating of this highly interesting question, conceives a cylinder of air to extend indefinitely in a vertical direction, and to be divided into equal parts of a moderate length, so that the density of every division may be considered as uniform; and by abstracting the diminution of Gravity and the increase of the centrifugal force, which are inconsiderable at the distance of 200 or 300 miles from the Earth's surface, the weight of air in every portion of the cylinder will be proportional to its density. If now, continues Mr. Ivory, we admit the elastic force to be proportional to the density, as it would be in an atmosphere of uniform temperature, it will follow, that the weights of the several divisions of the cylinder will vary in the same proportion as their elasticities. But in the lowest part of the cylinder, the weight of the small quantity of air contained in one division, is incomparably less than its elastic force, which is an equipoise to the whole atmosphere; and the same thing will therefore be true of every portion of the cylinder, however high it is placed. Hence an atmosphere constituted as we have supposed, must necessarily be infinite in its extent. For if it were finite, since there is no pressure at the surface, the weight of a volume of air situated there would be in equilibrium with its elastic force, whereas it has been proved that the former is always an inconsiderable part of the latter.

(102.) But in the foregoing reasoning, says Mr. Ivory, a cause has been neglected which diminishes the elasticity of the air as we ascend above the Earth's surface, without affecting the force of Gravity in any degree. In the higher parts of the atmosphere a continually increasing degree of cold is found to prevail, the effect of which is to contract all bodies in their dimensions; and therefore, by the operation of this cause, as we ascend in the atmosphere, the expansive force of a given volume of air is constantly diminished and brought nearer to an equality with its weight. To estimate this effect with greater precision, let p', z', t', denote the Barometric pressure, the density, and the temperature by the centigrade Thermometer at the Earth's surface; and let the same letters, without the accent, denote corresponding elements at any height x; then if $\beta = \frac{3}{800}$, the expansion for one centigrade degree, the known laws that obtain in the expansion of elastic fluids will lead to this formula, *viz.*

$$\frac{p}{p'} = \frac{1+\beta t}{1+\beta t'} \times \frac{z}{z'}.$$

Now, here it may be remarked, that $\frac{p}{p'}$ is the measure of the elastic force at the height x in parts of the same force at the surface; and we see also that it depends on the temperature, as well as on the relative density $\frac{z}{z'}$. At the Earth's surface the quantity $\frac{1+\beta t}{1+\beta t'}$ is equal to unity, but continually diminishes as the temperature becomes less in ascending. We cannot conceive that it will become negative, nor can any bounds be set to its approach to zero. But when $\frac{1+\beta t}{1+\beta t'}$ is evanescent, or when $t = -266°$, the elastic force of the air will cease, and gravity will stop the further dilatation of the atmosphere. This reasoning, observes Mr. Ivory, is independent of the law of the densities; and it proves both that the atmosphere may be finite in its extent, and that it may have a finite density at its upper surface.

(103.) But it may be objected, that the effect of temperature on the air's elasticity has been verified only to a certain extent; and that in the case of air of a great rarity, and subjected to extreme degrees of cold, the law of dilatation and contraction may be very different from what it has been proved to be in the limited range of our experiments. This observation is probably well founded, but it will not destroy the force of what has been advanced. We know that air always gives out heat when it is compressed into a less volume, and absorbs heat when it expands. As long, therefore, as that fluid retains its elasticity, so long, we must conclude, will temperature continue to modify the changes of bulk which that force produces. The law of dilatation and contraction may, no doubt, undergo some change in different circumstances, but every expansion must be productive of cold, and every new degree of cold must diminish the elastic force of a given volume of air. Gravity continuing to act with nearly the same energy, while the elastic force of the air is continually diminished, these two forces will at length become equivalent, and will counterbalance one another, which is all that is necessary for imposing a limit to the extent of the atmosphere. We have proved, says Mr. Ivory, that air, if it were confined by the action of Gravity alone, would extend indefinitely into space; and it is not unreasonable to consider the effect of temperature as a contrivance for accurately attaching to the terrestrial globe a fluid so necessary in every point of view to the economy of nature.

(104.) Since it is found, continues Mr. Ivory, that all elastic fluids follow the same laws in regard to heat and pressure, the foregoing reasoning will be found equally true, whether we conceive the atmosphere as composed of one homogeneous fluid, or as a collection of many elastic gases and vapours, however much they may differ from one another in Specific Gravity.

His conjecture respecting the altitude of the Earth's atmosphere.

(105.) It may even be possible, adds Mr. Ivory, to form some reasonable conjecture as to the actual height of the finite atmosphere. Gay Lussac ascended in a balloon to the altitude of 3816 English fathoms, or nearly four miles and a quarter above the level of the Seine at Paris; the proportion of the heights of the Barometer in the balloon and at the surface of the Earth being 0.467 nearly, which is therefore the relative elasticity of the air. The temperatures, as observed at the extremities of the elevation, were 30°.8, and −9°.5 on the centigrade scale; and if we increase 0.467 to what it would have been, had the temperature remained unchanged during the ascent, we shall find 0.500 for the density of the air at the height ascended, in parts of the density at the surface of the Earth. Thus, in the decreasing scale of elasticities, the diminution is from 1 to 0.467; but in the decreasing scale of densities, it is only from 1 to 0.500.

The quantities of the one scale continually fall behind those of the other at a rate that must bring them to zero, whatever be the gradation of the latter. If we divide 3816 fathoms, the whole height ascended, by 40°.3 the difference of temperature, the elevation for depressing the Thermometer one degree will come out equal to 95 fathoms; and if we suppose that the same rate prevails in all parts of the atmosphere, the whole height will be 266×95 fathoms, or nearly 29 miles. The observations of the twilight show that this is less than the true altitude; and hence we must infer, that the Thermometer falls at a slower rate in the higher, than in the lower parts of the atmosphere. But, taking the observed rate of 95 fathoms for the first 40 degrees, and allowing, on an average, a double, or even a triple, elevation for the remaining 226°, we shall still find that the atmosphere will extend only to a moderate height above the Earth's surface.

Mr. Dalton's views respecting the finite extent of the atmosphere.

(106.) Mr. Dalton, in a Paper on the constitution of the atmosphere, published in the *Philosophical Transactions* for 1826, and before alluded to, has also referred to its finite extent. He commences his observations by referring to the 23d Proposition of the IId Book of the *Principia*, wherein Newton demonstrates, that if homogeneous particles of Matter were endued with a power of repulsion in the inverse ratio of their central distances, that, collectively, they would form an elastic fluid agreeing with atmospheric air in its mechanical properties. Newton does not, however, infer from this demonstration that elastic fluids must necessarily consist of such particles; and his argument requires that the repulsive power of each particle terminates, or very nearly so, in the adjacent particles.

(107.) From the Scholium to this Proposition, Newton was evidently aware of the difficulty of conceiving how the repulsive action of such particles could terminate so abruptly as his supposition demands; but in order to show that such cases exist in nature, he finds a parallel one in Magnetism.

Principle on which he founds a limit to the atmosphere.

(108.) Following up his reasoning Mr. Dalton observes, that on the hypothesis of the density of any atmosphere diminishing in Geometrical progression to intervals of ascent in Arithmetical progression, every atmosphere must be unlimited, or of infinite extent. But if an atmosphere is constituted of particles on the Newtonian hypothesis, *it must have a limit; and which limit will exist where the repulsion of two particles becomes equal to the weight of one of them.*

Comparison of the relative heights of two atmospheres.

(109.) We have no data, continues Mr. Dalton, from which to determine the *absolute* height above the surface of the Earth to which any one atmosphere can ascend; but we can form a pretty accurate comparison of the *relative* heights to which two atmospheres would ascend, especially if the relative weights of their atoms be known.

(110.) For instance, says he, we know that the diameter of an elastic particle of carbonic acid is nearly, or exactly, the same as that of a particle of hydrogen under the same pressure; also that their weights are as 20 to 1. At two miles' elevation, the elasticity of an atmosphere of carbonic acid gas is diminished one half; and at 40 miles' elevation, that of hydrogen is diminished one half. Now let it be supposed that at 30 miles' elevation the carbonic acid atmosphere ceases to exist, or terminates, at which elevation its elasticity must be, according to the Geometrical progression, nearly $\frac{1}{33000}$; then, by the same law, the elasticity of the hydrogen atmosphere must be $\frac{1}{33000}$ at the height of $15 \times 40 = 600$ miles; also the diameters of the particles of the two gases are still equal at those elevations, because they vary as the cube roots of the elasticities inversely; that is, if the diameters of the particles of carbonic acid and hydrogen at the surface of the Earth be denoted by 1, that of carbonic acid at 30 miles will be represented by $\sqrt[3]{33000}$, and that of hydrogen at 600 miles' elevation will also be $\sqrt[3]{33000}$. But by the hypothesis, this distance is capable of supporting a weight as 20, (namely, the weight of one atom of carbonic acid;) the hydrogen atmosphere, therefore, must be further elevated, till it is capable of supporting a weight only as 1, (namely, the weight of an atom of hydrogen;) this will take place when the elasticity is still further diminished in the ratio of 20^3 to 1^3, or 8000 to 1. Hence, we shall have to extend the atmosphere about $13 \times 40 = 520$ miles further before it can terminate, or the height of 1120 miles. In this estimate we have not taken into consideration the variable force of Gravity. At the height of 1400 miles the force of Gravity is reduced one half, nearly; on this account the elevation of the hydrogen atmosphere will be increased between one and two hundred miles more, so as to make it amount to twelve or thirteen hundred miles. The variation of temperature in ascending does not materially affect Mr. Dalton's views.

(111.) Thus it appears, that, upon the assumption made by the Manchester Philosopher, the hydrogen atmosphere must be 40 times the altitude of the carbonic acid atmosphere. If he had assumed the utmost height of the carbonic acid atmosphere less than 30 miles, the disproportion of the two heights would have been still greater; and if more than 30 miles, it would have been less; but, in this case, the absolute difference would be greater.

(112.) By applying these principles to the terrestrial atmosphere, composed as it is of azote, oxygen, carbonic acid, and aqueous vapour, and fixing the limit of altitude in a full atmosphere (of 30 inches of mercury) of oxygen gas at 45 miles, Mr. Dalton finds that of an atmosphere of the same gas of 6.3 inches of mercury will be found to be about 38 miles, the atom of oxygen being 7; and that of azotic gas of 23.7 inches weight will be found 54 miles, if the atom of azote be taken as 5; but if the atom of azote be double this weight, as is supposed by many, but Mr. Dalton thinks without sufficient reason, then the height of the azotic atmosphere will be only 44 miles. The very fine and attenuated carbonic acid atmosphere must ascend to the height of 10 miles, if a full atmosphere of this gas ascend to 30 miles; and that of aqueous vapour to the height of 50 miles, allowing the Specific Gravity of steam to be .625, and the weight of its atom 8.

Views of Mr. Luke Howard.

(113.) Mr. Luke Howard, in alluding to this interesting subject, remarks, that the surface of the atmosphere is less elevated, and better defined, than many imagine. A portion of air, says he, rarefied by means of the air-pump, does indeed exhibit an elasticity, which seems limited only by the imperfection of the instrument. For the most minute residuum still appears to fill the vessel, and to press against it in all directions. But this is done at a temperature which, compared with that of the extreme boundaries of the atmosphere, is probably that of the steam in a high-pressure engine to the water in a well. We know that, in ascending into the atmosphere, the temperature is found to decrease with the decreasing density of the air; and even under a vertical Sun, between the Tropics, a line of perpetual snow on the mountains indicates a boundary within our reach, which the heat never has ascended in mass to penetrate. There is consequently no source from whence air, conveyed to the summit of the atmosphere, could obtain heat necessary to such extreme rarefaction; the whole sensible heat of the atmosphere being derived originally from the Earth's surface, and distributed in an inverse proportion to the elevation. At an elevation, therefore, not perhaps on a mean more than ten times that of the highest mountains, or fifty miles at the Equator, and considerably less at the Poles, there exists a perpetual zero of temperature, and with it an effectual limit to the further expansion of the atmosphere. Here, the spheroidal body of gases, enveloping our globe, has probably a well-defined surface, (its extent considered,) where the air, though greatly attenuated, is much less rare than we can make it in the receiver of an air-pump; in a word, a fluid, capable of rising and falling, like the waters of the Ocean, by alterations of Gravity.

On the Distribution of Temperature on the Surface of the Earth. Isothermal Lines, &c.

Distribution of heat over the surface of the globe.

(114.) The distribution of heat over the surface of the globe, says Humboldt, belongs to that class of phenomena of which the general principles have long been known, but which were incapable of being submitted to an exact calculation, till experiment and observation had furnished the data from which the theory might obtain the corrections of the different elements it requires.

Connected with the most interesting inquiries.

(115.) An investigation of the temperature of the surface of the globe is a problem connected with the most interesting inquiries. It involves in its consideration the conditions of the arid plains of a tropical climate, where the various orders of vegetable beings are so powerfully influenced by a vertical Sun; or passing from these into the luxuriant regions of the olive and the vine, and to the milder and more uniform temperature of Italy and Spain; and thence again to the variable climates, and the more verdant Kingdoms of the North, until at length we arrive at the region of blighted vegetation, where nothing can exist but the birch and the pine, and the chain of vegetable existence is at last terminated in the hoary desolation of the Arctic Zone.

(116.) Amidst this great circle of Physical changes, the Philosopher looks for materials on which to rear the beautiful theories of his creation; though it is much to be feared, that theoretical considerations have too often usurped the place of the laborious and less inviting task of experimental observation.

(117.) It is a remarkable circumstance in the history of this interesting problem, that Philosophers have been accustomed to consider the distribution of heat in a particular region, as the type of the laws which govern the whole globe; and, in place of estimating the distribution of heat in its general relations to continents and seas, it has been usual to consider as exceptions, every thing which differed from the adopted type; or, by pursuing a method still more dangerous in investigating the laws of Nature, to take the mean temperatures for every five degrees of latitude, and confounding together places under different meridians.

The distribution of heat depends on many causes.

(118.) The distribution of heat depends by its nature on many diversified causes. The Sun may exert its influence on a single point, but that influence will be immediately modified by the influence of local circumstances, and hence the distinction that has for a long time been made between the *solar* and the *real climate* of a place. It will be sufficient to mention, in order to render this distinction evident, how much the temperatures of different latitudes are influenced by the mixture of different winds; the vicinity of seas which are immense reservoirs of an almost invariable temperature; the unequal and varied surface, the Chemical nature, the colour, the radiating power, and the rate of evaporation from the soil; the direction of the chains of mountains, which act either in favouring the play of descending currents, or in affording shelter against particular winds; the shapes of different Countries, their mass and prolongation towards the Poles; the quantity of snow which covers them in winter, their temperature, and their reflection in summer; and, finally, the fields of ice, which form, as it were, circumpolar continents, variable in their extent, and whose detached parts, dragged away by currents, modify in a sensible manner the climate of the temperate zone. These modifying causes will be sufficient to show, that a great and necessary distinction exists between the solar and real climate of a place. We must not, however, forget, that the local and multiplied causes which modify the action of the Sun upon a single point of the globe, are themselves but *secondary* causes, the effects of the motion which the Sun produces in the atmosphere, and which are propagated to great distances.

Halley's theory.

(119.) It is from theory alone that we must expect to determine the distribution of heat over the surface of the globe, so far as it depends on the immediate and instantaneous action of the Sun. In the year 1693, previous to the use of comparable Thermometers, and to precise ideas of the mean temperature of a place, Halley laid the first foundations of a theory of the heating action of the Sun under different latitudes.* He proved that these actions might compensate for the effect of the obliquity of the rays. The ratios which he points out do not, however, express the mean heat of the Seasons, but the heat of a summer-day at the Equator and under the Polar Circles, which he finds to be as 1.834 to 2.310, or as 100 to 127.

Mairan's theory.

(120.) In two Memoirs,† Mairan attempted to solve the problem of the solar action, by treating it in a much more extended and general manner, and for the first time compared the results of theory with those of observation; and as he found the difference between the heat of summer and winter much less than it ought to be by calculation, he recognised the permanent heat of the globe and the effects of radiation. Without mistrusting the observations he employed, he conceived the strange theory of central emanations, which increase the heat of the atmosphere from the Equator to

---

* *Phil. Trans.* for 1693.

† *Mém. de l'Acad.* 1719 and 1765.

the Pole. He supposed these emanations to decrease to the parallel of 74°, where the solar summers attain their maximum, and that they then increase from that latitude to the Pole.

Euler's theory.

(121.) Euler was not more successful than Mairan in his theoretical Essays on the solar heat. He supposed the negative sines of the Sun's altitude during the night to give the measure of the nocturnal cooling, and obtained the extraordinary result,[*] that, under the Equator, the cold at midnight ought to be more rigorous than during winter under the Poles. Fortunately this transcendant analyst attached but little importance to the result, and to the theory from which it was deduced.

Investigations of Lambert.

(122.) Lambert,[†] dissatisfied with the route followed by his predecessors, directed his attention to two very different objects. He investigated analytical expressions for the curves which express the variation of temperature in a place where it had been observed, and resumed in its greatest generality the theorem of the solar action. He gave formulæ, from which he found the heat of any day at all latitudes; but being perplexed with the determination of the nocturnal dispersion of the acquired heat, or the subtangents of the nocturnal cooling, he gave tables of the distribution of heat under different parallels, and in different Seasons, which differ, however, so widely from observation, that it would be difficult to ascribe their deviations to the radiating power of the Earth, or to the influence of disturbing causes.

Of Mayer.

(123.) In 1755, Mayer, the celebrated reformer of the Lunar Tables, published an Essay[‡] essentially differing from those we have quoted, and in which the learned author attempted to deduce the mean heat empirically, by the application of coefficients furnished by observation. We shall hereafter allude more particularly to this interesting performance, when we come to treat of the formulæ of temperature.

Of Kirwan

(124.) Kirwan, in his Work on Climates, and in a learned Meteorological Memoir, contained in the VIIIth volume of the *Memoirs of the Royal Irish Academy*, attempted at first to follow the method pursued by Mayer; but richer in observations than his predecessors, he soon perceived that, after long calcutions, his results agreed ill with observation.[§] In order to try a new method, he selected, in the vast extent of sea, those places whose temperature suffered no change but from permanent causes. These were in that part of the Pacific Ocean comprised between the parallels 45° North and 40° South latitude, and that portion of the Atlantic Ocean, contained between the parallels of 45° and 80°, from the coasts of England to the Gulf Stream. Kirwan also endeavoured to determine, for every month, the mean temperature of these seas in different latitudes; and these results afforded him terms of comparison with the mean temperatures observed on the solid part of the terrestrial globe. But it is easy to conceive, says Humboldt, that this method has no other object, but to distinguish in climates, that is in the total effect of *calorific influences*, that which is due to the immediate action of the Sun on a single point of the globe. Kirwan first considered the Earth as uniformly covered with a thick stratum of water, and then compares the temperatures of this water at different latitudes, with observations at the surface of continents identified with mountains, and unequally prolonged towards the Poles.

(125.) This interesting investigation may enable us, says Humboldt, to appreciate the influence of local causes, and the effect which arises from the position of seas, on account of the unequal capacity of water and Earth for absorbing heat. It is even better fitted for this object, than the method of means deduced from a great number of observations made under different meridians; but in the actual state of Physical knowledge, the method proposed by Kirwan cannot be followed. A small number of observations made far from the coasts, in the course of a month, fixes, without doubt, the mean annual temperature of the sea at its surface; and, on account of the slowness with which a great mass of water follows the changes of the temperature of the surrounding air, the extent of variations in the course of a month is smaller in the Ocean than in the atmosphere. But it is still greatly to be desired,[*] that we should be able to indicate by direct experience, for every parallel and for every month, the mean temperature of the Ocean under the temperate zone.

Of Cotte. Of Humboldt.

(126.) Kirwan was succeeded by many ingenious and interesting writers, among whom may be mentioned the useful and laborious compiler Cotte; but it is to the enlightened and enterprising traveller Humboldt, that we owe our comparatively enlarged notions of the distribution of terrestrial heat. In his Memoir on Isothermal Lines, published in the *Mémoires d'Arcueil*, tom. iii.,[†] he has entered with the utmost generality on the consideration of all the circumstances connected with this interesting inquiry; and in the excellent translation given of it by Brewster, in the early volumes of the *Edinburgh Philosophical Journal*,[‡] that Philosopher justly remarks, "that it must be constantly referred to in all subsequent speculations on Meteorology, and should be familiar to every person who pursues this important study."

His Isothermal lines.

(127.) Humboldt was led to the consideration of this highly interesting subject, by visiting the most elevated plains of the New Continent, and tracing the different vicissitudes of climate existing in the mighty chain of the Cordilleras. To connect the system of climates of the Old World with those of the New, this accomplished traveller endeavoured to find at every 10° of latitude, under different meridians, a small number of places whose mean temperature had been correctly ascertained, and through these, as so many standard points, he supposed his *isothermal lines*, or lines of *equal heat, to pass*. These lines were traced upon a map, in a manner analogous to the ordinary Magnetic lines of dip and variation, and their properties contemplated in

[†] The interesting Papers contained in the *Mémoires d'Arcueil*, owe their origin to a Society of distinguished men, who assembled once a fortnight, at the elegant retreat of the elder Berthollet, in the little village of Arcueil near Paris. The day was spent in perusing the latest Scientific publications, reading and discussing Philosophical papers, projecting new experiments, and in other Philosophical occupations. Besides La Place, who appeared rather as a patron and counsellor, the members consisted of Humboldt, Decandolle, Biot, Gay Lussac, Malus, Thenard, the younger Berthollet, and Collet-Descostils.

[‡] *Edinb. Philosophical Journal*, vols. iii., iv., and v.

a twofold point of view; first with relation to the same *horizontal* plane on the surface of the Earth; and, secondly, as rising on the declivities of mountains in a *vertical* plane, embracing in this comprehensive view, the three rectangular coordinates of latitude, longitude, and elevation above the sea.

Choice of Meteorological positions to enable him to determine the isothermal lines.

(128.) In tracing the courses of these magnificent lines through the different regions of the Earth, the choice of Meteorological positions, and the character of the observations made at them, became of the highest importance. No observations could be adopted, but such as had been spread over a wide surface of time, measured by instruments constructed with Philosophic accuracy, and registered with fidelity and care. Many good observations were rejected, says Humboldt, solely because the absolute height of the place of observation was unknown. This was the case with the observations made in Asia Minor, in Armenia and Persia, and with the greater part of Asia; and at the time that Humboldt wrote, the phenomenon, for such it may with the most perfect truth be called, was presented, of 500 well-determined points in the Equinoctial regions of the New World, the greater number of which were simple villages and hamlets of recent growth, containing only the germs of civilization, whereas the heights of Erzerum, of Bagdad and Aleppo, of Teheran, Ispahan, Delhi, and Lassa, places whose names have been known from a remote antiquity, and associated in our recollections with all the charms of Oriental Poetry and Romance, have their levels above the surrounding seas, and their temperatures at this moment undetermined.

(129.) In another part of our Paper we shall discuss the admirable precautions adopted by Humboldt in taking his averages of temperature, and also in reducing his different temperatures to general expressions. We now proceed at once to trace the course of the *Isothermal lines* on the surface of the globe, and at the level of the sea.

Temperatures not the same under the same parallels.

(130.) A slight attention to the difference of climates, at once reveals that the temperatures are not the same under the same parallels; and that advancing 70° to the East or West, a sensible alteration in the heat of the atmosphere is found. Places situated, however, under the same latitudes do not differ in America and Europe by so many degrees of temperature, as has been commonly supposed.

Remarks on the foregoing Table.

(131.) This Table[*] indicates the difference of climates, expressed by that of mean temperature, and by the number of degrees which it is necessary to go Northward in Europe, in order to find the same quantity of annual heat as in America; and the differences under the column of latitudes, are the differences between the latitude of a place in Europe and a place in America, which have the same mean temperature; and the differences under the column of mean temperatures, are the differences between the mean temperatures of a place in Europe and of one in America, having the same latitude. As a place could not be found in the Old World, whose mean temperature was 48°, the same as that of Williamsburg, Humboldt supplied it with an interpolation between the latitudes of two points, whose mean temperatures are 56°.5, and 59°.4. By an analogous method, and by employing only good observations, he found also:

Position of the Isothermal line of 32°.

1°. *That the Isothermal line of* 32° *passes between Uleo and Enontekies in Lapland, (latitude* 66° *to* 68°, *East longitude, from London,* 19° *to* 22°,) *and Table Bay in Labrador, (latitude* 54°, *West longitude* 58°.)

Of 41°.

2°. *The Isothermal line of* 41° *passes by Stockholm (latitude* 60°, *East longitude* 18°) *and the Bay of St. George in Newfoundland, (latitude* 48°, *and longitude* 59°.)

Of 50°.

3°. *The Isothermal line of* 50° *passes by Belgium (latitude* 51°, *East longitude* 2°) *and near Boston, (latitude* 42° 30′, *West longitude* 70° 59′.)

Of 59°.

4°. *The Isothermal line of* 59° *passes between Rome and Florence, (latitude* 43° 0′, *East longitude* 11° 40′,) *and near Raleigh in North Carolina, (latitude* 36° 0′, *and West longitude* 76° 30′.)

---

[*] See Humboldt's *Prolegomena de distributione geographicâ plantarum, secundum cœli temperiem et altitudinem montium*, p. 68.

The differences afforded by these lines of equal heat.

(132.) The direction of these lines of equal heat, gives for the two systems of temperature known by precise observations, *viz.* part of the middle and West of Europe and that of the coast of America, the following differences:

TABLE XVII.

Latitude.	Mean Temperature of the West of the Old World.	Mean Temperature of the East of the New World.	Difference.
30°	70°.52	66°.92	3°.60
40	63.14	54.50	8.64
50	50.90	37.94	12.96
60	40.64	23.72	16.92

Isothermal lines approach each other towards the South, and converge towards the North.

(133.) In tracing the directions of the Isothermal lines from Europe to the Atlantic Provinces of the New World, they are found to approach each other from parallelism towards the South, and to converge towards the North, particularly between the Thermometric curves of 41° and 50°. In pursuing these lines to the West, the Thermometric means prove that they do not again rise, the quantity of heat which each point of the globe receives under the same parallels being nearly the same on the East and West sides of the Alleghany range.[*] The presence of the *Gleditsia Monosperma*, the *Catalpa*, the *Aristolochia Sypho*, and other vegetable productions several degrees further to the North, in the basin of the Ohio, than on the coast of the Atlantic,[†] led at one time to the supposition, that there was a difference of temperature amounting to three degrees; but Humboldt has now clearly explained, that the migration of vegetables towards the North are favoured in the basin of the Mississippi, by the form and direction of the valley which opens from the North to the South; whereas in the Atlantic Provinces, the valleys are transverse, and oppose great obstacles to the passage of plants from one valley to another.

Other remarks relating to the parallelism of Isothermal lines.

(134.) If the Isothermal lines remain parallel, or nearly so, to the Equator, from the Atlantic shores of the New World to the East of the Mississippi and the Missouri, it cannot be doubted that they rise again beyond the Rocky Mountains, on the opposite coast of Asia, between 35° and 55° of latitude. In New California, the olive is cultivated with success along the Canal of Santa Barbara, and the vine from Monterey to the North of the parallel of 37°, which is that of the Chesapeake Bay. At Nootka, in the Island of Quadra and Vancouver, and almost in the latitude of Labrador, the smallest rivers do not freeze before the month of January. Through 122° 40′ of West longitude, the Isothermal line of 50° of temperature appears to pass almost as in the Atlantic part of the Old World, at 50° of latitude. The Western coasts of the two worlds resemble one another to a certain point.[*] But these returns of the Isothermal lines do not extend beyond 60°. The curve of 32° is already found to the South of the Slave Lake, and it comes still further South in approacing Lakes Superior and Ontario.

The nodes of the Isothermal lin of 55°.4 known round the whole globe.

(135.) In advancing from Europe towards the East, the Isothermal lines again descend,[†] but the number of fixed points are few. The few good materials which Humboldt possesses, have enabled him, however, to trace the curves of 32° and 55°.4; and the nodes of the latter curve are known round the whole globe. It passes to the North of Bourdeaux, (latitude 45° 46′ North, longitude 0° 37′ West,) near Pekin (latitude 39° 54′ North, longitude 116° 27′ East) and Cape Foulweather to the South of the embouchure of the Colombia, (latitude 44° 40′ North, and longitude 104° West,) its nodes being distant at least 162° of longitude.

The Isothe mal line of 32° bears a remarkable analogy to the Magnetic Equator.

(136.) It is worthy of observation, that the position of the Isothermal line of 32° bears a remarkable analogy to the Magnetic Equator, whose singular inflexions in the South Sea create so many diversities in the inclination of the needle. The direction and the inflexions of the curve of 32° influence the neighbouring Isothermal lines, and we may even believe, continues Humboldt, that, in the distribution of climates, the line of 32° determines the curve of greatest heat, creating as it were an *Isothermal Equator*, and that in America and Asia, through 78° of West and 102° of East longitude, the Torrid Zone commences more to the South of the Tropic of Cancer, or that it there presents temperatures of less intensity. An attentive examination of the phenomena, however, proves that this is not the case. Whenever we approach the Torrid Zone below the parallel of 30°, the Isothermal lines become more and more parallel to one another and to the Earth's Equator; and hence Humboldt infers, that the great colds of Canada and Siberia do not extend their action to the Equatorial plains.[‡]

Isothermal Equator.

Partial inflections c Isothermal lines.

(137.) There are partial inflexions of the Isothermal lines, forming systems by themselves, modified by particular local causes. An example of the kind is presented in the strange inflexions of the Thermometric curves on the shores of the Mediterranean, between

---

[*] The following comparison of the mean temperatures has been deduced with great care.

CINCINNATI.		PHILADELPHIA.	
Lat. 36° 6′ N., Long. 84° 24′ W.		Lat. 39° 56′ N., Long. 75° 16′ W.	
Winter	32°.9	Winter	32°.2
Spring	54.1	Spring	51.4
Summer	72.9	Summer	73.9
Autumn	54.9	Autumn	56.5
Mean	53.7	Mean	53.5

[†] Humboldt, *Essai sur la Géographie des Plantes*, p. 154.

[*] On account of the influence of West and South-West winds. See Dalton's *Meteorological Observations*, p. 125.

[†] In comparing places from West to East, and nearly under the same parallel, we find:

WEST.	Lat.	Mean Temp.	EAST.	Lat.	Mean Temp.
St. Malo	48° 39′	54°.5	Vienna	48° 13′	50°.5
Amsterdam	52 21	53.4	Warsaw	52 14	48.6
Naples	40 50	63.3	Pekin	39 54	54.9
Copenhagen	55 41	45.7	Moscow	55 46	40.1
Upsal	59 52	41.9	Petersburgh	59 56	38.8

The elevation of Pekin is inconsiderable. That of Moscow is 984 feet. The absolute temperature of Madrid, to the West of Naples, is 59°; but the city is elevated 1978 feet above the level of the sea.

[‡] If we have long regarded the Old World, says Humboldt, as warmer between the Tropics than the New World, it is first because, till 1760, travellers used Thermometers of spirits of wine, coloured, and affected by light; secondly, because they observed them either under the reflection of a wall, or too near the ground, and when the atmosphere was filled with sand; and thirdly, because, in place of calculating the true *mean*, they used only the Thermometric maximum and minimum.

Marseilles, Genoa, Lucca, and Rome,* and those which determine the difference between the climate of the Western coast and the interior of France. The causes of these aberrations depend much less on the quantity of heat received by a part of the globe during the whole year, than upon the unequal distribution of heat between winter and summer.

Distribution of heat in Isothermal lines.

(138.) The distribution of heat over different parts of the year, differs in the same Isothermal line. This is remarkably exemplified in the succeeding Table :

Table XVIII.—*Differences of the Seasons from the Equator to the Polar Circle.*

Isothermal lines of	Cisatlantic Region. Long. 1° W. and 17° E.			Transatlantic Region. Long. 58°——72° W.		
	Mean Temperature.			Mean Temperature.		
	Winter.	Summer.	Diff.	Winter.	Summer.	Diff.
68°	59°.0	80°.6	21°.6	53°.6	80°.6	27°.0
59	44.6	73.4	28.8	39.2	78.8	39.6
50	35.6	68.0	32.4	30.2	71.6	41.4
41	24.8	60.8	36.0	14.0	66.2	52.2
32	14.0	53.6	39.6	1.4	55.4	54.0

(139.) This Table shows the increase of the difference between the winters and summers from 28° and 30° to the parallels of 55° and 65°. This increase is more rapid in the transatlantic zone, where the Isothermal lines of 32° and 50° approach one another very much; but it is remarkable, that, in the two zones which form the two systems of different climates, the division of the annual temperature between winter and summer is made in such a manner, that upon the Isothermal line of 32°, the difference of the two seasons is almost double that which is observed on the Isothermal line of 68°.

(140.) There are also some differences worthy of examination between the winters and summers, in following the same Isothermal line from West to East. The differences between the seasons of the year are less near the convex summits of the Isothermal curves, where these curves rise again towards the North Pole, than near the concave summits. The same causes which affect the inflection, or the greatest curvature of the Isothermal lines, tend also to equalize the temperatures of the seasons.

(141.) The whole of Europe, says Humboldt, compared with the Eastern parts of America and Asia, has an insular climate, and, upon the same Isothermal line, the summers become warmer and the winters colder, as we advance from the meridian of Mont Blanc towards the East or West. Europe may be considered as the Western prolongation of the Old Continent; and the Western parts of all continents are not only warmer at equal latitudes than the Eastern parts, but even in the zones of equal annual temperature, the winters are more rigorous, and the summers hotter on the Eastern coasts than upon the Western coasts of the two continents. The Northern part of China, like the Atlantic region of the United States, exhibits seasons strongly contrasted,* while the coasts of New California, and the embouchure of the Colombia, have winters and summers almost equally temperate. The Meteorological constitution of these countries in the North-West, resembles that of Europe as far as 50° or 52° of latitude. In comparing the two systems of climates, the concave and convex summits of the same Isothermal lines, we find at *New York*, the summer of *Rome* and the winter of *Copenhagen ;* at *Quebec*, the summer of *Paris* and the winter of *Petersburgh*. At *Pekin*, also, where the mean temperature of the year is that of the coasts of *Brittany*, the scorching heats of summer are greater than at *Cairo*, and the winters as rigorous as at *Upsal*.

Mean temperature of the year on the same Isothermal line.

(142.) The mean temperature of the year being equal to the fourth part of the winter, spring, summer, and autumnal temperatures, we shall have upon the same Isothermal line of 53°.6,

At the *concave* summit in America, 74° 40′ W. long. $$53^\circ.6=\frac{32^\circ+52^\circ.3+75^\circ.6+54.^\circ5}{4}.$$

At the *convex* summit in Europe, 2° 20′ West long. $$53^\circ.6=\frac{40^\circ.1+51^\circ.8+68^\circ.4+54^\circ.1}{4}.$$

At the *concave* summit in Asia, 116° 20′ East long. $$53^\circ.6=\frac{-24^\circ.8+54^\circ.7+80^\circ.6+54^\circ.3}{4}.$$

Analogy between the Eastern coasts of Asia and America.

(143.) This analogy between the Eastern coasts of Asia and America sufficiently proves, says Humboldt, that the inequalities of the seasons depend on the prolongation and enlargement of continents towards the Pole; of the size of seas in relation to their coasts; and on the frequency of the North-West winds, which are the *Vents de Remous* of the Temperate Zone, and not on the proximity of some plateau or elevation of the adjacent lands. The great plateaus of Asia do not stretch beyond 52° of latitude; and, in the interior of the New Continent, all the immense basin bounded by the Alleghany range, and the rocky mountains, and covered with secondary formations, is not more than from 656 to 920 feet above the level of the Ocean, according to the levels taken in Kentucky, on the banks of the Monongahela, at Lake Erie.

(144.) The following Table indicates, for all the habitable parts of the Temperate Zone, the division of the same quantity of annual heat between the seasons of summer and winter. The numbers which it contains, says Humboldt, are either the result of direct observations, or of interpolations between a great number of observations made in neighbouring places, and situated under the same meridian. Humboldt traced each Isothermal curve from West to East, giving the preference to places situated near the summits of the curve, as presenting at the same time the greatest differences in the distribution of the annual heat. The longitudes are reckoned from the Observatory at Greenwich.

Determinate type for the division of Heat.

(145.) It is impossible to examine the preceding Table without observing, that the division of the annual heat between summer and winter follows, on each Isothermal line, a determinate type; that the deviations of that type are contained between certain limits, and that they obey the same law in the zones which pass by the concave or convex summits of the Isothermal lines: for example, by 58°—68° of West longitude, and 116° of East longitude.

(146.) The following Table shows the oscillation, or the *maxima* and *minima*, observed in the division of the heat between the seasons. Humboldt has also added to it the means of the winters and summers found at different degrees of longitude, and under the same Isothermal line.

TABLE XX.

Isothermal Lines.	Degrees of Longitude examined.	Oscillations observed in the Means.		Means calculated.	
		Winters.	Summers.	Winters.	Summers.
32°	83	3°.2 to 24°.8	51°.8 to 53°.6	14°.0	52°.7
41	107	14.0 24.8	62.6 68.0	19.4	65.3
50	200	23.0 37.4	62.6 78.8	30.2	70.7
59	87	39.0 44.6	75.2 77.0	41.9	75.2
68	84	53.6 59.0	71.6 80.6	56.3	77.9

Isocheimal lines.

(147.) If we endeavour to discover on *different* Isothermal lines, points at which equal degrees of *winter* temperature prevail, a new system of lines will be created, which have been denominated *Isocheimal lines*. In Europe, it has been found that these *Isocheimal lines* cut systems of *Isothermal lines* which are 9° distant; and hence it is that the Isocheimal lines deviate much more than the Isothermal lines from the terrestrial parallels. The latitudes of two places that have the same annual temperature cannot differ more than from 4° to 5°, while two places, whose mean winter temperature is the same, may differ more than 9° or 10° of latitude. The further we advance to the East, the more rapidly these differences increase.

Isotheral lines.

(148.) If, again, we connect on *different* Isothermal lines, points at which equal degrees of *summer* temperature prevail, another system of lines will arise, which have been denominated *Isotheral lines*. These *Isotheral lines* are found to follow a direction exactly contrary to the *Isocheimal lines*. The same summer temperature prevails at Moscow, in the centre of Russia, as towards the mouth of the Loire, notwithstanding a difference of 11° of latitude,—the effect of the Earth's radiation on a vast continent deprived of mountains.

Temperature as it affects vegetable produce.

(149.) It would be interesting to our readers, and to ourselves, did our limits permit, to follow Humboldt through the whole of his inquiries respecting the connection of the Isothermal lines with the varied productions of the vegetable world; to trace the temperatures necessary for the coffee-tree, the olive, and the vine, or the different conditions of the atmosphere which the varieties of grain require. We may, however, remark, that the olive is cultivated in our continent between the parallels of 36° and 44°, wherever the annual temperature is from 62°.6 to 58°.1, and where the mean temperature of the coldest month is not below 41°.0 or 42°.8, and that of the whole summer 71°.6 or 73°.4. The region of potable wines extends in Europe between the Isothermal lines of 62°.6 and 50°, which correspond to the latitudes of 36° and 48°. The cultivation of the vine extends, though with less advantage, even to countries whose annual temperature descends to 48°.2 and 47°.48; that of winter to 33°.8, and that of summer to 66°.2 and 68°. These Meteorological conditions are fulfilled in Europe as far as the parallel of 50°, and a little beyond it. In America, they do not exist further North than 40°. On the continent of Western Europe, the winters, whose mean temperature is 32°, do not commence till on the Isothermal lines of 48°.2 and 50°, in from 51° to 52° of latitude; while in America, we find them already on the Isothermal lines of from 51°.8 to 53°.6, under from 40° to 41° of latitude.

(150.) In all places whose mean temperature is below 62°.6, the revival of nature takes place in Spring, in that month whose mean temperature reaches 42°.8, or 46°.4. When the temperature of a month

rises to { 41°.9, the Peach tree (*Amygdalus Persica*) flowers.
46°.8, the Plum tree (*Prunus domestica*) flowers.
51°.8, the Birch tree[*] (*Betula alba*) pushes out its leaves.

Barley, in order to be cultivated advantageously, requires, during ninety days, a mean temperature of from 47°.3 to 48°.2.[†] By adding the mean temperature of the months above 51°.8, that is, the temperatures of those in which deciduous trees vegetate, we shall have a sufficiently exact mean of the continuance and strength of vegetation. As we advance towards the North, the duration of vegetable life is confined to a shorter interval. In the South of France, there are 270 days of the year in which the mean temperature exceeds 51°.8; that is to say, the temperature which the birch requires to put forth its first leaves. At St. Petersburgh, the number of these days is only 120. These two *cycles of vegetation*, so unequal, have a mean temperature which does not differ more than 5°.4.[*]

Method of determining the exact mean of the continuance and strength of vegetation.

(151.) The whole of the preceding observations, it will have been perceived, relate to the temperature of that part of the lower strata of the atmosphere resting on the solid surface of the globe, in the Northern hemisphere, and it now remains to follow the steps of Humboldt in his interesting inquiries respecting the temperature of the Southern Hemisphere.

Temperature of the Southern hemisphere.

(152.) In few departments of Natural Philosophy have Philosophers differed more widely in opinion, than in the comparison of the temperatures of the two hemispheres. From the beginning of the XVIth century, the notion prevailed that the Southern hemisphere was by far the coldest. Mairan and Buffon[†] combated this opinion theoretically, but on inaccurate grounds. Æpinus[‡] established it anew; and the discovery of the vast extent of ice round the Southern pole by the immortal Cook, appeared to widen the difference between these comparative temperatures. Le Gentil, and, particularly, Kirwan,[§] had the merit of having first demonstrated, that the influence of the circumpolar ice extended much less into the temperate zone than was generally admitted. The less distance of the Sun from the winter solstice, and his long continuance in the Northern Signs, act in an opposite manner[‖] on the temperature of the two hemispheres; and as Lambert has demonstrated in his theorem, that the quantity of light which a Planet receives from the Sun increases in proportion to the true anomaly, the different temperatures of the two hemispheres cannot be the effect of unequal radiation. The Southern hemisphere receives the same quantity of light, but the accumulation of heat in it is less,[¶] on account of the emission of the radiant heat which takes place during a long winter. This hemisphere being also in a great measure covered with water, the pyramidal extremities of the continents have there an irregular

---

[*] The geographical distribution of insects, also, may be made to illustrate the general phenomena of temperature and climate. Latreille has remarked, in his *Introduction à la Géographie Générale des Arachnides et des Insectes, ou des Climats propres à ces Animaux*, that the *temperature* adapted to the developement of one species, is not always proper for that of another; and the *extent* of country which certain species occupy, has necessarily *determinate limits* which they cannot exceed, at least suddenly, without ceasing to exist. The Southern insects of the Western Hemisphere, do not extend so far to the North as in the Eastern. The intelligent Entomologist ought always to take into consideration the height above the sea of the places in which he collects his specimens, and likewise their *mean temperature*, and it may be added, to record precisely their geographical positions.

climate. Summers of a very low temperature are succeeded, as far as 50° of South latitude, by winters far from rigorous. The vegetable forms also of the torrid zone, says Humboldt, the arborescent ferns, and the orchideous parasites, advance towards 38° and 42° of South latitude. The small quantity of land in the Southern hemisphere,* contributes not only to equalize the seasons, but also to diminish the annual temperature of that part of the globe. This cause, Humboldt thinks, is much more active than that of the small eccentricity of the Earth's orbit. The continents in summer radiate more heat than the seas, and the ascending current, which carries the air of the equinoctial and temperate zones towards the circumpolar regions, acts less in the Southern than in the Northern hemisphere. The cap of ice which surrounds the Pole to the seventy-first and sixty-eighth degree of South latitude, advances more towards the Equator, whenever it meets a free sea; that is, wherever the pyramidal extremities of the great continents are not opposed to it. There is reason, Humboldt thinks, to believe, that this want of dry land would produce an effect still more sensible, if the division of the continents was as unequal in the equinoctial as in the temperate zones.†

The difference of temperature between the two hemispheres, cannot be great near the limit which separates them.

(153.) Theory and experience prove, that the difference of temperature between the two hemispheres, cannot be great near the limit which separates them.‡ Le Gentil had already observed, that the climate of Pondicherry is not warmer than that of Madagascar, at the Bay of Antongel, in 12° of South latitude. Under the parallels of 20, the Isle of France has the same annual temperature, *viz.* 80°.1, as Jamaica and St. Domingo. The Indian Sea between the East coasts of Africa, the Isles of Sonde and New Holland, form a kind of gulf which is shut up to the North by Arabia and Hindostan. The Isothermal lines there appear to go back to the South Pole; for further to the West, in the open sea between Africa and the New World, the cold of the Southern hemisphere already causes itself to be felt from the twenty-second degree, on account of insulated mountains and particular localities. The mean temperature of Rio Janeiro is only 74°.3, whilst, notwithstanding the North winds which bring the cold air of Canada during winter into the Gulf of Mexico, the mean temperatures of Vera Cruz (lat. 19° 11′) and of the Havannah (lat. 23° 10′) are 77°.9. The differences of the two hemispheres become more sensible in the warmest months.

TABLE XXI.

RIO JANEIRO.	Mean Temp.	HAVANNAH.	Mean Temp.
June	68°.0	December	71°.8
July	70.2	January	70.2
January	79.2	July	83.3
February	80.6	August.	83.8

Equality in the division of annual heat, in 34° of North and South latitude.

(154.) The great equality in the division of annual heat in 34° of North and South latitude, is, as Humboldt remarks, very surprising. If we attend to the three continents of New Holland, Africa, and America, we shall find, that the mean temperature of Port Jackson (lat. 33° 51′) is, after the observations of

Hunter, Peron, and Freycinet	66° 7
That of the Cape of Good Hope (lat. 33° 53′)	66.9
That of the City of Buenos Ayres (lat. 34° 36′)	67.5

Two particular temperatures correspond to the same latitude in the Northern hemisphere, according as we compare the concave or convex parts of the Isothermal lines.

(155.) Again, 60°.8 or 69°.8 of annual temperature corresponds to the same latitude in the Northern hemisphere, according as we compare the American* system of climates or the Mediterranean one;—the concave or the convex parts of the Isothermal lines. At Port Jackson, where the Thermometer descends sometimes below the freezing point, the warmest month is 77°.4, and the coldest 56°.8. We find here, continues Humboldt, the summer of Marseilles and the winter of Cairo.† In Van Diemen's Land, corresponding nearly in latitude to Rome, the winters are more mild than at Naples; but the coldness of the summers is such,‡ that the mean temperature of the month of February appears to be scarcely 64°.4, or 66°.2; whilst at Paris, under a latitude more distant from the Equator by 7°, the mean temperature of the month of August is also from 64°.4 to 66°.2, and at Rome above 77°. Under the parallel of 51° 25′ South, the mean temperature of the Malouine Isles is ascertained to be 47°.3. At the same latitude North, we find the mean temperature in Europe from 50° to 51°.8, and in America scarcely from 35°.6 to 37°.4. The warmest and coldest months are at London 66°.2 and 35°.6; at the Malouine Isles 55°.8 and 37°.4. At Quebec, the mean temperature of the water is 14°; at the Malouine Isles 39°.6, though those isles are 4° of latitude further from the Equator than Quebec. These numerical ratios prove, says Humboldt, that, to the parallels of 40° and 50°, the corresponding Isothermal lines are almost equally distant from the Pole in the two hemispheres; and that, in considering only the system of transatlantic climates between 70° and 80° of West longitude, the mean temperatures of the year, under the corresponding geographical parallels, are even greater in the Southern than in the Northern hemisphere.

The division of heat between different parts of the year, gives a particular character to Southern climates.

(156.) The division of heat between the different parts of the year, gives a particular character to Southern climates. In the Southern hemisphere, on the Isothermal lines of 46°.4 and 50°.0, we find summers which in our hemisphere belong only to the Isothermal lines of 35°.6 and 40°.0. The mean temperature is not precisely known beyond 51° of South latitude, but it may be observed, that the eternal snows, which in 71° of North latitude support themselves at the height of 2296 feet above the level of the sea, descend even into the plains, both in South Georgia§ and in Sandwich Land, in 54° and 58° of

---

* Humboldt calculates that the dry lands in the two hemispheres are in the ratio of 3 to 1.

† Humboldt remarks, that the dry lands between the tropics are in the two hemispheres as 5 to 4, and without the tropics as 13 to 1.

‡ In Van Diemen's Land the Thermometer descends in February, in the morning, to 45°.5. The mean of mid-day is 60°.8. At Paris it is in August 73°.4. In Van Diemen's Land, in February the mean of the maxima is 78°.8; of the minima 54°.5. At Rome these means are 86° and 64°.5. D'Entrecasteaux, *Voyage*, tom. i.

§ It is the more surprising, says Humboldt, to find, in the Island of Georgia, snow on the banks of the Ocean, because 2° 39′ nearer the Equator, at the Malouine Isles, the mean temperature of the summers is 53°.1, or 9° greater than at the point in our hemisphere in 71° of

South latitude. But these phenomena, however striking they may appear, do not by any means prove that the Isothermal line of 32° is 5° nearer the South Pole than the North Pole. Nor would an equal altitude of the line of perpetual snow in both hemispheres by any means indicate an equal mean temperature of the year. This limit depends particularly[*] on the coldness of summer, and this again on the quick condensations of the vapour caused by the passage of the floating ice. Near the Poles, the foggy state of the air diminishes in summer the effect of the solar irradiation, and in winter that of the radiation of the globe.

Lower strata of the atmosphere is influenced by it.

(157.) The lower strata of the atmosphere, resting upon the aqueous surface of the globe, receive the influence of the temperature of the waters. The sea radiates less absolute heat than the continents; it cools the air by the effect of evaporation; it sends the particles of water cooled and heavier towards the bottom; and it is heated again, or cooled, by the currents directed from the Equator to the Poles, or by the mixture of the superior and inferior strata on the sides of banks.

The mean temperature of the air next the sea, is lower than that of the continental air.

(158.) It is from these causes combined, that, between the tropics, and, perhaps, as far as 30° of latitude, the mean temperatures of the air next the sea are 3°.6 or 5°.4 lower than that of the continental air. Under high latitudes, and in climates where the atmosphere is coolest in winter, much below the freezing point, the isothermal lines rise again towards the Poles, or become convex when the continents pass below the seas.[†]

Four different phenomena of the temperature of the Ocean

(159.) With respect to the temperature of the Ocean, Humboldt refers to four very different phenomena:

1st. The temperature of the water at the surface corresponding to different latitudes, the Ocean being considered at rest, and destitute of shallows and currents.

2d. The decrease of heat in the superimposed strata of water.

3d. The effect of billows on the temperature of the surface of water.

4th. The temperature of currents, which impel, with an acquired velocity, the waters of our zone across the immovable waters of another zone.

Zone of warmest waters.

(160.) The region of warmest waters, observes Humboldt, no more coincides with the Equator than the region in which the waters reach their maximum of saltness. In passing from one hemisphere to another, we find the warmest water between 5° 45′ of North latitude, and 6° 15′ of South latitude. Perrins found their temperature to be 82°.3, Quevedo 83°.5, Churruca 83°.7, and Rodman 83°.8. To the East of the Galapagos Isles, Humboldt found it to be 84°.7. The variations of the mean result do not extend beyond 1°.3; and it is remarkable, as Humboldt observes, that in the parallel of warmest waters, the temperature of the surface of the sea is from 3°.6 to 5°.4 higher than that of the superincumbent air. As we advance from the Equator through the torrid zone, the influence of the seasons on the temperature of the surface of the sea becomes very sensible; but as a great mass of water follows very slowly the changes in the temperature of the air, the means of the months do not correspond at the same epochs in the Ocean and in the air. Besides, the extent of the variations is less in the water than in the atmosphere, because the increase or decrease in the heat of the sea takes place in a medium of variable temperature; so that the *minimum* and the *maximum* of the heat which the water reaches, are modified by the atmospherical temperature of the months which follow the coldest of the warmest months of the year. It is from an analogous cause, continues Humboldt, that in springs which have a variable temperature, for example, near Upsal,[*] the extent of the variations of temperature is only 19°.8, while the same extent in the air from the month of January to August, is 39°.6. In the parallel of the Canary Islands, Von Buch found the minimum of the temperature of the water to be 68°, and the maximum 74°.8. The temperature of the air in the warmest of the coldest months, is, in that quarter, from 64°.4 to 75°.2. In advancing towards the North, we find still greater differences of winter temperature between the surface of the sea and the superincumbent air. The cooled particles of water descend till their temperature reaches 39°.2, the point at which water attains its maximum of density; and hence in 46° and 50° of latitude, in the part of the Atlantic which is nearest to Europe, the *maximum* and *minimum* of heat are

In the water at its surface	68°.0 and 41°.9
In the air from the mean of the warmest and coldest months..........................	66°.2 and 35°.6

The excess in the mean temperature of the water over that of the air, attains its maximum beyond the Polar circle, where the sea does not wholly freeze. If it is true that even in these high latitudes the bottom of the sea contains strata of water which, at the maximum of their Specific Gravity, have 39°.2, or 41° of heat, we may suppose that the water at the bottom contributes to diminish the cooling at the surface. These circumstances have a great influence on the mildness of countries in continents separated from the Pole by an extensive sea.

Temperature of the upper regions of the air.

(161.) We must hasten, however, to conclude this very interesting part of our Essay, by a few observations concerning the distribution of temperature in the upper regions of the air, reserving our remarks respecting the gradations of temperature in ascending to the upper regions of the atmosphere.

Peculiarity of inflexions of Isothermal lines.

(162.) Since the heat of the higher regions of the atmosphere depends on the radiation of the plains, we cannot find under the same geographical parallels, in the transatlantic climates, the Isothermal lines at the same height above the level of the sea, as in the system of European climates. The inflexions which these lines experience, when traced on the surface of the globe, necessarily influence their position in a vertical plane, whether we unite points in the atmosphere placed under the same meridians, or consider only those that have the same latitude. Future inquiries may enable us to trace the Isothermal lines through the different regions of the air; and we may briefly remark, that on the back of the Cordilleras, at 2000 metres of elevation, we find the mean temperature of

---

latitude, where the limit of perpetual snow exists at 2296 feet of absolute elevation. But it must be observed, first, That the Malouine Isles are near a continent which is heated in summer. Secondly, That Georgia is covered with mountains, and placed not only in a sea open to the North, but is also under the influence of the perennial ices of Sandwich Land. Thirdly, That in Lapland 20° of latitude produce, in certain local circumstances, 10°.8 of difference in the temperatures of the summers.

[*] Baron Von Buch's *Travels in Lapland*, vol. ii.

[†] Humboldt's *Relat. Histor.* tom. i. p. 67. 230. 242.

[*] Gilbert's *Annalen*, 1812, p. 129.

Calabria and of Sicily. In our temperate zone, in 46° of latitude, we meet, at the same elevation, with the mean temperature of Lapland. In the plains of the Orinoco we find the temperature of the month of August of Rome; at Popayan (2988 feet) the temperature of the same month of Paris; at Quito (4894 feet) that of the month of May; and in the Paramos (5904 feet) the temperature of March, at the same city.

(163.) Humboldt also finds, in prosecuting this interesting inquiry, that every hundred metres of perpendicular height diminishes the mean temperature of the year, by the same quantity that a change of 1° of latitude does in advancing towards the Pole. If we compare only the mean temperature of summer, the first 1000 metres are equivalent to 0°.81 Fahrenheit. From 40° to 50° of latitude, the mean heat of the plains in Europe decreases 12°.6 of Fahrenheit; and this same decrease of temperature takes place on the declivity of the Swiss Alps from 0 to 1000 metres of elevation.

(164.) In the following Table of the distribution of heat, which embraces a general view of Humboldt's results, the temperatures are expressed in degrees of Fahrenheit; the longitudes are reckoned from East to West of the meridian of Greenwich. The mean temperatures of the Seasons have been calculated, so that those of the months of December, January, and February, form the mean temperature of winter. An asterisk (*) is prefixed to those places whose mean temperatures have been most accurately determined, in general, by means of 8000 observations. The Isothermal lines have a convex summit in Europe, and two concave summits in Asia and Eastern America.

General Table of Humboldt's results.

On the Mean Temperature of the Equator.

(165.) The determination of the mean temperature of the Equator,* is a Meteorological element of the greatest importance and value. If we survey the magnificent line to which this part of our inquiry extends, we shall immediately perceive that many obstacles, besides those of a Physical kind, present themselves at the very threshold of our investigation. In the Equatorial regions of America, it passes through a region almost unknown, and in which the light of civilization and liberty has been but recently kindled; and in its passage across the still more inhospitable deserts of Africa, obstacles still more formidable are presented. Nor would observations at Sumatra, Borneo, Celebes, and Gilolo, unless made on a very extended scale, and under circumstances variously modified, determine, with any tolerable approach to precision, the average temperature of this great line. The Ocean, too, occupies by far the greatest portion of the Equatorial regions, the land occupying but 80 degrees of the great circle, and water the remaining portion of 280 degrees. Under these circumstances, we cannot feel surprised at the remark made by Humboldt, that at the present day we are not acquainted with more than one mean temperature observed with any degree of precision between the parallels of 3° North and 3° South, and that is of St. Louis de Maranham in Brazil, 2° 29′ South latitude, made by Colonel Antonio Pererira. Deprived thus of actual observations at the Equator, Philosophers have endeavoured to deduce its mean temperature from observations made at a distance from it. Mayer, for example, by knowing the mean temperature under two different parallels, endeavoured by means of an empirical equation to deduce the mean Equatorial temperature. This he estimated at 84°, and in this value he was followed by Kirwan.

Known only between the parallels of 3° North, and 3° South.

(166.) But it is evident, that observations made in the temperate regions of Europe, could not supply the mean temperature of a line, situated so remotely from them, and it became therefore desirable to collect the mean temperatures of places situated as nearly as possible to it. Accordingly Humboldt collected his elements in the Old and New World, and among them are the following:

Humboldt's observations.

TABLE XXIII.

Old World.	Latitude.	Mean Temp.	New World.	Latitude.	Mean Temp.
Senegambia ..	15° 0′	79°.07	Cumana	10° 27′	81°.86
Madras......	13 5	80.42	Antilles......	17 0	81.05
Batavia......	6 12	80.42	Vera Cruz....	19 11	78.08
Manilla......	14 36	78.08	Havannah....	23 10	78.08

(167.) From a review of all the circumstances connected with these places, Humboldt was led to adopt 81°.5 as the mean temperature of the Equator; and our learned contemporary, Dr. Brewster, employed it, with some modifications, as the coefficient of his formula for mean temperature. In the second volume of the *Transactions of the Astronomical Society of London*, however, Mr. Atkinson, in an elaborate Paper on Astronomical and other Refractions, has questioned the accuracy of Humboldt's conclusion; and we shall, therefore, present to our readers the grounds of his objections.

(168.) Let t, t', t'', represent, says Mr. Atkinson, the observed mean temperatures in the latitudes l, l', l'', &c.; and if the mean temperature be supposed to vary as any function $\varphi\,(l)$ of the latitude, we shall obtain the following equations:

Doubted by Mr. Atkinson.

$$\begin{aligned} x \,.\, \varphi\,(l) + z &= t \\ x \,.\, \varphi\,(l') + z &= t' \;..........\; \text{(A)} \\ x \,.\, \varphi\,(l'') + z &= t'', \\ \text{\&c.} \qquad & \text{\&c.} \end{aligned}$$

x and z being unknown, but constant quantities, to be determined from the equations.

---

* The determination of what may with propriety be termed an *Isothermal Equator*, or *Curve of greatest heat*, will, if the future progress of Meteorology be successful, open a beautiful and instructive object of inquiry.

(169.) If the form of the function (φ) were rightly assumed, and the observations made of the temperature were accurate, the resolution of any two of the above equations would determine the values of x and z. Neither of these conditions can, however, be fulfilled with accuracy, and we must therefore be contented with a close approximation. To accomplish this, we must first observe that the difference between the first and second equations gives

$$x\{\varphi(l) - \varphi(l')\} = t - t',$$

from which we deduce

$$x = \frac{t - t'}{\varphi(l) - \varphi(l')} \dots\dots\dots (B).$$

This value for x being substituted in the first equation, we obtain by transposition

$$z = t - \frac{(t - t') \cdot \varphi(l)}{\varphi(l) - \varphi(l')} \dots\dots\dots (C).$$

(170.) Hence the values both of x and z being found in functions of the observed temperature, will furnish the necessary elements for the determination of the function (φ). This function, however, is probably of a complicated nature, it being obvious that the mean temperature of any place must be influenced by the state of those countries from which the prevailing winds at that place blow;—by the extent and nature of the land that surrounds it, by the proximity of open seas, or of seas that are frozen, and by a variety of other causes. The obliquity of the Sun's rays is, however, the principal cause of the diminution of temperature, as we proceed from the Equator towards either Pole; but this obliquity is dependent on the latitude; and hence we may consider the variation in the temperature, as some function of the latitude, as has already been done in the equations of condition, and afterwards endeavour to estimate what correction must be applied on account of such disturbing causes, as may exist in the place selected for consideration. Or, if we have a sufficient number of good observations within a given district, we may, says Mr. Atkinson, by a judicious application of the powers of calculation, deduce a formula, which shall present in its results a near approximation for any other place within the same district, and which may even be extended beyond it, without producing any material error.

(171.) If now we suppose with Humboldt, that $\varphi(l) = \cos^2 l$,* the equations before deduced for the values of x and z, will assume the forms of

$$x = \frac{t - t'}{\cos^2 l - \cos^2 l'}$$

and

$$z = t - \frac{(t - t')\cos^2 l'}{\cos^2 l - \cos^2 l'};$$

and if we apply these equations to the mean temperatures of Cumana and Fort Churchill, as recorded by Humboldt in his Paper on Isothermal lines, the values of which are respectively 81°.86, and 25°.3, we shall obtain for x the value of 80°.53, and for z that of 3°.98 nearly.

(172.) These values being substituted in the general equation, give

$$80^\circ.53 \cos^2 l + 3^\circ.98 = t;$$

so that when the latitude vanishes, the value of t becomes

$$80^\circ.53 + 3^\circ.98 = 84^\circ.51,$$

which is hence the mean temperature of the Equator according to the observations made at Cumana and Fort Churchill. If, again, we suppose the value of l to be 90°, we obtain for the mean temperature of the pole 3°.98.

Mr. Atkinson's observations.

(173.) Mr. Atkinson next endeavours to obtain a formula of the same kind by means of the four observations contained in the following Table, drawn from the same Paper of Humboldt.

TABLE XXIV.

Names of Places.	Latitude.	Mean Temperature.
Cumana	10°27′	81°.86
Antilles	17 0	81.05
Vera Cruz	19 11	78.08
Havannah............	23 10	78.08

and for this purpose, he assumes

$$(80^\circ.53 + x')\cos^2 l + 3^\circ.98 + z' - t = \mathrm{E},$$

some unknown error, x' and z' being corrections so adapted to the formula, as to make it agree with the temperatures of the places last recorded. Applying this formula to each, we shall obtain the following equations of condition:

$$.967\,x' + z' + 0^\circ.00 = \mathrm{E}'$$

$$.915\,x' + z' - 3.42 = \mathrm{E}''$$

$$.892\,x' + z' - 2.27 = \mathrm{E}'''$$

$$.845\,x' + z' - 6.03 = \mathrm{E}'''',$$

and if we regard the sum of the squares of the errors E′, E″, E‴, E⁗, as a minimum, and deduce the values of x' and z' according to the method of minimum squares, we shall have $x' = -40.664$, and $z' = 89.72$. Hence the formula which best represents the observations made at Cumana, the Antilles, Vera Cruz, and the Havannah, if the law of variation be as $\cos^2 l$, is

$$39^\circ.866 \cos^2 l + 43^\circ.7 = t.$$

This will give for the mean temperature of the Equator, where l vanishes, $t = 83^\circ.566$; and for the Pole, when the $\cos l$ becomes zero, $t = 43^\circ.7$; a result altogether inadmissible, since it makes the temperature of the Pole 5°.8 greater than that of Quebec. Both the numerical elements of the formula require therefore modification.

(174.) To obtain a formula which shall agree with as many places as possible between Cumana and Fort Churchill, Mr. Atkinson presents the following equations of condition.

---

* Mr. Atkinson found it necessary to adopt the same law of variation for the temperature as that employed by Humboldt.

TABLE XXV.

Names of Places.	North Latitude.	Equations of Condition.	Observed Mean Temperature.	Temperature by the Formula.	Difference.*
Cumana	10° 27′	$.967\,x'+z'+0°.00=E^{\text{i}}$	81°.86	85°.26	+3°.40
Antilles	17 0	$.915\,x'+z'-3.42=E^{\text{ii}}$	81.05	80.79	−0.26
Vera Cruz	19 11	$.892\,x'+z'-2.27=E^{\text{iii}}$	78.08	78.88	+0.80
Havannah	23 10	$.846\,x'+z'-6.03=E^{\text{iv}}$	78.08	74.91	−3.17
Natchez	31 28	$.728\,x'+z'-2.23=E^{\text{v}}$	64.80	64.91	+0.11
Philadelphia	39 56	$.588\,x'+z'-3.57=E^{\text{vi}}$	54.90	53.06	−1.84
Cincinnati	39 6	$.602\,x'+z'-1.12=E^{\text{vii}}$	53.60	54.28	+0.68
New York	40 40	$.575\,x'+z'-3.49=E^{\text{viii}}$	53.80	51.99	−1.81
Cambridge	42 25	$.545\,x'+z'-2.53=E^{\text{ix}}$	50.40	49.42	−0.98
Quebec	46 47	$.469\,x'+z'-0.16=E^{\text{x}}$	41.90	42.95	+1.05
Nain	57 10	$.294\,x'+z'+1.25=E^{\text{xi}}$	26.40	28.10	+1.70
Fort Churchill	59 2	$.265\,x'+z'-0.00=E^{\text{xii}}$	25.30	25.62	+0.32

The application of minimum squares to these equations, will give $x'=4°.38$, and $z'=-0°.84$. The formula, therefore, which best represents the whole of these mean temperatures, on the hypothesis adopted by Humboldt after Mayer, that the temperature varies as the square of the cosine of the latitude, is

$$84°.91\cos^2 l+3°.14=t,$$

and which gives for the Equatorial temperature 88°.05, and for the Polar 3°.14.

(175.) The next step of Mr. Atkinson's inquiry is, to deduce the mean temperature of the Equator from the supposition that the law of variation is not as the square of the cosine, but as some other function of the latitude; and for this purpose he adopts $\cos^n l$ to represent it, the exponent n being some unknown but constant quantity, to be determined by subsequent investigations. In this case the formulæ (B) and (C) will assume the form of

$$x=\frac{t-t'}{\cos^n l-\cos^n l'}\;\ldots.(D),$$

and
$$z=t-\frac{(t-t')\cos^n l}{\cos^n l-\cos^n l'}\;\ldots.(E).$$

(176.) These values being substituted for x and z in the third of the conditional equations (A) will give

$$\frac{(t-t')\cos^n l''}{\cos^n l-\cos^n l'}+t-\frac{(t-t')\cos^n l}{\cos^n l-\cos^n l'}=t'',$$

and from which we deduce

$$\frac{t-t''}{t-t'}=\frac{\cos^n l-\cos^n l''}{\cos^n l-\cos^n l'},$$

a function from which an approximative value of n may be obtained, in terms of the latitudes l, l', l'', and of the observed temperatures t, t', t''.

(177.) To obtain this value of the exponent n, Mr. Atkinson selects three observations near the Equator, three near the middle regions of North America, and other three towards the Northern parts of the same great country, as in the following Table:

TABLE XXVI.

Names of Places.	North Latitude.	Observed Temperature.
Cumana	10° 27′	81°.86
Antilles	17 0	81.05
Vera Cruz	19 11	78.08
Philadelphia	39 56	54.90
Cambridge	42 25	50.40
New York	40 40	53.80
Nain	57 10	26.40
Okak	57 20	29.80
Fort Churchill	59 2	25.30

(178.) These temperatures and latitudes Mr. Atkinson has combined by *threes*, and deduced the value of n for each combination. The following are the results:

Cumana Philadelphia Nain } $n=0°.91$	Cumana Cambridge Okak } $n=1°.70$	Cumana New York Fort Churchill } $n=1°.20$
Antilles Cambridge Okak } $n=2.06$	Antilles New York Fort Churchill } $n=1.55$	Antilles Philadelphia Nain } $n=1.30$
Vera Cruz New York Fort Churchill } $n=1.80$	Vera Cruz Philadelphia Nain } $n=1.10$	Vera Cruz Cambridge Okak } $n=1.06$

(179.) These form of course only a part of the system of combinations which might be framed, but there is little probability that the mean of the whole would differ more than three or four hundredth parts from the mean of the nine values of n, and which is found to be $1°.46$, or $\frac{3}{2}$ nearly.

(180.) This value of n being substituted in the formulæ (D) and (E), will produce the equations

$$x=\frac{t-t'}{\cos^{\frac{3}{2}} l-\cos^{\frac{3}{2}} l'},$$

and
$$z=t-\frac{(t-t')\cos^{\frac{3}{2}} l}{\cos^{\frac{3}{2}} l-\cos^{\frac{3}{2}} l'}.$$

---

[*] The last three columns have been added by Mr. Atkinson, to show the errors of the formula resulting from the equations of condition; and from which we may readily perceive the degree of reliance that ought to be placed on it.

(181.) To apply these formulæ, Mr. Atkinson adopts the observations made at the Antilles and Fort Churchill, and finds $x = 98^\circ.48$, and $z = -11^\circ.05$; and hence the formula for the temperature will become

$$91^\circ.48 \cos^{\frac{3}{2}} l - 11^\circ.05 = t.$$

(182.) The general expression for finding the equations of condition will therefore become

$$(98^\circ.48 + x') \cos^{\frac{3}{2}} l - 11^\circ.05 + z' - t = E,$$

which being applied to each of the places at, or near, the level of the sea, whose mean temperature is known by observation, will furnish as many equations of condition as there are places, as in the following Table:

TABLE XXVII.

Names of Places.	North Latitude.	Observed Temperature.	Equations of Condition.	References for Temperature.
Cumana	10° 27′	81°.86	$.9752\,x' + z' + 3^\circ.13 = E_1$	*Edin. Phil. Jour.* vol. iii. p. 263.
Antilles	17 00	81.05	$.9352\,x' + z' + 0.00 = E_2$	Ditto.
Vera Cruz	19 11	78.08	$.9179\,x' + z' + 1.26 = E_3$	Ditto.
Havannah	23 10	78.08	$.8815\,x' + z' - 2.32 = E_4$	Ditto.

Natchez	31 28	64.80	$.7877\,x' + z' + 1.73 = E_6$	Ditto.
Williamsburg	38 08	58.00	$.6976\,x' + z' - 0.35 = E_7$	Ditto. p. 257.
Philadelphia	39 56	54.90	$.6715\,x' + z' + 0.17 = E_8$	Ditto.
New York	40 40	53.80	$.6606\,x' + z' + 0.21 = E_9$	Ditto.
Cambridge	42 25	50.40	$.6343\,x' + z' + 1.02 = E_{10}$	Ditto.
Ipswich	42 38	50.00	$.6310\,x' + z' + 1.09 = E_{11}$	Ditto.
Nain	57 10	26.40	$.3992\,x' + z' + 1.87 = E_{12}$	Ditto.
Okak	57 20	29.80	$.3965\,x' + z' - 1.80 = E_{13}$	Ditto.
Fort Churchill	59 02	25.30	$.3691\,x' + z' + 0.00 = E_{14}$	Ditto. p. 265.

(183.) By the application of minimum squares, we find $x' = -1^\circ.40$, and $z' = +0^\circ.52$; and therefore the formula that harmonizes best with the whole of the preceding observations, is

$$97^\circ.08 \cos^{\frac{3}{2}} l - 10^\circ.53 = t,$$

which furnishes for the mean temperature of the Equator 86°.55, and for that of the Pole − 10°.53.

Attempt to deduce the mean temperature of the Equator, from places situated above the level of the sea.

(184.) Such is the result of this new expression for the law of the variation of the temperature adopted. But Mr. Atkinson truly remarks, that could we discover any near approximation to the law by which the altitude and the corresponding variation of temperature are connected, we might, in all probability, deduce the mean temperature of the Equator from a few of the places situated above the level of the sea, and whose latitudes are less than any previously employed. By a very laborious investigation, founded on an expression for the diminution of temperature, and which will be given in the section of our Paper devoted to that interesting inquiry, together with the Table of results deduced from it, Mr. Atkinson has found, that from the limits of perpetual snow at the Equator to Winter Harbour in Melville's Island, the formula

$$97^\circ.08 \cos^{\frac{3}{2}} l - 10^\circ.53 - \frac{h}{251 + \frac{h}{200}} = t,$$

at the elevation h in the free atmosphere, will correspond in its results very nearly with the mean temperatures observed. Hence he observes, that a formula which answers so very nearly the whole way from latitude 10° 27′ North to 74° 47′ North, will not be far wrong if it be extended to the Equator itself. The law, also, he continues, which holds so nearly the whole way from the level of the sea up to more than 15,000 feet of elevation, cannot well lead to any error of consequence in the first 3000 or 4000 feet of altitude. We have, therefore, only to calculate by the formula, what corrections must be applied, on account of latitude and altitude, to the observed mean temperature of any place, situated not too far from the Equator, and whose elevation above the level of the sea does not exceed 4000 feet, to enable us to find the mean temperature of the Equator itself, with almost as great a degree of accuracy as that with which the mean temperature of the place of observation has been obtained. There are only nine places in South America whose mean temperature has been given by Humboldt, and whose latitude is less than 11°, and altitude below 3500 feet. By applying this method to each of them, Mr. Atkinson has obtained the results of the following Table:—

TABLE XXVIII.

Names of Places.	Height.	Latitude.			Observed Mean Temperature.	Correction on account of Height.	Correction on account of Latitude.	Temperature of Equator, as deduced from each Place.
					Fahr.	Fahr.	Fahr.	Fahr.
La Plata	3437	2°	24′	N.	74°.66	+12°.81	+0°.13	87°.60
Neiva	1702	3	10	—	77.00	6.56	0.22	83.78
Tocayma	1581	4	16	—	81.50	6.10	0.40	88.00
Carthago	3149	4	46	—	74.84	11.80	0.50	87.14

Antioquia	1666	7	01	N.	77.00	6.42	1.09	84.51
Caripe	2959	9	50	—	65.30	11.13	2.13	78.56
Cumana	....	10	27	—	81.86	......	2.41	84.27
Caraccas	2906	10	31	—	69.44	10.94	2.44	82.82
							Mean =	84.53

Consequent temperatures of the Equator.

(185.) The mean temperature, therefore, would appear to be 84°.53; but if Caripe be excluded, as it seems probable it ought to be, from its differing so much from any of the rest, the mean among the remaining eight would be 85°.275. And should it be thought that those places whose altitude is below 2000 feet are better adapted to give a correct result, by taking the mean of the five places so situated, we shall obtain 84°.93 for the mean temperature of the Equator.

Mr Atkinson's general results.

(186.) The general results of Mr. Atkinson are, therefore, as follows:

1°. *The whole of Humboldt's observations in both North and South America, at or near the level of the sea, indicate that the mean temperature of the Equator, at the same level, is* 86°.55 *Fahrenheit.*

2°. *All the observations, nine in number, made within* 11° *of the Equator, where the height does not exceed* 3500 *feet, indicate that its temperature is* 84°.53. *But if Caripe be excluded, the remaining eight give* 85°.275 *for the mean temperature of the Equator.*

3°. *If those places only be taken which are within the same limits, and whose height is less than* 2000 *feet, they indicate that its mean temperature is* 84°.93.

Humboldt's reply to Atkinson's objections.

(187.) Humboldt, in referring to the objections of Mr. Atkinson, has entered on the consideration of the question, with all that amplitude and generality for which he is so deservedly celebrated. In an able Paper *On the Temperature of the different Parts of the Torrid Zone at the Level of the Sea*, published in the *Annales de Chimie* for September, 1826, he discusses particularly the question of the mean Equatorial temperature, and adduces strong and plausible reasons that he has not underrated the temperature of that line. If the Equatorial temperature, says he, were that of the Equatorial zone surrounding the whole globe, and bounded by the parallels of 3° North and 3° South, we must first examine the temperature of the Equatorial Ocean, forming as it does so very considerable a proportion of the Earth's circumference in this region. The mean temperature of the Ocean, says Humboldt, between the limits alluded to, varies in general between 80°.24 and 82°.4. I say in general, continues the distinguished traveller, because we sometimes find between these limits maxima restricted to zones scarcely a degree wide, and whose temperature rises in different longitudes, from 83°.7 to 84°.7. I have observed this last temperature, says he, which may be regarded as very high in the Pacific Ocean, to the East of the Galapagos Islands, and recently M. Baron Dirckinc, of Holmfeldt, a well-informed officer of the Danish Navy, who, at my request, made a great number of thermometrical observations, has found (in latitude 2° 5′ North, and longitude 81° 54′ West) almost in the parallel of Punta Guascama, the surface of the water at 87°.1. These maxima, however, do not belong to the Equator itself. They occur sometimes to the North, and sometimes to the South of it, and often between the latitudes of 2½°. and 6°. The great circle which passes through the points where the waters of the Ocean are the warmest, cuts the Equator at an angle which seems to vary with the Sun's declination. In the Atlantic Ocean we may sometimes even pass from the Northern to the Southern temperate zone, in the zone of the warmest waters, without observing the Thermometer to rise above 82°.4. The maxima are according to

The maximum temperatures do not belong to the Equator itself.

Perrins	82°.76
Churrucca	83.66
Quevedo	83.48
Rodman	83.84
Dr. Davy	82.58
Mean	83.26

The air resting on the Equatorial waters is colder than the Ocean.

(188.) The air also which rests upon these Equatorial waters is from 1°.8 to 2°.7 colder than the Ocean; and it results from these facts, that over nearly five-sixths of the circumference of the globe, the Equatorial aqueous zone, instead of presenting a mean temperature of 84°.5, has probably not one of 83°.3; and Mr. Atkinson himself admits, that the union of the aqueous and continental parts tends to diminish the mean temperature of the Equator.

Humboldt's further remarks on Atkinson.

(189.) In alluding to Mr. Atkinson's investigations to deduce the mean temperature of the Equator from the assumed law of increase of heat from the Pole to the Equator, by the observations made at Cumana, and from the temperatures observed on the declivity of the Cordilleras, to a height of 500 toises, corrected according to his hypotheses for the latitude, and for the progressive diminution of heat in a vertical plane, Humboldt remarks, that in studying in all its generality the problem of the distribution of heat on the surface of the globe, and in freeing it of the accessory considerations of localities, (for example of the effects of the configuration, the colour and the geographical relations of the soil; of those of the predominance of certain winds, of the proximity of seas, of the frequency of clouds and fogs, and of the nocturnal radiation towards a sky more or less serene,) we shall find that the mean temperature of a station depends on the different ways in which the influence of the meridian altitude of the Sun manifests itself. This altitude determines at once the duration of the semi-diurnal arcs, the length and the transparency of the portion of the atmosphere which the rays traverse before reaching the horizon; the quantity of the absorbed or heating rays, (a quantity which augments rapidly when the angle of incidence, reckoned from the level of the surface, increases;) and, lastly, the number of solar rays which a given horizon embraces. The law of Mayer, with all the modifications that have been introduced into it, is an empirical law, which represents the generality of the phenomena by approximation, and often in a satisfactory manner, but it cannot be employed against the testimony of direct observations. If the surface of the globe, from the Equator to the parallel of Cumana, was a desert like that of Sahara, or a Savannah uniformly covered with grass like the Llanos of Calabozo and of Apure, there would undoubtedly be an increment of mean temperature from 10½° of latitude to the Equator, but it is very probable that this increase does not amount to 2½° of Fahrenheit. If I have fixed, continues M. Humboldt, the mean temperature of the Equator in round numbers at 81½°, it was to attribute to the Equatorial zone from 3° North to 3° South the mean temperature of Cumana 81°.86 This city, surrounded with arid sands, situated under a sky always serene, and whose thin vapours seldom resolve themselves into rain, possesses a more burning climate than all the places which surround it, and which like it are on the level of the sea. In advancing Southward in America, towards the Equator, by the Orinoco and Rio Negro, the heat diminishes, not on account of the elevation of the soil, which from the fort of St. Carlos is very little, but on account of the forests, the frequency of rains, and the transparency of the atmosphere.

Remarks on the law of Mayer.

Remarks relative to Cumana.

Examples of mean temperature.

(190.) Below 10½° of latitude, we know only the mean temperatures of

	Latitude.	Fahr.
Batavia	6° 12′ S.	80°.42
Cumana	10 27 N.	81.86

(191.) Between 10½° of latitude, and the extremity of the torrid zone, we have

	Latitude.	Fahr.
Pondicherry	11° 55′ N.	85°.28
Madras	13 4	80.42
Manilla	14 36	78.08
Senegal	15 53	79.70
Bombay	18 56	80.06
Macao	22 12	73.94
Rio Janeiro	22 54 S.	74.30
The Havannah	23 9 N.	78.26

And after the observations of Pereira,

Maranham	2 29 S.	81.32

(192.) Hence it appears that the only place in the Equinoctial regions, whose mean temperature exceeds 81°.86, is Pondicherry, whose climate can no more serve to characterise the Equatorial region than the Oasis of Mourzouk, where the unfortunate Ritchie and Captain Lyon assure us that they saw, during whole months, (perhaps from the sand disseminated in the air,) the Thermometer at 117° and 128°, can characterise the climate of the temperate zone in the North of Africa. The three or four degrees nearest to the Equator, continues Humboldt, are a *terra incognita* for climatology. We are still ignorant of the mean temperatures of Grand Para, Guayaquil, and even Cayenne.

Humboldt concludes that the mean temperature never reaches the quantity assigned by Mr. Atkinson.

(193.) From every consideration, therefore, M. Humboldt concludes that the Equatorial temperature never reaches 84°.56, as is supposed by Mr. Atkinson. Father Beza, says he, the first traveller who recommended observations on the warmest and coldest periods of the day, believed that he had found in 1686 and 1699, in comparing Siam, Malacca, and Batavia, "that the heat is not greater under the Equator than under 14° of latitude." I am of opinion, continues Humboldt, that there is a difference, but that it is very small, and marked by the effect of many causes, which act simultaneously on the mean temperature of a place. The observations hitherto collected do not afford us any measure of a progressive increase between the Equator and the latitude of Cumana.

Necessity for further observations.

(194.) There can be little doubt but the numerical elements we possess relating to the tropical regions in general, require still further observations to correct and improve them; but there is one circumstance connected with Mr. Atkinson's calculations, which merits consideration. Mr. Atkinson has confined his investigations entirely to the temperatures of the New World, and omitted those of the Old World; and although Humboldt has shown that the temperature of the Equatorial regions is nearly the same under all meridians, yet Dr. Brewster has proved that the gradations of temperature from the Equator to the Poles are not the same in the Old and New Worlds; and it is probable, that a set of observations made in different latitudes of the Eastern hemisphere, would furnish some other result for the mean temperature of the Equator. Humboldt, on the contrary, has generalized his views, and formed his estimate of the mean Equatorial temperature from observations made under different meridians, and situated as nearly as possible to the Equator. Indeed of the two, observations made in the Old World are to be preferred to those in the New, because the distribution of heat is subject to fewer anomalies. Still the investigations of Mr. Atkinson are of a nature to make us pause on the inquiry, and not to be hasty in adopting a numerical value for an element of so important a kind as the mean temperature of the Equator. Dr. Brewster, however, is decidedly of opinion that Humboldt has not underrated the mean temperature of that line, and adduces several observations in support of his opinion in the VIth volume of the *Edinburgh Journal of Science.*

(195.) His first series of observations are for Ceylon, as follows:

	Mean Temp.
Trincomalee	80°.56
Point de Galle	81.10
Colombo	80.75
Kandy*	78.50
Ditto, according to Dr. Davy	79.20

If now we deduce the Equatorial temperature from

---

* A correction of 5°.7 is added for altitude, according to Mr. Atkinson's formula.

Dr. Brewster's attempt to deduce the mean temperature of the Equator.

these observations, either by the formula Eq. temp. $= \frac{T}{\cos L}$, according to the principle of Brewster's formula, or by the formula Eq. temp $= \frac{T}{\cos^2 L}$, according to the principle of Mayer's formula, we shall obtain the following results:

	Mean Temperature of Equator.	
	Eq. temp. $= \frac{T}{\cos L}$	Eq. temp. $= \frac{T}{\cos^2 L}$
Trincomalee	81°.46	82°.37
Point de Galle	81.55	82.02
Colombo	81.34	81.93
Kandy	79.14	79.78
Do. according to Dr. Davy	79.34	80.49
Means	80.66	81.32

Mean of both = 80°.99.

Deduction for Ceylon.

It follows, therefore, from the Ceylon observations, that the mean temperature of the Equator is less than 81½°.

For Batavia and the Sandwich Islands.

(196.) By a series of observations furnished by Professor Moll, of Utrecht, for Batavia, Dr. Brewster finds the mean temperature of the Equator to be 81°.32; and from a series of observations made at the Sandwich Islands, he also deduces 81°.04 for the measure of the same element.

Further deductions from observations made at Prince of Wales's Island, Singapore, and Malacca.

(197.) In the VIIIth volume of the same *Journal*, Dr. Brewster has given the results of observations made at Prince of Wales's Island, within 5° of the Equator, and at Singapore and Malacca, within 1° and 2° of the same line. At Singapore, according to the observations of Colonel Farquhar, the

Mean annual temperature at 6 A.M. and 6 P.M. for 1822 = 79° 45′
——————— 12h noon ——————— 84 00

and to deduce the mean daily temperature from these, Dr. Brewster applies certain corrections deduced from the hourly observations made at Leith Forth for 1824 and 1825; *viz.* that the mean daily temperature exceeds the mean of the morning and evening observations by 0.29, and is less than that of noon by 2°.51, (the grounds of which corrections will hereafter be explained,) we shall find the mean Equatorial temperature to be 80°.47.

Corrections applied to them.

Objections obviated.

(198.) It may be objected, however, that corrections deduced from a Northern climate marked with the vicissitudes of summer and winter, cannot be strictly applied to the tropical regions of the Earth, where the variations in the monthly temperature are so exceedingly small. To meet this objection, Dr. Brewster has deduced the corrections from the hourly temperatures of the three summer months, during which the variations of the daily curve must have a greater resemblance to those of the torrid zone. These corrections are − 3.08 and − 3.00, and, though differing from those used above, produce, as will be seen, very little difference in the mean results.

Mean Temperature of the Pole.

Mean temperature of the Pole.

(199.) The probable mean temperature of the Pole is an interesting problem in Meteorological inquiry. In the absence of all positive observations, we are left entirely to conjecture. It is obvious the Poles of the world must undergo some remarkable alterations of temperature, between the periods when the Sun, constantly shining on one of them, sinks below its horizon, to shed a lustre on the other. In the present state of our knowledge, we can only approximate to the temperature of the Pole, by availing ourselves of the observations of those who have so intrepidly navigated the icy seas of the North.

Mr. Scoresby's observations.

(200.) Previous to the publication of Scoresby's *Account of the Arctic Regions*, the North Polar temperature had been universally assumed by Meteorologists, at 30°, 31°, or 32° of Fahrenheit; and it was that active, ingenious, and enterprising man, who first ventured to place the temperature of the North Pole below the quantity that had been commonly assigned to it. The mean temperatures of the parallels of 76° 45′ and 78° North, were deduced by Mr. Scoresby from a series of 650 observations, made by himself in nine successive years. In the former latitude he found the mean temperature to be 18°.86, and in the latter 16°.99, whereas the temperatures usually assigned to these latitudes by the formula of Mayer, then commonly employed by Meteorologists, differed from the former observation nearly 16°, and from the latter more than 17°. The difference between the actual temperatures, and those estimated by the empirical formula, Mr. Scoresby attributed to the frigorific influence of the ice; and having found what this anomaly amounted to at the Pole, he subtracted it from Mayer's Polar temperature, to obtain the real temperature of the Pole, which he thus found to be 10°. But this result, Dr. Brewster remarks, is obviously too great; for since Mayer's formula errs much in excess, in those parallels where there is no accumulated ice to produce an anomaly, it must give at least an equal error in excess, for the parallel of 76° 45′. Now this error in the latitudes of 63° and 65° in Lapland is 8°; and therefore calling it also 8°, which is far too low for the latitude of 76° 45′, we have for the mean temperature, uninfluenced by the ice, 33°.8 − 8°.0 = 25°.8; from which subtracting the Polar anomaly of 21°, as computed by Mr. Scoresby, we obtain 4°.8 for the mean temperature of the Pole.

Dr. Brewster's remarks on them.

Mean temperature of the Pole influenced by the meridian on which it is approached.

(201.) Later inquiries, however, have shown, that in attempting to calculate the temperature of the Pole, a considerable alteration will take place, whether we endeavour to approach the Pole on a meridian of the Old World, or one of the New. In the Old Continent, for example, the mean heat in the parallel of 60° is 40°, whereas in the same latitude in the New World, we shall encounter a cold of 24°; and in the parallel of 78°, the second latitude adopted by Mr. Scoresby, this cold will have increased to 4°. If then we deduct for the frigorific influence of the ice, says Dr. Brewster, according to Mr. Scoresby's ingenious process, we shall find the Polar temperature to be many degrees below the *zero* of Fahrenheit's scale. Or to state the argument more popularly, since the cold at the Pole is 10°, as inferred from observations made in the *mildest* meridian, it must fall greatly below this, and even *below zero*, if inferred from observations made in the *coldest* meridian. The winds which blow from the continent of Greenland, from the Northern extremities of America, and from the frozen coast of Siberia, must produce at the North Pole an influence scarcely to be felt in the Spitzbergen seas. Dr. Brewster proves from the observations made in the second voyage of Captain Parry, that the temperature of the North Pole must be less than − 3° of Fahrenheit.

New views of Dr. Brewster.

(202.) But Dr. Brewster has communicated quite a new aspect to this interesting inquiry, in his Paper on the mean temperature of the globe published in the *Edinburgh Transactions*, by comparing the observations made by Parry in his voyage of 1819, 1820 with those deduced by Scoresby in the Spitzbergen seas. By means of 4300 observations made in the parallel of 74° 45′, and in the meridian of 110° West, Captain Parry found the mean temperature to be so low as 1°.33, whereas, as we have before remarked, Mr. Scoresby found the temperature in the latitude of 78° to amount to 16°.99. A comparison of these observations indicates a very singular state of the Isothermal lines at the Pole itself. The thermometric curve of 17°, which rises in the meridian of Spitzbergen to 78° of North latitude, descends in the meridian of Melville Island to 65°; and unless we imagine the climate of those regions to be subject to no law, we are forced to conclude that the Geographical Pole of the globe is not the coldest point of the Arctic hemisphere; and that there are *two points of greatest cold* not many degrees from the Pole, and in meridians nearly at right angles to that which passes through the West of Europe.

Two points of greatest cold.

Their probable positions.

(203.) Observations are still wanting to determine the exact positions of the Isothermal Poles; but they appear to be situated in about 80° of North latitude, and in 95° of East, and 100° of West longitude; the Transatlantic one being nearly 5° to the North of Graham Moore's Bay in the Polar Sea; and the Asiatic one to the North of the Bay of Taimura, near the North East Cape.

Further approximation to one of the Poles of maximum cold.

(204.) By combining the results of Dr. Richardson with the observations made by Parry in his second voyage, Dr. Brewster finds the Pole of maximum cold to lie within a quadrilateral figure, formed by joining the four points of observation, *viz.* Fort Enterprise, Melville Island, Igloolik, and Winter Island. Observations, however, continued for many years, on more distant Isothermal lines, will be necessary to give the accurate position of the Pole of maximum cold; while observations made near the Pole itself are extremely valuable in fixing its probable temperature.

These Poles are not limited to the same temperature.

(205.) But we are by no means confined to the supposition that these Isothermal Poles are limited to the same temperature, or confined to nearly opposite meridians; and Brewster imagines, that we may obtain even a better expression of the temperatures, by placing the Poles at different distances from the Equator, and ascribing to them different intensities of cold. The existence of a cold and a warm meridian, is a proof that there are causes which powerfully influence the mean temperature of the year, independently of the position of the Earth's axis with respect to the Sun; so that the effects which they produce can have no symmetrical relation to the Pole either in position or intensity.

Formulæ of Temperature.

General remarks on formulæ of temperature.

(206.) No greater contrast, it may be remarked, can well be exhibited than the beautiful uniformity of the celestial movements, and the capricious and ever-changing character that distinguishes the atmosphere of the Earth; and it is therefore somewhat remarkable, that the attempt to discover some law or connection among the anomalous Meteorological results, should have been made by a man distinguished for his splendid researches in the heavens, and for his successful attempt to reform and improve the lunar tables. From an allusion made in a preceding division of this Essay, our readers are prepared to anticipate the name of Mayer; and occupied as he was in the difficult task of unravelling the intricate problems connected with the movements of the Moon, and of endeavouring to trace uniformity and order in the midst of changes more considerable and capricious than distinguish any other body of our system, it was natural that the energies of such a mind, being directed to Meteorological registers, should produce some important and beneficial change.

Inquiries of Mayer.

His method analogous to that pursued by Astronomers

(207.) The method adopted by this eminent man is analogous to that which Astronomers in general have pursued with so much certainty and success, when they correct by small steps the mean place of a planet, by means of the inequalities of its motion. It does not, as Humboldt has remarked, present the result of the solar action disengaged from the influence of foreign circumstances; but estimates, on the contrary, the temperatures such as they are distributed over the surface of the globe, whatever be the cause of that distribution; and hence the object was, by having the mean heat of two places situated under different parallels of latitude, to discover by the aid of a convenient formula the temperature of every other parallel.

Difficulty of the undertaking at the time Mayer wrote.

(208.) To accomplish this at the time when Mayer wrote was a question of no ordinary difficulty. The mean temperature of the Equator, which forms so important an element of the inquiry, could only be arrived at by a rude sort of an approximation; nor were the mean temperatures of three points on the Earth's surface at that time accurately known. The materials for the creation of his formula were only to be found, with any tolerable accuracy, between the parallels of 40° and 50° of North latitude; and from a diligent examination of these, he imagined that the temperature at the surface of the Earth varied as the square of the sine of the latitude. His formula was exhibited under the form of

$$T = 84 - 52 \sin^2 L,$$

which by a ready transformation by the arithmetic of sines, becomes

$$T = 58 + 26 \cos 2 L.$$

Mayer regarded the Equatorial temperatu as 84°.

(209.) By allowing the latitude to vary in the first of these formulæ, we shall perceive that Mayer regarded 84° as the mean Equatorial temperature, since when the latitude is zero, $\sin^2 L$ vanishes, and the value of T becomes that quantity. On the other hand, he estimated the temperature of the Pole at 32°, because when the latitude is 90°, $\sin^2 L$ being radius, the value of T must become that of the freezing point.

The temperature c the parall of 45° as 58°.

(210.) In the second formula, the mean temperature of the parallel of 45° was estimated at 58°, and the coefficient 26° was regarded as the difference between the last-mentioned temperature and that of freezing water at the Pole.

If these formulæ be adapted to Reaumur's scale, we shall have

$$T = 24 \cos^2 L,$$

which, by the arithmetic of sines, becomes

$$T = 12 + 12 \cos 2 L.$$

Labours Kirwan.

(211.) Kirwan, who adopted the views of Mayer, gave an example by which he deduced the constant coefficient of the formula, as well as the Equatorial temperature. Thus regarding the elements referred to as indeterminate quantities, the formula may be exhibited under the form of

$$T = \alpha - \beta \sin^2 L;$$

and taking the temperatures of the parallels of 40° and 50° at 62°.1 and 52°.9, we shall obtain the equations

$$\alpha - \beta \sin^2 40° = 62°.1,$$

and

$$\alpha - \beta \sin^2 50° = 52°.9.$$

These equations reduced will give for α the Equatorial temperature 84° nearly, and for the coefficient β 53° nearly. Hence the temperature of the Pole must be regarded as 31°.

Playfair's Geometrical illustration of Mayer's formula.

(212.) Playfair, by adopting Mayer's formula under the form

$$T = 58 + 26 \cos 2 L,$$

above deduced, furnishes a neat Geometrical construction for determining the mean temperature. In any line graduated into equal parts to represent the divisions of the Thermometric scale, (fig. 1. plate 1. METEOROLOGY,) take A C = 84, the mean Equatorial temperature, (according to Mayer,) and A B = 58, which in the formula indicates the mean temperature of the parallel of 45°. From B, as a centre, let a semicircle be described with the radius B C equivalent to 26, the coefficient of the last term of the formula. Take the arch C G equal to the double latitude of any parallel; and from G draw G O at right angles to A C, then will A O represent the mean temperature of that parallel, according to the scale of Fahrenheit.

Lichtenberg's application of Mayer's formula.

(213.) M. Lichtenberg, the Editor of Mayer's posthumous Works, applied this formula to thirteen observations of mean temperature made between the Cape of Good Hope and Stockholm; and their agreement was considered at that time to be remarkable.

Formula of Daubuisson.

(214.) In the year 1819, M. Daubuisson, in his *Traité de Géognosie*, resumed the subject of the Earth's temperature, and gave the formula

$$T = 27° \cos^2 L$$

for finding the mean temperature according to the centigrade scale. This formula is superior in accuracy to Mayer's; but M. Daubuisson considers it as applicable principally between the parallels of 30° and 60° North latitude. The coefficient 27° is regarded by the author of the formula as the mean temperature of the Equator, in order to make the results agree with observations made in the temperate regions, whereas the mean temperature of the Equator, as ascertained by Humboldt, is 27°.5.

Brewster's comparison of Mayer's formula with the observations of Humboldt.

(215.) Among other advantages resulting from the publication of Humboldt's Memoir on Isothermal lines, was Dr. Brewster's comparison of Mayer's formula with the observations collected by that distinguished traveller. Brewster found by comparing the temperature of the Equator with that of the parallel of 45°, and also with that of the highest latitude in Humboldt's series, that the cold increased much more rapidly towards the Poles than had been believed; and upon extending the comparison to the intermediate temperatures, he found the mean heat of any place to be well represented by the radius of its parallel of latitude; or, in other words, that the temperature varies as the cosine of the latitude. By adopting 81°.5 for the mean temperature of the Equator, Brewster's formula therefore assumed the form of

$$T = 81°.5 \cos L \ldots\ldots (F),$$

Brewster's formula.

and which will be found to agree exceedingly well with observations made at the following places; the positive and negative errors approaching very nearly to an equilibrium.

TABLE XXIX.—*Of Mean Temperatures.*

Comparison of the temperature of different meridians.

(216.) Reasoning on general principles, we should first imagine that the distribution of heat over the meridians of the New World, would coincide with observations made in the Old World; but as the condition of more distant climates was better known, the severity of a Canadian and a Siberian winter became proverbial. Humboldt has shown, that though the temperature of the Equatorial regions is nearly the same under all meridians, yet in higher latitudes it declines rapidly in the New World, and also under the Eastern meridians of Asia. According to this view, it would seem as if some correction were necessary for longitude, and that the latitude is not the only Geographical element that requires consideration. The subject, however, must be approached with extreme caution, on account of the limited number of observations that have been made in the regions referred to; and Dr. Brewster has hence contented himself with the following modification of his first formula, to denote the temperature of the New World,

$$T = 81°.5 \cos^2 L \times 1°.13.$$

Modification of Brewster's formula.

This formula makes the Equatorial and Polar temperatures of the New World coincide with those of the Old World, while in intermediate latitudes, the calculated and observed results do not differ, upon an average, so much as 1°, as may be seen by a reference to the columns of the succeeding Table.

TABLE XXX.

Latitude.	Temperature of Old World.	Temperature of New World.	Difference between Old and New World.	Temperature of New World calculated by the formula.	Difference between Observation and Calculation.

50	50.90	37.94	12.96	38.06	+0.12
60	40.64	23.72	16.92	23.02	−0.70

Two points of maximum cold.

(217.) In following up this interesting inquiry, Dr. Brewster was led to imagine, as we have before remarked, the existence of two points of maximum cold within the frigid zone as extremely probable, and deduced a formula of mean temperature according to such a supposition. The gradation of heat on the Transatlantic meridian is so essentially different from that in the West of Europe, that it is impossible to represent the two classes of phenomena by a single formula, in which the limiting temperatures are to be found at the Equator and the Pole. Such, indeed, are the anomalies existing in the distribution of heat in the Polar latitudes, that observation alone must determine the form of the Isothermal lines. Dr. Brewster endeavoured to trace their resemblance to the Isochromatic curves, and to calculate the temperatures by the product of the sines of the distance of the place from the two Isothermal Poles; but he found, after much laborious inquiry, that this law did not accurately represent the facts, and that they might be more accurately represented by the formula

Formulæ relating to the Pole of maximum cold.

$$\text{Mean temp.} = 82°.8 \sin D;$$

upon the supposition that the greatest cold is 0° of Fahrenheit, or

$$\text{Mean temp.} = 86°.3 \sin D - 3\tfrac{1}{2}°,$$

upon the supposition that the maximum degree of cold is $-3\frac{1}{2}°$ of Fahrenheit, 82°.8 being the mean temperature of the Equator in the warmest meridian, and D the distance of the place nearest the Isothermal Pole.

Application of the formulæ.

(218.) To bring these formulæ to the severest possible test, Dr. Brewster contrasted them with observations made in intermediate meridians, both in the Old and the New World. In this comparison he began with the Asiatic Pole, supposing it to have a temperature of $-3\frac{1}{2}°$, and to be placed in 80° North latitude, and 95° East longitude; and by employing the formula before given

$$\text{Mean temp.} = 86°.3 \sin D - 3\tfrac{1}{2}°,$$

Erroneous assumption.

he found that the observed temperature exceeded the temperature calculated by the formula, in eleven cases out of thirteen; from which he very properly inferred that he had assumed too great a degree of cold for the Asiatic Pole. By assuming the temperature of this Pole at zero of Fahrenheit, as supposed in the formula

$$\text{Mean temp.} = 82°.8 \sin D,$$

Corrections of the formulæ.

he found that the differences between the observed and calculated temperatures of the same thirteen places, were far within the limits of the errors of observation; but that being negative in general, a more correct approximation might be found by supposing the Asiatic Pole to have a temperature of 1° Fahrenheit, which is $4\frac{1}{2}°$ warmer than the Transatlantic Pole. The last formula in this case became, therefore, transformed into

$$\text{Mean temp.} = 81°.8 \sin D + 1° \ldots. (G)$$

which, applied to the thirteen places before alluded to, gave the following results:

TABLE XXXI.

Names of Places.	Distance from Asiatic Pole.	Mean Temperature Observed.	Mean Temperature Calculated.	Difference.
Enontekies.......	20° 39′	31°.03	29°.85	−1°.18
Uleo.............	23 16	33.08	33.31	+0.23
Umeo............	25 06	33.26	35.70	+2.44
St. Petersburgh....	27 11	38.84	38.37	−0.47
Stockholm	29 44	42.30	41.57	−0.73
Moscow	29 55	43.16	41.80	−1.36
Warsaw	36 06	48.56	49.20	+0.64
Astracan.........	37 25	49.08	50.70	+1.62
Vienna	40 37	51.76	54.25	+2.49
Pekin............	40 56	54.86	54.59	−0.27
Nangasaki	48 57	60.80	62.69	+1.89
Seringapatam.....	68 04	77.00	76.92	−0.08
Columbo	73 12	79.50	79.33	−0.17

Application of the theory to observations made round the Transatlantic Pole

(219.) A comparison of theory with observations made round the Transatlantic Pole, affords results equally satisfactory. In this case Dr. Brewster had recourse to the formula

$$\text{Mean temp.} = 86°.3 \sin D - 3\tfrac{1}{2}° \ldots. (H),$$

the Pole being supposed to be situated in 80° North latitude, and 100° West longitude, and to have a temperature of $-3\frac{1}{2}°$.

TABLE XXXII.

Position o the Easter Pole of ma imum col in the Sout ern hemi- sphere.

(220.) By comparing the mean temperature of Van Diemen's Land with that of the Cape of Good Hope, as ascertained by many accurate observations reduced by Mr. Colebrooke, we obtain a position for the Eastern Pole of maximum cold in the Southern hemisphere, corresponding with the position of the opposite Pole in the Northern hemisphere. In order to determine this point, Dr. Brewster computed the mean temperature of Hobart Town, by supposing the Poles of maximum cold to have the same position in the Southern as they have in the Northern hemisphere. If we suppose the Pole nearest to Hobart Town to have the same degree of cold as the American Pole, then the mean temperature of Hobart Town will be 53°.11, differing little more than half a degree from the observed mean temperature; and if we suppose it to be the same as the Asiatic Pole, the mean temperature will be 54°.67, differing 2° from observation. It deserves to be remarked, however, that *both* these computed results *lie between* the mean temperature actually observed at Hobart Town and Macquarie Harbour.

Mr. Atkinson's comparative Tables of the different formulæ.

(221.) Having reviewed the different formulæ that have been presented for the purpose of finding the mean temperature of a place, we shall add the following comparative Tables of their application; for which we are indebted to Mr. Atkinson's excellent Paper before quoted. The places selected are all situated nearly at the level of the sea.

Mean Errors				−0.12		+2.61		+1.72		−0.64

Errors of the several formulæ.

(222.) From this Table, it appears that Brewster's first formula gives the temperature *too low* by 0°.12, and the second *too high* by 2°.61. Mayer's formula is *too high* by 1°.72, and Daubuisson's *too low* by 0°.64, at the level of the sea. These differences Mr. Atkinson denominates *corrections* for the level of the sea.

Application of the same formulæ to places situated above the level of the sea.

(223.) The same formulæ may also be compared by means of places situated *above* the level of the Ocean, and thus some notion be formed of their comparative accuracy; and Mr. Atkinson has prepared the following Table to illustrate this view of the subject.

TABLE XXXIV.

Means	424				+3.21		+4.63		+4.95		+2.58

* The heights of these four places are derived from the *Edinburgh Philosophical Journal*, vol. v. p. 32.

Errors of the several formulæ.

(224.) Hence it appears, that at the mean elevation of 424 feet, Brewster's first formula makes the temperature *too high* by 3°.21, and his second by 4°.63. Mayer's also gives it too high by 4°.95, and Daubuisson's by 2°.58. These numbers being the *corrections* to be applied when the temperature of a place is required 424 feet above the level of the sea.

Remarks relative to the preceding Tables.

(225.) As the places in Table XXXIV., with the exception of Montmorency and Paris, lie further to the East than those in Table XXXIII., it is manifest that the results obtained by employing the corrections deduced from the latter Table will not be the same as those obtained by adopting the former; for Humboldt, as we have before remarked, has shown, that temperature varies with the longitude as well as the latitude, only in a much less degree. If, therefore, the given place be situated in the Western regions of Europe, or near the primary meridian, the corrections in Table XXXIII. are to be preferred; but if it lie in about 15° or 20° of East longitude, the corrections in Table XXXIV.; and if it be situated in a region about the middle between these, the corrections in both Tables should be employed, and the mean of the whole taken.

Attempt to estimate the temperature of a given place by supposing the ground taken away from beneath it.

(226.) Hence, says Mr. Atkinson, if we wish to know what the temperature would be directly below a given place, supposing the ground taken away from beneath it to a great extent, we have only to calculate its temperature by each of the above four formulæ. Then if the *first* set of corrections be applied to the calculated temperatures, each to each, the four results would be the temperature, as deduced from the formulæ respectively, on the supposition that the ground was removed from under the place, *down to the level of the sea.* But, if the second set of corrections had been applied, the mean of the results would be the temperature of a point, directly below the place, but 424 feet above the level of the sea. And if the mean temperature of the place itself had been accurately observed, the difference between the *observed* and *calculated* temperatures would be *the change of temperature due to the whole height*, if the first set of corrections had been employed; but if the *second* set of corrections had been adopted, the *difference* would be the *alteration of temperature* due to the *height diminished* by 424 feet.

Differences between the calculated temperatures of certain places, and their observed temperatures.

(227.) The next Table exhibits the *differences* between the temperatures of the eleven places mentioned in it, calculated as directed above, and the *observed* mean temperatures of the same places. From what has been already mentioned respecting the apparent connection between the longitude and the mean temperature, it might be expected that the differences as deduced from the corrections in Table XXXIII. would give different results from those deduced from the corrections in Table XXXIV., and accordingly Mr. Atkinson found it to be so. But as the eleven places adopted in the succeeding Table occupy nearly the central parts of that portion of Europe in which the eighteen places in Tables XXXIII. and XXXIV are situated, it seems highly probable that the mean of the whole will be a tolerable approximation to the truth.

---

* The heights of these three places are taken from the *Edinburgh Philosophical Journal*, vol. iv. p. 276.

† The heights of these four places, as given above, are obtained by taking a mean between the heights adopted in the note at p. 275, vol. iv., and those given in the Table and its notes, p. 32—39, vol. v. of the same Journal. There is, probably, a mistake in the observed mean temperature of Munich. Had it been rejected, the mean result of the whole would have been a little different from the above, but varying still more from the quantity generally adopted by Philosophers. It may serve, however, as an example, to show how necessary it is to employ a great number of places in investigations of this kind, particularly where the altitude is not great. When the height is considerable, a small error in the mean temperature makes a less difference.

Mean temperature of year deduced from a single month.

(228.) It is useful sometimes to be able to approximate to the mean temperature of the year, by the aid of observations made during a particular part of it; and accordingly some have been made to discover the month which approaches the nearest to it. Kirwan supposed that the mean temperature of April approached the nearest to that of the year, but Humboldt conceives it to be October. In the next Table, some comparative results are afforded of the two months.

Table XXXVI.

Playfair's formula for ascertaining the mean temperature of any day.

(229.) Playfair, following the steps of Kirwan, adopted the temperature of the latter end of April as the mean temperature of the year, and endeavoured to create a formula which should enable him to approximate to the mean temperature of any day. This formula is the following

$$y = \mathrm{T} + \mathrm{F} \sin (\lambda - 30) \ldots . (\mathrm{I}),$$

in which T denotes the mean temperature of the given place, F a constant coefficient determined by observation, λ the mean longitude of the sun computed from the first of Aries, for any day of the year, the mean temperature of which is y.

(230.) That the mean temperature of the latter end of April is however nearly that of the year, may be seen by the following admirable series of observations, made in the Observatory of the Academy of Sciences at Stockholm, during a period of fifty years, and embracing no less than 54,750 observations. An excellent account of it will be found in Kongl. Vetenskap's *Academiens nya Handlingar*, tom. xxix. p. 294, for 1808, or the *Annals of Philosophy* for 1813, vol. i. From these observations, it appears that the mean temperature of the place of observation, from 54,750 observations, is 5¾°, or 5°.765 above the freezing point of the thermometer of Celsius, or 42°.377 Fahrenheit. The year has been divided by M. Ofverbom, the author of the abstracts of the observations, into 73 *penthemerons*, or periods of five days each, with some little anomaly for the intercalary days; and we have added the whole series, in order that our readers may be able not only to judge of the mean temperature of April, but also of the other months of the year.

Observations made at Stockholm to determine the mean temperature of the different months of the year.

Table XXXVII.

Uniformity of heat at any point of the globe.

(231.) It is also some argument in favour of the preceding observations, and of the advantages to be derived from the employment of formulæ of temperature, that the quantity of heat which any point of the globe receives, is much more equal during a long series of years, than we should be led at first to conceive from the uncertain testimony of our sensations, and the variable product of our harvests. In a given place, says Humboldt, the number of days during which the North-East or South-West winds blow, preserve a very constant ratio; because the direction and force of these winds, which bring warmer or colder air, depend upon general causes,—on the declination of the sun,—on the configuration of the coast,—and on the position of the neighbouring continent. It is less frequently a diminution in the mean temperature, than an extraordinary change in the division of the heat between the different months, which occasions bad harvests. M. Humboldt also states, that a careful examination of a series of good Meteorological observations, made during ten or twelve years between the parallels of 47° and 49°, proved that the *annual* temperatures varied only from 1°.8 to 2°.7; those of *winter* from 3°.6 to 5°.4, and those of the months of winter from 9° to 10°.8. The next Table illustrates the mean temperature of Geneva for twenty years.

TABLE XXXVIII.

Years.	Mean Temp.	Years.	Mean Temp.
1796	49°.3	1806	51°.4
1797	50.5	1807	49.3

Mean of 20 Years..............			49°.67

Thermometrical oscillations for Paris.

(232.) In the succeeding Table is shown the Thermometrical oscillations during eleven years at Paris, for the whole year, the winter, the summer, the coldest and warmest months, and the month which represents most accurately the mean annual temperature.

TABLE XXXIX.

Observations of M. Bouvard.	Mean Temperature.					
	Of the Year.	Of Winter.	Of Summer.	Of January.	Of August.	Of October.
Paris 1803	51°.1	36°.7	67°.6	34°.3	67°.6	50°.5
1804	52.0	41.0	65.5	43.9	64.6	52.7
1805	49.5	36.0	63.1	34.9	64.8	49.3
1806	53.4	40.6	65.3	43.0	64.6	51.8
1807	51.4	42.3	67.8	36.1	70.5	54.3
1808	50.5	36.7	66.2	36.3	66.6	48.2
1809	50.9	40.5	62.4	40.8	64.2	49.6
1810	50.9	36.5	63.3	30.6	63.7	52.9
1811	52.7	39.2	65.1	26.6	63.7	57.6
1812	49.8	39.6	63.1	34.7	64.2	51.1
1813	49.8	36.1	61.7	32.5	62.6	53.1
Mean of these 11 Years.	51.1	38.7	64.0	36.6	65.1	51.9

(233.) With reference to this Table it may be remarked, that the greatest aberration from the mean of the year, is in 1806, amounting to + 2°.3, the positive errors amounting to + 5°.1, and the negative to − 5°.2. For the winter temperature, the greatest deviation from the mean is + 3°.6, in 1807, the sum of the positive errors being + 11°.0, and of the negative − 11°.5. In like manner for the summer temperature of Paris, the maximum deviation is + 3°.2, the sum of the positive errors being + 9°.9, and of the negative − 9°.4. And if we take the corresponding years from Table XXXVIII. we shall find the maximum deviation from the mean amounting to − 2°.8, the positive errors amounting to + 8°.8, and those of a negative kind to − 7°.6. So that in two places distant, like Paris and Geneva, eighty leagues from each other, the variations seem to be very uniform in the annual temperature; and also if the succeeding Table be referred to, uniform in the seasons, although the Thermometrical quantities differ widely from each other.

Variations of annual temperature between Paris and Geneva seem very uniform.

TABLE XL.

Years.	Mean Temperature of Summer at Geneva.	Mean Temperature of Winter at Geneva.
1803	67°.6	32°.2
1804	66.2	38.3
1805	63.0	33.8
1806	64.6	38.5
1807	68.2	35.8
1808	63.5	33.8
1809	63.1	35.1

Formula for greater elevations.

(234.) But it is often useful to be able to approximate to the mean temperature of places situated at greater elevations above the sea; and, accordingly, Mr. Atkinson has furnished the formula

$$97^{\circ}.08 \cos^{\frac{3}{2}} \text{lat.} - 10^{\circ}.53 - \frac{h}{251 + \frac{h}{200}} \ldots\ldots\ldots (K)$$

for the mean temperature of a place at the elevation h.

Remarks on it. (235.) In submitting the formula, however, to the test of actual observation, the Table which he has furnished, although very copious and valuable, is confined to observations made in America, and must therefore be received with caution. At the same time also it should be remarked, that it is open to another objection, grounded as it is on the high temperature he has attempted to assign to the Equator. Still it must be admitted, that the temperatures deduced from it approach more nearly to the actual values found by observation, than could have been anticipated from the great elevations of the places computed, and the variable conditions of temperatures found in tropical valleys, and on the plateaus by which those regions are distinguished. The great range of observation from the Equator to Winter Harbour in Melville Island, embraced by the Table, is also another feature which entitles it to consideration.

TABLE XLI.

Names of Places.	Latitude.	Height.	Observed Mean Temperature.	Temperature by the formula.	Difference.	Localities.
		Feet.	Fahr.	Fahr.	Fahr.

Convenience of Brewster's formula. (236.) Of all the formulæ, however, which have been contrived to enable us to approximate readily to the probable mean temperature of a place, at the level of the sea, that before given, and represented under the form of

$$81.5 \cos L,$$

is most distinguished for its simplicity, and on the whole agrees best with observation; and as it is often useful to be able at once to refer to a Table which shall indicate, within certain limits, the mean temperature of a given parallel, we have computed the following Table.

TABLE XLII.

Temperature of the Interior of the Earth.

Introductory remarks.

(237.) Fourier, in his elaborate and interesting Treatise on the analytical theory of Heat,* has properly remarked, that the question of terrestrial temperatures offers one of the most beautiful applications of the theory of Heat. The different parts of the surface of the globe, says he, are unequally exposed to the impression of the solar rays, and the intensity of this action depends on the latitude of the place, on the changes which take place during the day and the night, and on the effects of other inequalities of a less sensible kind. Between this variable condition of the surface, and that of the temperature of the atmosphere, some relation must exist, which a well-devised theory must ultimately unfold.

Howard's observations on the influence of the Earth's temperature on the atmosphere.

(238.) The heat existing from day to day in that portion of the atmosphere which is next the Earth, is at no time, says Mr. Howard, the simple product of the direct action of the solar rays on that portion; and the accumulation of heat near the surface, is evidently due to the stopping of the rays at that surface; to their multiplied reflections and refractions, in consequence of which they are as it were absorbed and fixed, for a time, in the soil and in the incumbent atmosphere. By this process, the Earth, when in a cold state at the end of winter, becomes gradually heated to a certain depth as the warm season advances; and, on the other hand, as the Sun declines in autumn, the heated soil acts as a warm body on the atmosphere, and gives out again the heat it had received, and as it were stored up. Similar vicissitudes during the day and the night, according as the Sun's action is exercised or withdrawn from the terrestrial surface, contribute in their part to that unceasing variety which characterises all the conditions of the great body of air surrounding it.

Influence of the solar rays on the Earth's surface.

(239.) It appears from experiments that have been made, that were the Earth's surface at a mean temperature, and the solar rays suddenly intercepted, it would require about thirty days to cool it down seven degrees, and about the same time to heat it to its former temperature, on their return. In fig. 2 is a diagram, constructed originally by Mr. Howard to illustrate this interesting subject. The oblique circle marked with the signs of the Zodiac denotes the varying declination of the Sun, and the irregular line which intersects it in something like opposite nodes, represents the curve of temperature for a year. The area comprised between the line of temperature and the Sun's path, and shaded with parallel lines, represents the cold produced by absorption on the side turned towards Spring; and the nearly similar portion covered with dots, and turned towards autumn, the heat derived by the atmosphere from the Earth's radiation. A like figure might be constructed to illustrate the vicissitudes of day and night, and may serve to illustrate, in a general way, the effect which the temperature of the Earth exercises on the great volume of the air.

Condition of the Earth's internal temperature.

(240.) Our knowledge, however, of the actual condition of the Earth's internal temperature, must be derived from observations made below its surface. By pursuing the subject, Philosophers have discovered that, at a certain depth below the surface, the temperature preserves a nearly constant character during the circling changes of the year; and this permanent temperature is less, according as the place is more distant from the Equator. The great volume of the Earth, therefore, may be supposed to be separated into two portions;—the exterior, which may be regarded as a kind of envelope, of a thickness incomparably less than the length of the terrestrial radius, and subject to the greatest vicissitudes of temperature; and an internal mass, or nucleus, of a form nearly spherical, the surface of which may be subject to a constant temperature,* through all the points of what may be denominated, in a general way, a given parallel, but which undergoes a variation in passing from one parallel to another.† It

Division of the Earth's volume into two portions.

---

* *Théorie Analytique de la Chaleur, par* M. Fourier, à Paris, 1822.

* To investigate the conditions of a great internal Isothermal plane, will open, at some future time, a noble subject for Philosophical inquiry.

† To treat this inquiry in all its generality, would be to follow Fourier through all the stages of his profound and valuable Work; to advance with him through his multiplied and refined applications of the Differential Calculus, to pass through the successive orders of his integrals, and sum the varied and important series which have enabled him to trace the law of the propagation of heat in a solid sphere. Our limits will by no means permit us to do this, and we can only recommend his elaborate Work to the deepest attention of our readers.

We may, however, briefly remark, that the general equations relating to the propagation of heat belong to the calculus of partial is the consideration of the former of these, that more immediately interests the Meteorologist, and to which we shall now briefly direct the attention of the reader.

Observations made in Caves at the Observatory of Paris.

(241.) Among the most interesting and important observations that have been made to prove the existence of a plane below the surface of the Earth, which preserves during all the mutations and changes of the year a nearly invariable temperature, may be mentioned the results obtained in the Caves below the Observatory at Paris, and of which the following Table contains an abstract for three years, together with the temperature of the Earth's surface during the same period, both in degrees of the centigrade scale.

Table XLIII.

Months.	Mean Temperature of the Caves for 1826.	Mean Temperature on the Surface of the Earth for 1826.	Mean Temperature of the Caves for 1827.	Mean Temperature on the Surface of the Earth for 1827.	Mean Temperature of the Caves for 1828.	Mean Temperature on the Surface of the Earth for 1828.
January	12°.161	− 1°.7	12°.172	− 0°.2	12°.194	+ 5°.9
February	12.165	+ 6.4	12.175	− 0.9	12.202	+ 5.2
March	12.170	+ 7.4	12.175	+ 8.0	12.230	+ 7.0
April	12.174	+10.2	12.176	+11.4	12.191	+10.8
May	12.170	+12.6	12.176	+14.6	12.195	+15.1
June..................	12.182	+18.8	12.176	+17.0	12.197	+17.5
July	12.171	+20.7	12.166	+19.8	12.193	+19.1
August..............	12.171	+21.2	12.171	+18.0	12.190	+17.6
September	12.170	+17.1	12.181	+16.2	12.210	+16.6
October..............	12.170	+13.4	12.182	+13.1	12.210	+10.8
November	12.168	+ 5.4	12.184	+ 5.8	12.215	+ 7.4
December.	12.171	+ 5.8	12.187	+ 6.9	12.212	+ 4.5
Mean	12.170	+11.44	12.177	+10.8	12.203	+11.5

From these observations it may be inferred, that while an uniform temperature is nearly preserved through the whole series of observations made in the Caves, an *increase* of temperature will be found from the surface to the point where the limit is attained, during the months of January, February, March, April, November, and December; but during the remaining months, a *decrease* of temperature takes place, till it has gained a like point of uniformity.

(242.) If Caves of a like nature existed in different latitudes, and observations of an equally accurate kind could be made in them, a most important series of results might be obtained, respecting the internal temperature of the Earth. But as this is obviously impossible, observations have been made at various depths, as circumstances would permit. Saussure, among others, made an interesting set of observations near Geneva, in October 1785. At the depth of 4 feet, he found the temperature to be 60°.8; at 16 feet 56°; at 21 feet 53°.6; and at 28 feet 51°.8; the temperature, at the surface, having been 60°.3, by Fahrenheit's scale. A thermometer, also, which had been placed 31 feet below the surface of the earth, when examined in summer, indicated a temperature of 49°.5; whereas a similar observation made in winter was 52°.2. It is

Observations of Saussure.

---

differences, and though their forms are very simple, they are not susceptible of integration by the ordinary methods.

The question of the propagation of heat depends on the integration of an equation of the form

$$\frac{dv}{dt} = K\left(\frac{d^2 v}{dx^2} + \frac{2}{x} \cdot \frac{dv}{dx}\right),$$

so that the integral is satisfied when $x = X$, at the same time $\frac{dv}{dx} + hv = 0$. The functions h and K represent, respectively, the ratios $\frac{h}{K}$ and $\frac{K}{C\,D}$, the four elements being specific coefficients which the progress of the inquiry developes. The function v denotes the temperature observed in a spherical lamina whose radius is x, after the time t. X is the radius of the sphere, and v is a function of x and t, equivalent to Fx when we suppose $t = 0$. The function Fx is given, and represents the initial and arbitrary state of the solid.

In applying this general equation to the propagation of heat in a solid sphere, it assumes the form

$$\frac{vx}{2} = \frac{\sin n_1 x \int x \sin n_1 x \, F x \, . \, dx}{X - \frac{1}{2 n_1} \sin 2 n_1 X} e^{-kn_1^2 t}$$

$$+ \frac{\sin n_2 x \int x \sin n_2 x \, F x \, dx}{X - \frac{1}{2 n_2} \sin 2 n_2 X} e^{-kn_2^2 t} + \&c.$$

which satisfies all the conditions of the problem.

In treating of the practical applications of the subject, it may be remarked, that we can only arrive at a knowledge of it, by measuring the temperatures of subterraneous excavations, or of those springs which issue from the depths of the earth. The small depths, however, to which the persevering industry of Man has penetrated, form but a small portion of the terrestrial radius. Cordier has properly remarked, in his excellent Paper on Subterranean Temperatures, that as it is proposed to apply ultimately to the great, the inferences deduced from the minute, the smallest errors will exercise a prodigious influence upon what is to be inferred respecting the temperature of the entire mass of the globe. If we proceed according to the approximative law deduced from the experiments hitherto published, an error of one degree of Fahrenheit in excess, for a depth of 180 feet in a given Country, will cause the point at which it is presumed water would boil, to approach within 1600 feet of the place of observation. And, again, if we compare the depth of the deepest mine in which observations have been accurately made on subterranean temperatures, with the entire length of the terrestrial radius, we shall find the latter dimension to exceed the former, nearly in the ratio of 20,000 to 1; a ratio sufficient to inspire the most salutary caution, when the attempt is to deduce the Physical condition of the antecedent from that of the consequent.

worthy of remark, that the greatest of these temperatures was found in winter. A series of observations made near the same place, and continued for ten years, proved that the minimum temperature occurred when the greatest heat prevailed in the atmosphere, and the maximum at the time of the greatest cold.

Observations of Mr. Fox.

(243.) Mr. Fox,[*] of Falmouth, also has made many interesting observations relative to the influence of the seasons on the temperature at considerable depths. In fig. 3., which refers to Dolcoath mine in Cornwall, A represents the bottom of the engine shaft 235 fathoms deep; B C the deepest galleries, or levels, on the course of the vein at 230 fathoms deep, and D E galleries 220 fathoms deep on the same vein. A great portion of the water finds its way to A, whence it is pumped by a steam-engine, the quantity discharged in 24 hours being 500,000 gallons. At the point *a*, a stream issued whose temperature was 82°, and at *e*, another stream, whose temperature was 78°, the air near A being 80°.[†] A hole, three feet in depth, was made at O in the deepest level, 15 fathoms from the engine shaft. It was usually quite dry, and for some years no men had been employed nearer to it than at A. In this hole was inserted the bulb of a thermometer, four feet in length, the space round the lower extremity of the instrument being carefully filled with clay. The persons employed below D E were usually two, and occasionally three at a time, on an average two and a quarter constantly. In D E there were four or five at a time.

In the galleries,	10 fathoms higher up,		10 men at a time.	
Ditto	10	ditto	14	ditto.
Ditto	10	ditto	14	ditto.

The total number of men was 360, but, as each worked only six hours at a time, 100 may be regarded as the average number constantly at work in the mine. From the erroneous views which have been entertained up to a late period on this very important subject, the minute attention given to all the conditions of this experiment will not be undervalued.

No alteration from the seasons.

(244.) The thermometer which was placed at O in January 1821, being examined in September 1822, exhibited no alteration from the seasons; but other thermometers buried eight inches in the rock, at different stations, in many of the superior galleries of the mine, (that nearest the surface being 100 fathoms deep,) indicated temperatures varying, according to the depth, from 57°.5 to 70°. The surface of the mine is about 62 fathoms above the level of the sea, the deepest workings being in granite, and those nearer the surface in clay slate.

(245.) The Treskerby Mine, which is worked under circumstances of strata and elevation very similar to Dolcoath, had the following observations made in it. In December 1819 the temperature at the surface being 50°, those of two streams proceeding from the opposite extremities of the deepest gallery, 149 fathoms below the surface, were 72° and 76°. The temperature of these streams was precisely the same in January 1820, when the surface was two degrees below the freezing point. In September of the same year, the temperatures of the streams were respectively 73° and 76°, when the air at the surface was 67°.

Monthly observations made in Cornwall.

(246.) Mr. Fox has also recently given us a series of Monthly observations, made in the Mines of Huel Gorland and Dolcoath, in the IIId volume of the *Transactions of the Royal Geological Society of Cornwall.* The thermometers were circumstanced like those first alluded to. The results are contained in the next Table.

TABLE XLIV.

Months.		Huel Gorland.	Dolcoath.
1823	June	52°.74	53°.60
	July	53.94	53.35
	August	55.30	56.60
	September	56.20	57.80
	October	53.70	52.70
	November	49.10	49.67
	December	46.00	47.57
1824	January	44.00	44.44
	February	43.63	44.85
	March	42.80	44.08
	April	43.78	44.62
	May	46.69	47.85
	Means	48.99	49.94

The mean annual temperature of Falmouth in the vicinity of these Mines is 50.67.

Observations of Mr. Ferguson.

(247.) Professor Leslie has likewise given us a series of excellent observations made by Mr. Ferguson at Abbotshall in latitude 56° 10′ North, in which mercurial thermometers with stems of unusual length were employed. The results are contained in the next Table.

TABLE XLV.

Months	1816.				1817.

---

[*] To this gentleman we are indebted for the first annunciation of the general law of an increase of temperature at considerable depths in the Earth, as well as for much of the information which has now so satisfactorily established its accuracy.

[†] To the same respectable authority we also refer for the fact that the mean temperature of the Earth's surface in a considerable portion of the mining district of Cornwall is below 50°.

Extensive observations now making by M. Arago.

(248.) Observations of a similar kind, but on a more extended scale, are at this time carrying on in the Garden of the Observatory at Paris, by the distinguished Astronomer M. Arago. The Scientific world waits with impatience for the results. It is obvious that all these observations must be much influenced by the peculiar conductibility of the solid mass, in or near which the thermometer of observation is placed.

The temperature below the Earth's surface varies with the latitude.

(249.) But the permanent temperature before referred to, although it may be constant for the same parallel, which however is extremely doubtful, varies considerably with the latitude, being less according as the place is more distant from the Equator. In the following Table it will be seen that between Vadso and Cairo, a difference of 40° of latitude, the temperature of the interior of the Earth varies 36°.5, and between the former place and Equinoctial America nearly 43°.

Table XLVI.

Places.	Latitudes.	Mean Temperature of the interior of the Earth.
Vadso................	70° 0′	35°.96
Berlin...............	52 31	49.28
Paris................	48 50	53.60
Cairo	30 2	72.50
Equinoctial America..........	......	77.00 78.08

Observations of Humboldt on springs.

(250.) Humboldt has remarked that from the Polar Circle to the Equator, and from the tops of mountains downwards to the plains, the progressive increase of the temperature of springs diminishes with the mean temperature of the ambient air. Wahlenberg also observes, that the mean temperature of the soil and subjacent rock rises higher and higher above that of the air, the further we advance towards the North.

Observations of Wahlenberg

The observations of Wahlenberg illustrating this remarkable result, were published by Von Buch in Gilbert's *Annals*, and compared with the temperature of the atmosphere. The following Table contains an abstract of the results, and perfectly illustrates the nature of the phenomenon.

Table XLVII.

Places.	Latitude.	Temperature of Spring.	Temperature of Atmosphere.	Difference.

Giworten Fiall, 1600 ſeet above the sea	66	34.2	25.2	9.0

Temperature of the air in mines.

(251.) Many interesting inquiries have also been made respecting the temperature of the air in mines, the results of which might be fairly regarded as representing the exact temperature of the zone of rock in which they are situated, had they been circumstanced like the Caves of the Observatory at Paris—uninfluenced by the presence of miners, freed from the access of water having the temperature of other strata, and also from the introduction of the external air.

Observations of M. Cordier.

(252.) The latest writer on this subject* is M. Cordier, who, in a Paper read before the Academy of Sciences in 1827 on subterranean temperatures, has ably discussed it. If we suppose for a moment, says he, what might take place in a mine of some extent, under the conditions here alluded to, we may fairly infer that the air in each stage would assume the temperature of the surrounding rock. And if we proceed on the hypothesis commonly received, and which seems justified by observation, that the heat increases in proportion to the depth, the air would continually circulate from the lower to the upper stages of the mine, and *vice versâ*, on account of the alteration of Specific Gravity, produced by the inequalities of heat at the different levels. A greater activity would prevail in these motions, the wider and less sinuous the subterranean excavations were, and the greater the number of their communications.

(253.) If, therefore, a uniformity of temperature would not be found to take place in the case of a mine circumstanced like one here alluded to, still less would it be found to prevail in common mines, to which the air has continual access, in which the filtering waters incessantly act as a cause of variation, and where the lights and workmen daily disengage large quantities of heat.

Influence o the external air.

(254.) Moreover, the external air, by continually mixing with the air contained in a mine, acts in the ratio of the temperature which it brings to each point, and of the mass which is introduced at the same point in a given time. These two elements are continually varying, and their influence necessarily extends to the most distant excavations. The temperature of the air which enters, varies every instant, and it is also influenced more or less in consequence of evaporation. At the same time the augmentation of temperature it may receive from the increasing effects of atmospheric pressure as the air penetrates into deeper cavities, cannot be considerable.†

Mean temperature of air introduced into a mine in a year, is less than the mean temperature of the year.

(255.) In pursuing these interesting considerations, Cordier has noticed the important fact, that the mean temperature of the mass of air introduced into a mine in the course of a year, is inferior to the mean temperature of the country for the same year. He estimates the difference at from three to five degrees of Fahrenheit, in most of the mines of our climates. Hence, not only does the introduction of the external air increase and diminish incessantly the temperature of the air contained in the different parts of each stage, but it also tends ultimately to lower the proper temperature of the whole excavation, and in an unequal manner, in different parts of the same level.

Effects of the filterin water.

(256.) The filtering water, which also operates as a disturbing cause, acts in an uniform manner, whether we consider its influence confined to a very short period, or extended to one very long. This cause tends to diminish the temperature of the air contained in the excavations in which it occurs, since it depends

---

* Since this was written, Mr. Henwood has published a very interesting Paper on the Temperature of Mines in the *Edinburgh Journal of Science*, No. XX.

† The increment of temperature produced by the increased atmospherical column has been much overrated. Cordier, with juster views, estimates the increased effect at about five or six tenths of a degree of Fahrenheit, for a depth of 180 feet.

upon the influence of the proper heat of the affluent waters; and these waters arrive at the point whereat they make their exit, with a temperature derived from more elevated zones of rocks. There is, indeed, an infinity of chances against the water of filtration and springs indicating a temperature perfectly equal to that of the rock from which they issue. The temperature of the rain-water which penetrates into the soil continually varies, being sometimes superior, and sometimes inferior to the mean temperature of the Country. The original degree of heat is also subject to many modifications, dependent on the depth to which the waters descend, the number and length of the canals, the slowness of the circulation, the length of time that it has been established, and the number and extent of the masses of water traversed, if there be any such in the lines of passage.

Anomalous results derived from the temperature of springs in mines.

(257.) A multitude of results have been obtained respecting the temperature of springs in mines, of the water of their engine pits, and also of those great inundations to which mines are occasionally subject, but the conclusions derived from them are by no means satisfactory. In many of them, the expressions of the increase of heat which have been found in the same mine, present variations, the extent of which infinitely surpasses that which might be admitted as resulting from anomalies arising from particular circumstances of the rock, or from those inaccuracies to which observations of this kind are liable.

Influence of workmen and lights.

(258.) Another disturbing cause arises from the heat disengaged by the workmen and the lights, which produces an effect the reverse of the preceding. According to the calculations of M. Cordier, the grounds of which are added in a note,* the presence of two hundred miners, and two hundred lamps suitably distributed, would be sufficient to raise a volume of air, which should fill a gallery whose length is 656,900 feet, (nearly 124 miles,) and transverse section 6 feet by 3 feet, one degree of Fahrenheit in an hour.

M. Cordier's results.

(259.) M. Cordier's results respecting the depths at which a depression of a degree of Fahrenheit's thermometer is found, are exceedingly variable. They may be useful to our readers in helping them onwards in the investigation, and we therefore subjoin them.

Observations derived from Springs in Mines.

1. By four observations made in three mines in Saxony, the depth at which a depression of a degree of Fahrenheit is found, varies from 102 to 64 feet, mean 83 feet.
2. By three observations made at Poullaouen, in Bretagne, the same result was obtained, from 351 to 82 feet, mean 206 feet.
3. By four observations at Huelgoët, a similar result was obtained, from 90 to 36 feet, mean 57 feet.
4. By one observation at Dolcoath, 45 feet was obtained.
5. And by one observation made at Guanaxuato, 46 feet.

Observations made on the Temperature of Water in Engine-Pits of Mines.

From these observations it was found, that the depth corresponding to the increase of one degree of heat would be, in round numbers, as follows:

1. By six observations made in four mines of Cornwall, from 37 to 27 feet, mean 32 feet.
2. By three observations made in three mines of Devonshire, from 71 to 35 feet, mean 60 feet.
3. By one observation made at the salt mine of Bex, in Switzerland, 48 feet.
4. And by two observations at Poullaouen, in Bretagne, from 137 to 95 feet, mean 116 feet.

Observations made on the Temperature of Water of great Inundations in Mines.

From these observations it was found, that the depth corresponding to the increase of one degree Fahrenheit, will be, in round numbers, as follows:

1. By seven observations, made in seven mines of Cornwall, from 75 to 23 feet, mean 52 feet.
2. By one observation in a mine of Saxony, 63 feet
3. And by one observation at Huelgoët, 56 feet.

Lastly, by means of Observations made on the Temperature of the Rock in Mines,

we find the depth corresponding to the increase of one degree of heat, as follows:

1. By two series of observations made during two years, in two points of the mine of Beschert Glück, in Saxony, the depth being from 101 to 68 feet, mean 84 feet.
2. By four series of observations made in 1815, in four points of the mine of Alte Hoffnung Gotes, in Saxony, from 175 to 64 feet, mean 93 feet.
3. By two observations made cursorily in the consolidated mines in Cornwall, 31 feet.
4. And by a series of observations which lasted 18 months, in a part of the Dolcoath mine, 54 feet.

(260.) Our limits will not permit us to do justice to

---

* According to the researches of M. Despretz on Animal Heat, a middle-sized man disengages, in twenty-four hours, by respiration, a quantity of heat equal to that which would raise one ounce of water to 205°.709 Fahrenheit, and this heat is only three-fourths of the quantity produced by the same individual during that time. Hence it follows that the total heat disengaged in an hour is equivalent to what would raise 4640 pounds of water one degree of Fahrenheit. By employing the ratio 1.000 : 0.2669, which according to MM. Berard and De la Roche expresses the difference of the Specific Heats of water and air, and adopting the Specific Gravity possessed by air at a temperature of 54° of Fahrenheit, it is found that a miner disengages hourly a quantity of heat capable of raising one degree of Fahrenheit, a cubic mass of air containing 34,456 feet, taken at the temperature of 54°.

Of the effects produced by the lights employed in mining two cases necessarily arise, according as oil or candles are employed. If linseed oil be employed, the combustion of one ounce will, according to the experiments of Rumford, raise the temperature of an ounce of water to 16°.28 of Fahrenheit; and hence Cordier remarks, that the presence of a lamp burning 15 grammes of oil, increases by one degree of Fahrenheit the temperature of a mass of air of 26,000 cubic feet, taken at the before-mentioned temperature of 54°. Thus, four of these lamps produce about as much heat as three workmen.

Count Rumford also found, that the heat furnished by the combustion of one ounce of tallow raised an ounce of water to 15°.064 Fahrenheit; and hence it follows that, in a single hour, the light obtained by the consumption of 7½ grammes of candles, raises 12,015 cubic feet of air one degree of Fahrenheit's scale, taken at the original temperature of 54° Fahrenheit.

These facts will be found of great value and importance to our readers, in pursuing the interesting problem of the Earth's temperature, as connected with the subject of mines.

Irregularity in distribution of Internal Heat.

Isothermal lines within the Earth.

this very important subject, and we can, therefore, only briefly remark, that the connection existing between some of the mutations of the atmosphere and the internal temperature of the Globe, renders it worthy of a more extended investigation. An idea started by Cordier, at the end of his excellent Paper, opens also a new field for Philosophical inquiry. "The differences," says he, "between the results collected in the same place, do not depend solely upon the imperfect nature of the experiments, but also upon a certain irregularity in the distribution of the subterranean heat in different Countries." This idea, replete with interest both to the Meteorologist and the Geologist, will, we trust, be effectually explored by the many active and patient cultivators of natural knowledge with which happily the present period abounds.* In the mean time we must not omit the observation of Mr. Fox, that "the Isothermal lines within the Earth may in some measure coincide with the form of its surface."

Influence of the Ocean.

(261.) We have only room to add the single remark, that the lower strata of the atmosphere are also influenced by the temperature of the waters of the Ocean; and forming as they do so considerable a portion of the Globe, could not be omitted in an inquiry of this kind. Although the sea radiates less absolute heat than continents, it exercises an important effect on the portion of the atmosphere resting on it, in consequence of evaporation. It sends the particles of water which are cooled, and therefore heavier, towards the bottom; and it is heated again, or cooled, by the currents directed from the Equator to the Poles, or by the mixture of the superior and inferior strata on the sides of banks. Having also alluded to some of the phenomena connected with the temperature of the Ocean in a preceding part of the Paper, we conclude by adding

TABLE XLVIII.

---

* We recommend the whole of Cordier's Paper to the particular attention of our readers. A translation of it may be seen in the Xth and XIth numbers of the *Edinburgh New Philosophical Journal*, edited by Professor Jameson. M. Cordier has also been occupied with some experiments of his own on this highly interesting subject, for which the learned wait with impatience.

Solar Radiation.

Solar Radiation.

(262.) Of the general laws which influence the radiation of caloric, we have already treated under HEAT. It will be our object in this part of the Essay on Meteorology, to direct the reader's attention to two beautiful examples of its power, denominated *Solar* and *Terrestrial* Radiation.

(263.) Many distinguished Philosophers have been occupied with the delicate and abstruse researches connected with the general question of radiation; but before the publication of Mr. Daniell's *Meteorological Essays*, the subject of Solar Radiation had hardly been emancipated from the region of conjecture. Dr. Wells, it is true, in his *Essay on Dew*, had shown its important relations to the vegetable kingdom, but scarcely any accurate attempts had been made to estimate the degree of Solar influence in any latitude, or at any elevation above the sea.

(264.) Mr. Daniell published his *Essays* in 1823, and it may, perhaps, surprise the reader of an after Age to learn, that at that date, and even at the time at which we are writing, no satisfactory answer can be given to the question—What is the maximum calorific impression which plants are subject to in any latitude? And influenced as the atmosphere is by the varying temperatures of the terrestrial substances acted upon by the Solar power, it becomes an interesting branch of Meteorological inquiry to examine, in all its generality, the principal conditions of this problem.

Difficulty of obtaining an exact measure of its power.

(265.) We shall, therefore, direct the reader's attention, in the first place, to Mr. Daniell's researches on this subject, and briefly review some of the objections that have been urged against them; at the same time earnestly impressing the importance of the question on the attention of the Philosophical inquirer. The thermometer employed by Mr. Daniell in his experiments on Solar Radiation was of the register kind, of a large range, having its bulb covered with black wool, and placed for observation about an inch above the Southern border of some garden mould, with a full exposure to the Sun. Mr. Daniell's results are contained in the following Table.

Experiments of Mr. Daniell.

TABLE XLIX.

Months.	Mean maximum of the air.	Mean maximum force of solar radiation	Maximum force of solar radiation.
January	39°.6	4°.4	12°
February	42.4	10.1	36
March	50.1	16.0	49
April	57.7	28.1	47
May	62.9	30.5	57
June	69.4	39.9	65
July	69.2	35.8	55
August	70.1	33.1	59
September	65.6	32.7	54
October	55.7	27.5	43
November	47.5	6.7	24
December	43.2	5.4	12

Solar Radiation varies with the declination,

(266.) From this Table it appears, that the power of the Solar Radiation varies with the declination. The greatest intensity, it will be remarked, occurs in June, while the maximum mean temperature of the atmosphere does not take place till July. This beautiful arrangement of nature has no doubt, as Mr. Daniell properly remarks, an important influence upon the processes of fructification, in the whole range of the vegetable kingdom. Agriculturists are well aware of the advantage of direct Solar heat in the flowering of wheat and other corn crops; an advantage which is never compensated by any elevation of temperature under a clouded sky.

and also during the different hours of the day.

(267.) But not only does the power of the Solar Radiation vary with the declination, and change with the successive seasons of the year, but during the day it likewise undergoes great modifications, increasing with the altitude of the sun from its appearance in the East until it has a little passed its meridian splendour; and again declining, till evening. In order to determine the system of changes, Mr. Daniell selected a perfectly calm and cloudless day in June, and his results are registered in the following Table.

Experiments to illustrate it.

TABLE L.

Time.	Temperature in the sun.	Temperature in the shade.	Difference.

Captain Sabine's experiments on the same subject at Sierra Leone.

(269.) At the time Captain Sabine was engaged in his inquiries with Captain Kater's pendulum in the tropical regions, he undertook to repeat Mr. Daniell's experiments. His first observations were made at Sierra Leone, and are recorded in the two succeeding Tables. The numbers in the column marked 1, are the means of two thermometers, one having a silvered and the other a blackened bulb. Those recorded in No. 2. were derived from a thermometer with a blackened bulb. The results of No. 3. are from a similar thermometer placed *in vacuo* in a glass-case. No. 4. indicates the temperature derived from a thermometer in the same glass-case with No. 3. but having its bulb enclosed in a double case of polished silver, not in contact with the glass or bulb. No. 5. denotes the numbers derived from a differential thermometer placed *in vacuo*, the sentient ball being coloured dark, and the other enclosed in a double case of polished silver. The divisions of this last were according to the millesimal scale.

Further experiments at Bahia and Jamaica.

(270.) Other experiments tending to like results were performed by Captain Sabine, at Bahia, on the coast of Brazil, and at Port Royal in the Island of Jamaica; and from their united testimony, compared with that derived from his own experiments in London, Mr. Daniell was led to the conclusion, that the intensity of the Solar Radiation diminishes as we approach the Equator. This distinguished Meteorologist became, also, confirmed in his views on the subject, when, by referring to some experiments performed by Captain Parry at Melville Island, he found greater effects recorded than were obtained in the same month, in the vicinity of London, thereby intimating an increase of Solar Radiation as we advance to the North. The results for Melville Island are entered in the next Table.

	2	+25	−22	47
	3	+21	−22	43

Scoresby's observations.

(271.) Mr. Daniell's views on this subject were, moreover, strengthened by some interesting remarks of Scoresby, in his *Account of the Arctic Regions*. The force of the Sun's rays, observes that enterprising man, is sometimes remarkable. Where they fall upon the snow-clad surface of the ice, or land, they are in a great measure reflected, without producing any material elevation of temperature; but when they impinge on the black exterior of a ship, the pitch on one side occasionally becomes fluid, while ice is rapidly generated at the other; or, while a thermometer placed against the black paint-work on which the Sun shines, indicates a temperature of 80° or 90°, or even more, a cold of 20° is sometimes found to prevail on the opposite side of the ship. This remarkable force of the Sun's rays is accompanied with a corresponding intensity of light.

Daniell's estimate of the temperatures referred to by Scoresby.

(272.) To form some estimate of the temperature referred to by Mr. Scoresby, the author of the *Meteorological Essays* performed the following experiment. He covered the bulb of a thermometer with pitch to the thickness of about one-tenth of an inch, and suffered it to remain till it had become quite hard. He then held it at some distance from a fire, and remarked the following temperatures. At 110° the pitch might have been moulded into any form, and from 120° to 136° it rapidly approached fluidity, and at the latter temperature dropped from the ball. The degree denoted cannot, therefore, be placed lower than 120°; and if ice were forming at the same time in the shade, the force of the Solar Radiation could not, Mr. Daniell observes, have been less than 90°.

Another observation of Scoresby.

(273.) Another observation of Mr. Scoresby is adduced by Mr. Daniell in confirmation of the subject. The Sun broke through the clouds, says the former observer, and produced a powerful effect upon the temperature. At two A. M. the thermometer was 3° or 4° below zero. At eight o'clock it was + 6°, and at ten A. M. about 14° in the shade. But the genial influence of the Sun was still more striking. In sheltered air, it produced the feeling of warmth; the black paint-work of the side of the ship, on which the Sun shone, was heated to a temperature of 90° or 100°, and the pitch about the bends became fluid. Thus, while on one side was uncommon warmth, on the other was intense freezing. The radiating force of the Sun, therefore, must, Mr. Daniell thinks, have been 80° in the month of April.

Observations on the Polar regions by Richardson, Back, and Kendall.

(274.) Since the publication of Mr. Daniell's *Essays*, the subject of Solar Radiation in the Polar regions has been resumed by Dr. Richardson, the naturalist to the expedition under Captain Franklin, and pursued with an earnestness worthy of their splendid enterprise. In an Appendix to Captain Franklin's *Second Journey*, Dr. Richardson, Captain Back, and Lieutenant Kendall have furnished the results of many interesting experiments; and, although they are not in all cases capable of comparison with each other, in consequence of the different results obtained by mercurial and spirit-of-wine thermometers, yet many most valuable conclusions may be drawn from them.

Solar Radiation varies with the declination.

(275.) In the first place it may be fairly inferred from the register kept by Captain Back and Lieutenant Kendall, that the force of Solar Radiation varies with the declination, and is some function of it. This will be apparent from the next Table, which, though not embracing the whole circuit of the year, affords very strong evidence in favour of such a supposition.

TABLE LV.

Year.	Month.	Mean Force of Radiation.
1826	November	10°.78
	December	6.99
1827	January	15.29
	February	34.55
	March	45.16
	April	53.18

These results were obtained by the aid of spirit thermometers; the bulb of that exposed to the solar influence being covered with thin paper, blackened with China ink and indigo, and sheltered from the wind by a thin glass bottle, and the other protected from the effects of radiation by two metal cylinders.* The hours of observation from which the results of the preceding Table were deduced, were 8, 10, and 11 A. M., and 1, 2, and 4 P. M.; and after the middle of February, an observation was also regularly made at noon. The maximum excess of temperature derived from the direct action of the Sun above the temperature indicated at the same time by the thermometer in the metal cylinders was always recorded by the observers.

Confirmed by some experiments of Richardson.

(276.) The same principle also is confirmed in some degree by the results obtained for the months of May, July, and August, by Dr. Richardson, with the aid of mercurial thermometers employed under the same circumstances as the preceding. These are shown in the next Table, and though so limited and brief, are to be highly valued, in the infancy of an inquiry like the present, obtained as they were under circumstances so trying and difficult.

TABLE LVI.

Year.	Month.	Mean Force of Radiation.
1827	May	35°.39
	July	28.00
	August	26.12

It must be remarked, however, that some little uncertainty exists in the numbers from which the results for July and August were obtained, on account of the observer, Mr. Dease, having lent his watch to the Eastern detachment of the expedition, a sacrifice which was however repaid by other interesting results.

Various maxima obtained in the Polar regions.

(277.) The following Table contains the maximum temperatures that occurred during the expedition, connected with the Solar Radiation, the highest and lowest temperatures of the air in the shade, and the difference between the temperature at sunrise, which was generally the lowest in the twenty-four hours, and that at two P. M., which, on an average, was the highest. All the observations are thrown into periods of ten or eleven days.

Horary ol servations made duri May, July and Augu

(278.) Amidst the cheerless solitude of the fort immortalized by the name of the English Franklin, the entire month of May, and the greater portions of July and August, were dedicated to the object of watching the power of the Solar Radiation, during many successive hours of the day. In the next Table the results of the first mentioned month are recorded, and embrace twelve successive observations for each day, the maxima being all denoted by asterisks.

---

* The thermometer was enclosed in a brass cylinder, an inch and a half in diameter, having a cover and bottom of the same material, fitted loosely to obtain a free passage to the air. This brass cylinder was shut up in another cylinder of tinned iron, four inches in diameter, which also gave free admission to the air. This apparatus completely answered the intended purpose; for even when the Sun shone brightly on the outer case, the enclosed thermometer indicated as low, and frequently a lower temperature, than one hung in the most shady spot that could be selected.

Time of maximum force of Solar Radiation.

(279.) The means of the successive columns of this valuable Table are recorded in that which next follows; and it appears from a comparison of the different numerical results, that the force of Solar Radiation is at its maximum when the Sun is on the meridian, but that the greatest temperature in the shade occurs an hour later. The Solar Radiation increases also from the morning to noon, and declines from noon to the evening.

TABLE LIX.

Month.	Hour.	Mean Temperature in the Shade by a Mercurial Thermometer.	Mean Excess of a Blackened Mercurial Thermometer in the Sunshine.

	5	40.59	18.14
	6	39.45	15.56

Graphical illustration of the power of Solar Radiation in the Polar regions and in London.

(280.) By contrasting also the last Table with the horary observations of Mr. Daniell, given in Table XLIX., we shall arrive at some other useful results. To enable us to make this comparison more readily, we have in some degree anticipated a subject into which we shall hereafter enter more fully, the method of exhibiting the alterations of atmospheric phenomena by means of graphical illustrations. For this purpose fig. 4 has been constructed from the Tables last quoted. The horizontal line A B in the diagram is divided so as to represent the times at which the observations were made; and the vertical lines springing from it represent the mean temperatures in the shade, and the effects of the solar radiation. Hence the curve E F denotes the mean temperature in the shade as recorded in Table LIX., and the still more irregular and dotted line C D the measure of the Solar Radiation. The nearly uniform line I K also in the diagram, denotes the temperature in the shade, as registered in Table XLIX., and the towering dotted curve G H represents, in like manner, the unequal and varied effects of the Sun's radiating power. The maximum temperature of the air in the shade for each hour during the month is denoted by the line L M, and the greatest power of the Solar Radiation for the same hours, by the dotted line N O.

Remarks relating to this comparison,

(281.) There is one thing, however, which we must mention with regard to this comparison, and that is, the curves for the Polar regions have been constructed for the means of an entire month, whereas those representing the labours of Mr. Daniell are confined to a single day. At the same time we must also bear in mind, that one system of results belongs to May and the other to June. Such are the limited materials we have to work with, that we can offer no better method of comparison.

and to tl aspect ol the grap cal curv

(282.) If we consider for a moment these different curves, one of the most obvious results is, that the power of Solar Radiation in the temperate and frigid zones is by no means the same. In the former region it would seem as if the Solar power was much more capricious in its changes, than in the colder regions of the North. The horary changes are much more rapid, and the entire aspects of the curves are different.

Dr. Ri- chardsoı remarks lative to intensity Solar Ri tion.

(283.) Dr. Richardson remarks, that the intensity of the Solar Radiation shown by the blackened thermometer was generally greatest when the sky was of a deep blue colour, and it was not much affected by scattered clouds, however dense, unless they passed over the face of the Sun. The temperature produced by the Sun's rays (except when the exposed thermometer was cooled by Southerly winds) generally increased, as might have been expected, gradually from sunrise to noon, and decreased again to sunset, but on an average the radiation was found to be more powerful in the forenoon, than at corresponding altitudes of the Sun in the afternoon. Dr. Richardson also found the radiation to be much stronger in the Spring months when the ground was covered with snow, than in the summer months when the altitude of the Sun was greater.

Intensit at equal titudes pendent the clea ness of atmosph

(284.) The difference of intensity of the Solar Radiation at equal altitudes of the Sun is, Dr. Richardson imagines, dependent upon variations in the clearness of the atmosphere; and, perhaps, the greater transparency of the air in the Spring, before the snow disappears, may, as he conceives, be explained somewhat as follows. In the month of March, for example, the Sun in the latitude of Port Franklin has sufficient power to heat the atmosphere considerably; but the snow then lies unmelted on the ground, and the temperature sinks very low in the night, frequently as low as it does at any time during the winter. Hence the cold, during the night, causes much of the moisture of the atmosphere to be deposited in the form of hoar frost; whilst, on the other hand, the warmth which the air acquires after sunrise renders its solvent power greater than the slow evaporation from snow, cooled most frequently below zero, can satisfy. The consequence is, that all the haze or mist floating in the air is completely dissolved shortly after sunrise, and the sky becomes clear to a degree which is unknown there in the summer, or in any season in more Southerly latitudes. The greater haziness of the sky after the Sun has passed the meridian, probably depends in some degree on the currents of air produced by the heat of the Sun, mingling portions of the atmosphere at different temperatures.

Solar R tion gr when p tial th clouds vailed.

(285.) During the summer, the power of the Sun was perceived to be the greatest, when partial thunder-clouds were floating over a deep blue sky, and after a few large drops of rain had fallen. When the Sun shone out at such times, its heat, Dr. Richardson remarks, was very oppressive.

Conne with re tion.

(286.) The highest peak of a chain of hills, distant about forty miles from Bear Lake, was visible in clear weather; and in particular states of the atmosphere a considerable portion of the range was seen, so that the amount of refraction of the air was in some degree indicated by the extent of hill that appeared over the low intervening grounds. The refraction measured in this way was greatest in a clear sky, when the temperature had been very low in the night, but was rising rapidly in the day, evidently through the influence of Solar Radiation.

(287.) The whole of Mr. Daniell's inquiries led him to the conclusion, that the power of Solar Radiation in the atmosphere increases from the Equator to the Poles. This opinion of Mr. Daniell has not been without its opponents. In the *Annales de Chimie* for August 1824, the accuracy of the experiments on which it is grounded, has been questioned. It has been urged that the thermometers were influenced by the vegetation on which they rested, that they were not always placed at equal distances from the ground and from the vegetation which covered it, nor were they equally secured from the action of currents of air. Mr. Daniell, in his reply to these objections in the XVIIIth volume of the *Journal* of the Royal Institution, observes that there is ample room for allowances of this kind, and yet to save the conclusion, that the power of Solar Radiation is less between the tropics than in higher latitudes.

Objections to Mr. Daniell's conclusion that solar radiation increases from the Equator to the Poles, in the Annales de Chimie.

(288.) Mr. Foggo in adverting to the same subject, in the XXVIIth number of the *Edinburgh Philosophical Journal*, is of opinion, that Mr. Daniell has confounded the actual power of the Sun's rays with the excess of temperature indicated by a thermometer exposed to the Sun above the temperature of the air, and that the situations of the thermometers of observation were not free from objection. Captain Sabine's thermometer with a blackened bulb, and covered with black wool, when placed on *grass*, did not, Mr. Foggo thinks, present the full measure of the solar influence in the experiments at Bahia. In support of this opinion, he adduces some experiments of his own, performed near Edinburgh, on the 7th of July. On a part of that day, when the temperature of the air was 59°, with a brisk wind, he exposed a large thermometer, having its ball covered with black wool, to the direct rays of the Sun, but unsheltered from the wind. On exposing the instrument to the direct action of the Sun, it rose to 95° in ten minutes. By laying it horizontally on short grass, it fell to 60°; but on restoring it to its former situation, it again rose to 94°. On the 29th of the same month, at $3^h\ 10'$ P. M., the same thermometer, which had been exposed all day in a sheltered corner, rose to 150°; when another instrument, similarly prepared, and resting in contact with the herbage, indicated only 119°. On the same day at two P. M. the former thermometer indicated 140°, and the latter 110°. Mr. Foggo, therefore, remarks, that we have here a difference of 30°, arising solely from the manner in which the instruments were exposed.

Mr. Foggo's objections.

His experiments.

(289.) These experiments are, however, too few in number to ground any hypothesis on; but they, nevertheless, open some room for supposing that, in the observatoins performed in the tropical regions, the full measure of the solar influence was not obtained; and we have indirect evidence from other quarters to strengthen such a view. Many detached observations exist in the writings of different travellers respecting the heat measured with *naked* thermometers, which seem to indicate a much higher measure of the solar influence. In Caffraria, Mr. Barrow saw an exposed thermometer mark 106°. The missionary Campbell, during his interesting journey in the winter through the Country of the Botchuanas, when the air at eight A. M. was 28°, saw the thermometer in the sun at noon rise to 84°. At Gondar, Mr. Bruce mentions a temperature of 113°; while at Benares 110°, 113°, and 118° respectively are recorded.

Tropical observations

(290.) Other detached observations respecting the temperature of the Earth, where it has been fully exposed to the effects of insolation, tend also to strengthen the supposition that the Solar Radiation is greater in the tropical regions than the observations of Captain Sabine would seem to indicate. At Sierra Leone, Dr. Winterbottom saw a thermometer placed on the ground rise to 138°. Humboldt also gives many instances of the temperature of the Earth amounting to 118°, 120°, and 129°; and at one time he found the temperature of a loose and coarse-grained granitic sand 140°.5; another, finer and more dense, 126°, the thermometer in the sun being at the same time 97°.16. It is probable, remarks the distinguished traveller, that the mean temperature of the dried mud, in which the alligators bury themselves during their state of periodical torpor, is more than 104° Fahrenheit.

Temperature of the Earth fully exposed to insolation.

(291.) Mr. Daniell is also of opinion, from some experiments performed by Captain Sabine on the mountains of Jamaica, and also from some observations made by Saussure, in his *Voyage dans les Alpes*, that the power of Solar Radiation increases from the surface of the Earth upwards.

Solar radiation increases upwards.

(292.) In the absence of positive experiments performed on a much more extended scale than we possess at present, it would be a departure from the rules of Philosophic prudence to adopt any hypothesis whatever. There are too many conditions involved; the range of observation is too wide, spreading out as it does from the Equator to the Poles; the circumstances of climate are too diversified; too little, indeed, is known concerning the force of Solar Radiation in those Countries most favoured by the presence of men devoted to the advancement of Meteorological knowledge, to justify the adoption of any theory to represent its varying conditions in other latitudes.

Concluding remarks.

Terrestrial Radiation.

(293.) It is a beautiful discovery of our own times, that if two bodies of different temperatures are placed at a certain distance from each other, even in a vacuum, that the one whose temperature is the highest, will gradually communicate its caloric to the other. In our Essay on HEAT we have unfolded some of the leading phenomena connected with this interesting inquiry, and we shall, therefore, only add such observations as will enable us to disclose its relations to Terrestrial Radiation.

Introductory remarks.

(294.) Since every portion of the Earth's surface incessantly loses heat by radiation, let us suppose that a small body, whose surface radiates freely, is placed beneath a clear and tranquil sky, on a vast uncovered plane. Such a body will emit calorific rays towards every point of the visible heavens, and unless it can receive heat in return from the upper sky, which (in the portion of this Essay devoted to Dew will be proved not to be possible in the case under consideration,) a body circumstanced like that in our hypothesis will undoubtedly be cooled. Applying this reasoning to the Earth's surface generally, when not exposed to the direct action of the sun, to the plains and the valleys, the mountains with all their varieties of surface and all their diversities of radiating power, and we shall recognise

Supposition of a good radiator being placed beneath a clear and tranquil sky.

Application to the Earth's surface generally.

an active and powerful principle, tending under some circumstances to cool the atmospheric strata in contact with it.

Inquiries of Dr. Wells.

(295.) The experiments of Dr. Wells which relate to the subject now under consideration, were directed in a great measure to establish the important fact, that a thermometer placed on the ground beneath a clear and tranquil sky, will exhibit a lower temperature than one suspended freely in the air. The clear and convincing experiments by which he established this important principle will be shown in the portion of our Essay just referred to. It was no part, however, of his inquiry to estimate the force of Terrestrial Radiation through the successive months of the year, and to communicate those general views which the later labours of Mr. Daniell have so successfully disclosed. We shall hereafter see that the laborious inquiries with which Dr. Wells was occupied, were sufficient, considering his health, to occupy all the energies of a single mind.

Of Mr. Daniell.

(296.) Mr. Daniell devoted considerable attention to the subject of Terrestrial Radiation, and in the following Table will be found the mean effect of radiation for every month, deduced from the averages of three successive years, together with its greatest observed intensity in the same intervals.

TABLE LX.

Months.	Mean Minimum of the Air.	Mean Depression from Radiation.	Maximum Depression from Radiation.
January	32°.6	3°.5	10°
February	33.7	4.7	10
March	37.7	5.5	10
April....	42.2	6.2	14
May	45.1	4.2	13
June...............	48.1	5.2	17
July	52.2	3.6	13
August.............	52.9	5.2	12
September..........	50.1	5.4	13
October	42.1	4.8	11
November	38.3	3.6	10
December...........	35.4	3.5	11

Analogy of his results with the law of radiation of Dulong and Petit.

(297.) The last column of the Table seems to indicate an approximation to the law of radiation established by Dulong and Petit, that the velocity of cooling *in vacuo*, or the force of radiation, increases as the terms of a geometrical progression for increments of temperature in arithmetical progression. The force of radiation as developed in the Table, has manifestly a tendency to increase with the heat, although the effect is concealed by too many disturbing causes to enable us to determine the law of the progression. From the third column we may also form an estimate of the clearness of the atmosphere, and the comparative brightness of the different months. April appears to be the clearest month of the year, and the cloudy state of July is deserving notice.

Important inferences of Mr. Daniell.

(298.) Mr. Daniell infers from his diary, that for ten months in the year in our climate, vegetation is liable to be affected at night, from the influence of radiation, by a temperature below that of the freezing point; and that even in the months of July and August, the radiant thermometer sometimes falls to 35°.

Comparative experiment of Captain Sabine at Bahia and Jamaica.

(299.) Captain Sabine performed also a number of comparative experiments on the same subject, in the tropical regions. At Bahia and Jamaica, he exposed upon grass to the aspect of the sky an alcohol thermometer, registering the extreme cold, and having its bulb covered with black wool. The following Tables contain a comparison of its indications with those of a register thermometer placed under shelter.

TABLE LXI.—*For Bahia.*

Day.	Temperature of Air.	Temperature of Radiation.	Difference.	Observations.
July 24	68°	63°.5	4°.5	Dew.
25	68	63.5	4.5	Dew.
26	72	62.5	9.5	Dew.
27	70	61.0	9.0	Dew.
28	64	60.5	3.5	
29	67	59.5	7.5	
30	65	64.0	1.0	

(300.) Captain Sabine remarks, that the register of the cold was the same, whether the thermometer was placed on a grass plat, or on a thick bed of rotboëlia, or on thick tufts of poa—a curious and valuable remark connected with the radiating powers of vegetables.

TABLE LXII.—*For Jamaica.*

Day.	Temperature of Air.	Temperature of Radiation.	Difference.
October 25	76°	72°	4°
26	76	69	7
27	76	65	11
28	76	66	10
29	76.5	65	11.5
30	76	65	11
November 3	76	67	9

(301.) Upon the mountains of Jamaica, 4000 feet above the level of the sea, Captain Sabine found the thermometer laid upon grass to afford the following results.

TABLE LXIII.

Date.	Time.	Temperature of Air.	Temperature of Radiation.	Difference.	Observations.
Oct. 31	P. M. 10h	65°	51°	14°	Clear and calm.
Nov. 1	A. M. 5	63	45	18	Ditto.
	P. M. 11	64	51	13	Clear and gentle breezes.
2	A. M. 5	64	55	9	Ditto.

(302.) From all these experiments, Mr. Daniell

Mr. Daniell's inferences.

infers that the same cause which obstructs the passage of radiant heat in the atmosphere from the Sun, opposes also its transmission from the Earth into space; and that the force of radiation for a given temperature, is less between the tropics than in the latitude of London, and that it obviously increases as we ascend above the Earth.

Objections made in the *Annales de Chimie.*

(303.) In the *Annales de Chimie* some remarks have been made, tending to prove that the results belonging to the tropical regions were obtained at times when the air was less clear or calm than at London, but there seems no reasonable ground for such a supposition. There are two circumstances, as Mr. Foggo justly remarks, which are sufficient of themselves to explain the anomaly:—first, the high temperature of the soil, which, in the torrid zone, frequently retains a heat of several degrees above that of the air, even when the latter has reached its minimum; and, secondly, the law established by Mr. Anderson, that the minimum temperature of the night is regulated by the constituent temperature of the aqueous atmosphere; the great quantity of moisture in the air equally preventing the diminution of its temperature beyond a certain degree, and checking the cooling of the ground by evaporation.

Remarks of Mr. Foggo.

Mr. Daniell's inference of an increase in Terrestrial Radiation as we go North.

(304.) Very little is yet known respecting the force of Terrestrial Radiation in the Polar regions. Mr. Daniell imagines from the intense cold which was found to prevail during calm weather in Melville Island, that a strong argument may be derived in favour of an increase of the radiating power as we go North. He also infers from the following remark by Mr. Scoresby, that the power of Terrestrial Radiation is developed in a very powerful degree.

Mr. Scoresby's remarks tending to the same point.

(305.) In cloudy weather, observes Mr. Scoresby, no freezing of the sea ever occurs when the temperature is above 29°; but in clear, calm weather, the sea, in the interstices of the ice, generally freezes on the decline of the Sun towards the meridian below the Pole, though the temperature be 32°, or higher. In the instance now alluded to, the freezing commenced when the temperature was 36°, being 7½° or 8° above the freezing point of sea-water. About two A. M. the thermometer in the air fell to 33°, by which time the bay ice was of such consistence, that the head-way of the ship, under a light breeze, was sometimes stopped by it.

The effects of radiation vary with the aspect of the sky.

Dr. Wollaston.

Mr. Leslie.

(306.) These effects of radiation vary with the aspects of the sky, operating vertically and in every oblique direction. Dr. Wollaston was the first to attempt to measure the effect, when a metallic mirror was presented to the upper sky; and we shall hereafter see, in the portion of our Essay devoted to Meteorological Instruments, that Mr. Leslie contrived his Æthrioscope to enable us to estimate the effects at intermediate altitudes.

Mr. Daniell's researches on the same subject.

(307.) Mr. Daniell, in estimating the effects of radiation under different aspects of the sky, employed the apparatus of Wollaston. The standard thermometer to which all his observations were referred, when not otherwise expressed, had its bulb covered with black wool. Another thermometer was placed upon the grass. The next Table exhibits a series of his interesting results relating to the force of radiation in a reflector and on the grass.

TABLE LXIV.

	Temperature of Air.	Temperature of Grass.	Temperature in Reflector.	Observations.
	42°	34°	30°	Very fine and clear.

Mr. Daniell's comparison of effects when the Sun is above and below the horizon.

Effect of colour.

(308.) Mr. Daniell's next attempt was, by means of the same apparatus, to compare the force of radiation when the Sun is above the horizon, with its power when that luminary is below. Under the most favourable circumstances, in a clear and tranquil atmosphere, he could never obtain an effect of more than five or six degrees with the thermometer covered with black wool. Imagining, however, that *colour* might in some degree modify the results, he had another reflector constructed precisely similar to the former, the radiating thermometer falling to an equal amount in each. In the focus of one of these reflectors he placed a thermometer, having its bulb covered with white wool, and in the focus of the other another thermometer, having its ball covered with black wool. A cloudless day was selected for the experiment, and the two instruments, placed side by side, were inclined at equal angles towards the Eastern sky. The following Table contains the results.

TABLE LXV.

Day.	Hour.	Radiation from Black Wool.	Radiation from White Wool.	Temperature of Air.	Observations.
May 16	P. M. 3½h	58°	53°	63°	Cloudless. During the experiment the reflectors were changed.
	4	58	53	63	
	8	44	43	54	
	11	36	36	47	
	During night	35	35	45	

Inference.

(309.) Hence it appears, that the amount of radiation from the white wool was equal, during the time the Sun was high in the heavens, to what it was during the night; while it was one half less from the black wool. During the absence of the Sun, the radiating power of the two was the same.

Other experiments.

(310.) Mr. Daniell repeated these interesting experiments under many varieties of circumstances; and in examining his results contained in the following Table, it is especially necessary to attend to the collateral circumstances.

TABLE LXVI.

Day.	Hour.	Radiation from Black Wool.	Radiation from White Wool.	Temperature of the Air.	Observations.
May 17	P.M. 1½h	64°	59°	65°	Overcast, with cumulo stratus.
	2	68	60	65	Clearing—reflectors to clearing space.
	2½	73	62	65	Faint sunshine.
	3½	74	62	66	Strong sunshine—reflectors turned, so that the shadows of the bulbs just appeared on the metal.
	4	76	64	68	
	11	51	51	55	Lightly overcast.
	Night.	42	42	51	Fine.

Remarks on the preceding Table.

(311.) On this Table Mr. Daniell makes the following remarks. The power of radiation was nearly neutralized in the black wool while the sky was overcast, but in the white wool it was only reduced to about one half. As the sky cleared, the reflectors being turned towards the Sun's place, the black thermometer rose above the temperature of the air, and the white thermometer still gave off more heat than it received. Exposed to the full power of the Sun, the reflectors being just turned out of the direct rays, the black thermometer rose 8° above the temperature of the air, and the white thermometer fell 4° below it. In estimating these different effects, it must be remembered, that the action of the reflector, in receiving and transmitting heat, is different. In the former case, the action is unduely increased, the heat which falls upon the surface of the speculum being thrown upon the thermometer in a concentrated form. In the latter case, the heat which radiates from the thermometer in the focus falls upon the concave metal, and is reflected into space in parallel lines. The effect is, therefore, only slightly augmented from the larger aspect of the sky. Mr. Daniell also found, whenever the reflector with the black woolled thermometer was turned towards a cloud, during the presence of the Sun above the horizon, that the mercury rose above the temperature of the air, excepting in the winter months; and a visible effect was produced even from the quarter most distant from the Sun. The concrete vapour, Mr. Daniell thinks, disperses the radiant matter, and acts upon it much in the way that ground glass operates upon transmitted light. No effect is produced by any cloud after the Sun has sunk below the horizon; and in an overcast night the action of radiation is perfectly neutralized. The following Table tends to illustrate this point; and to show the effects of two similar thermometers placed in the foci of similar reflectors, directed to different quarters of the heavens.

Action of the reflectors.

Effect of a cloud.

No effect after the Sun is below the horizon.

Experiment to illustrate it.

TABLE LXVII.

Date.	Hour.	Position of the Reflector.	Temperature of Black Wool.	Temperature of Air.	Observations.
July 2	Noon.	Horizontal inclined 30°.	76° 79	63°	Sky overcast—Cumulo stratus—Sun's place not visible—and brisk wind S.W.
	1 P.M.	Horizontal inclined 30°.	83 83	63	Sun's place just visible, but no shadows.
	2	Horizontal inclined 30°.	86 86	63	Ditto.
	2½	Horizontal inclined 30° E.	83 82	63	Sun's place not visible.
	3	Horizontal inclined 30° N.	79 79	63	Ditto.
		Inclined 30° N. 30° S.	76 79	63	Ditto.

	Night.	Inclined N. E.	40 40	48	Fine.
4	All Night.	Horizontal Vertical	41 43	51	Very fine.

Concluding remarks.

(312.) We commenced this division of our Essay by stating, that we owe to Mr. Daniell nearly all the information we possess on this very interesting subject; and being anxious to lay before our readers all that we are able to obtain, we draw from the same respectable source the following Table by way of conclusion, to denote the results obtained by a black radiating thermometer in a concave reflector, turned to the North, at an angle of 30°.

Table LXVIII.—*Observations of a Black Radiating Thermometer, in a Concave Reflector, turned to the North, angle 30°.*

On the Gradation of Heat in the Atmosphere.

Dalton's discovery that increased capacity of air is cause of cold of upper regions.

(313.) We owe to Mr. Dalton the discovery, that the natural condition of the equilibrium of heat in an atmosphere is found, when each atom of air in the same perpendicular column is possessed of the same quantity of heat; and, consequently, that such an equilibrium results, when the temperature gradually diminishes in ascending. This indeed is the natural consequence of the increased capacity for heat derived from rarefaction. When the quantity of heat is limited, the temperature is governed by the density. We shall hereafter refer to the delicate experiments and formulæ by which Professor Leslie determined the law of the progression.

Essential difference between cold from this cause and that arising from radiation.

(314.) There is an essential difference between that decrease of temperature which arises from the increased capacity of air for heat, and the cooling of the atmosphere produced by radiation. The amount of the former is governed by the altitude, and is a constituent element of the density due to the elevation; but by the exercise of the latter, the air is cooled below its natural standard, and thus becomes specifically heavier in its successive strata. From the unequal action of the Sun's rays, says Professor Leslie,[*] and the vicissitudes of day and night, a perpetual and quick circulation is maintained between the lower and upper strata; and for each portion of air which rises from the surface, an equal and corresponding portion must also descend. But that which ascends, acquiring an enlargement of capacity, has its temperature proportionally diminished, while the correlative mass, descending, carries likewise its heat along with it, and, by contracting its capacity, seems to diffuse warmth below. A stratum at any given height in the atmosphere is hence alike affected by the passage of air from below, and by the return of air from above, the former absorbing heat, and the latter evolving it. But the mean temperature at any height in the atmosphere is still on the whole permanent; and, consequently, those disturbing causes must be exactly balanced, or the absolute measure of heat is really the same at all elevations, suffering merely some external modification from the difference of capacity in the fluid with which it has combined. Hence that temperature is inversely as the capacity of air possessing the rarity due to the given elevation.

Knowledg of the gra dation of heat in th atmosphei obtained from the mensurati of heights

(315.) All our knowledge respecting the gradation of heat in the atmosphere, as resulting from the varied causes which operate upon it, has been derived from the useful observations that have been made with the barometer and thermometer, for determining the mensuration of heights; and the exactness of such measurements, within certain limits, cannot be questioned, because they have been verified in so many instances, by the nicest operations of Geometry, and the most delicate and refined operations of levelling. The numerous and diversified theoretical investigations which have been made respecting the beautiful problem of the terrestrial refractions, have also tended in no inconsiderable degree to throw a light on this important inquiry.[†]

Suppositi that the temperatu of a colu of air dim nishes wi the altitu

(316.) If we admit the temperature of a column of air to diminish in the same ratio as the altitude increases, and also suppose the rate of decrease, or the elevation necessary for depressing the thermometer a single degree, to be known, we shall be enabled to deduce with ease and facility the temperature at any altitude in the atmosphere, from the temperature observed at the Earth's surface, and also to compute the height of a column of air, by knowing the temperatures at its extremities. To determine the decrement of temperature, recourse must be had to actual observation.

Observed anomalie

A reference to the best authorities, however, is sometimes productive of considerable anomalies, even in circumstances where it is impossible to discern any cause for an apparent difference. In the following Table are forty-two measurements, taken from the *Mémoires sur la Formule Barométrique de la Mécanique Céleste*, by M. Ramond, made in circumstances of a very varied kind, and free from suspicion of errors of any considerable magnitude. Four of these, however, marked with an asterisk, deviate so widely from the rest, they may with propriety be omitted in estimating the mean.

Mean decrement resulting from the 42 Observations = 111.274 fathoms } for one degree of temperature.
Mean decrement by eliminating the Observations 22, 24, 38, and 42 = 90.058 fathoms }

ferences rom the able.

(317.) From this Table it appears, that the most rapid decrement of heat is at the rate of 61 fathoms, and the slowest 136 fathoms, to a centesimal degree. The mean rate deduced from all the observations is just 90 fathoms; and the extremes differ from the mean quantity, not by a small part of it, but by a half.

r. Ivory's marks on ano- alies.

And in reference to this subject, Mr. Ivory remarks,* that as we cannot doubt that the principle which distributes the difference of temperatures equally through the whole height of the column is nearly true, we must infer that the rate of decrease depends in a great measure upon circumstances peculiar to each particular case. In this respect, he says, causes seem to operate, which the observer is not only unable to appreciate, but even of the existence of which he has no indications. Very little confidence, therefore, can be placed in temperatures at different heights in the atmosphere, estimated by the rate of the decrease of heat; although the exactness of barometrical measurements is not by this means affected, the heat of the column of air being always determined by the temperatures actually observed at its extremities.

The instruments employed in determining the temperature may be one cause of the anomalies observed.

(318.) In endeavouring to account for the observed anomalies, Mr. Ivory remarks, that we may, perhaps, find in the nature of the instrument with which the heat is measured, some reason for the irregular deviations of the observed temperatures of the atmosphere from any theoretical law. The thermometer measures the temperatures of such bodies only as are in immediate contact with it. Local circumstances, impossible to be appreciated, may therefore so much affect a thermometer placed at the extremity of a column of air, as to make it indicate a temperature very different from that which would occur at a medium, and when all the causes which influence the propagation of heat through its entire length, have produced their due effect. In this manner the observed temperature may be made to diverge from that which is true, by the influence of a current of air in which the thermometer is placed; by the reflection of the Sun's rays from the surrounding

---

* *Philosophical Magazine*, July 1821.

objects; by evaporation, and the radiation of heat depending upon the nature of the adjacent soil; and by other causes.

The deductions of Ramond for the decrement of heat generally adopted by Philosophers.

(319.) The rate of the decrease of heat deduced from the above-mentioned observations of Ramond, *viz.* 90 fathoms to a centesimal degree, or 100 yards to a degree of Fahrenheit, seems to be the quantity most generally adopted by Philosophers. By means of this relation, the temperatures which prevail at given altitudes in the atmosphere are sometimes determined with great precision, although in other cases the calculation differs much from the truth. Thus adopting the great height of 3817 fathoms, as determined by Gay Lussac in his magnificent aerostatic ascent, the difference of temperature, at the rate of 90 fathoms to a degree, will be found to be 42°.4, which is a near approximation to 40°.3, the quantity actually observed. On the other hand, if we apply the same rule to the extreme cases in the Table of Ramond, we shall obtain results quite unsatisfactory. The decrease of heat in the atmosphere, observes Mr. Ivory, as determined by the ascent of balloons, seems to follow a slower rate than in the case of altitudes on the Earth's surface. There can be no doubt that this manner of experimenting is free from many causes of irregularity to which terrestrial observations are subject. We may, therefore hope that by this means much light will be ultimately thrown on the gradation of heat in the atmosphere; but a sufficient number of accurate experiments are wanting to establish a conclusion in which confidence can be placed. In the case of Gay Lussac's ascent, we obtain a rate of nearly 95 fathoms to a centesimal degree, which is not very different from the mean found by terrestrial altitudes.

Observations respecting the increments of altitude and the depressions of the thermometer.

(320.) Could we remove from the atmosphere the many causes by which the natural and regular propagation of heat is continually disturbed, there is no doubt that the temperature would be found to decrease nearly in the same ratio as the altitude increases. This, however, must be understood with limitations. If we conceive the height of a column of air to be divided into portions corresponding to a constant difference of temperature, it is much more probable that these portions will form a progression increasing or decreasing slowly, than that they will constitute a series of increments perfectly uniform. Such, however, are the anomalies attending observations of the temperature of the atmosphere, that it is extremely difficult to determine, by experiment, whether the heat decreases in a less or greater ratio than the altitude augments. According to some Philosophers, the increment of altitude necessary for depressing the thermometer a single degree, is a quantity continually increasing the higher we ascend. But the contrary opinion, that the heat decreases more rapidly than the altitude increases, is most generally adopted, and, among others, by Humboldt and Ramond.

Theory of Leslie.

(321.) Professor Leslie has given a precise and mathematical theory of the variation of heat in the atmosphere, and exhibited it in a formula distinguished for its simplicity and beauty. If b denote the altitude of the mercury in a barometer, at the lower of two stations, and β the height at the upper; then if t denote the difference of temperature in centesimal degrees, we shall have, according to the Professor, the following relation

$$t = 25\left(\frac{b}{\beta} - \frac{\beta}{b}\right) \dots\dots (L).$$

His first fo mula.

This formula was first published in 1811, in the admirable Notes to that Author's Treatise on Geometry.

His secon formula.

(322.) In the Paper on *Climate*, contained in the *Supplement* to the *Encyclopædia Britannica*, the Professor, however, has exhibited it under another form, by substituting the ratio of the densities at the extremities of the elevation, for that of the barometrical pressures. This alteration in the elementary conditions of the formula, gives it the form of

$$25\left(\frac{1}{\theta} - \theta\right) \dots\dots (M),$$

where θ represents the density of the air.

Mr. Ivory' remarks o the second formula.

(323.) On this modification of the formula, Mr. Ivory properly observes, that the ratios of the densities and the barometrical pressures are not rigidly equivalent. For at the top of the column, the temperature is always less than at the bottom, and the density of a mass of air depends both on the pressure and the temperature. In all Mr. Leslie's investigations, however, in the Paper above quoted, he seems to have estimated the density by the pressure alone, making no distinction between the two formulæ.

(324.) Of the ingenuity and sagacity displayed by Professor Leslie in the experimental investigation of the formulæ too much cannot be said; and although it is Mr. Ivory's opinion, that their accuracy is limited to small elevations, it is wonderful, considering the circumstances attending the experiments, that their author has been able to deduce a result at all conformable to Nature.

Analytic investiga tion of Le lie's first mula.

(325.) To investigate the analytical conditions of the first of Leslie's formulæ, let b, β, denote, as before, the barometrical pressures at the inferior and superior limits of a column of air, whose altitude in fathoms is x. Then neglecting the correction dependent on temperature, as unnecessary in the present inquiry, we shall obtain by the usual rule*

$$10000 \log. \frac{b}{\beta} = x;$$

and as the logarithms in this formula are of the ordinary sort, and that they are to the hyperbolic logarithms in the ratio of 4343 to 10000, we shall, therefore, have

$$10000 \log. \frac{b}{\beta} = 4343\, h\,.\log. \frac{b}{\beta};$$

and from which we may derive

$$h\,.\log. \frac{b}{\beta} = \frac{x}{4343}.$$

To simplify this last equation, let $a = \frac{1}{4343}$; and adopting l as the base of the hyperbolic logarithms, we shall obtain

$$h\,.\log. \frac{b}{\beta} = h\,.\log. l^{ax};$$

or passing from logarithms to numbers,

$$\frac{b}{\beta} = l^{ax}.$$

---

* Playfair, *Outlines of Natural Philosophy*, vol. i. p. 247. sec. 341.

Taking the reciprocal of this last equation, we have

$$\frac{\beta}{b} = l^{-ax},$$

and therefore

$$\frac{b}{\beta} - \frac{\beta}{b} = l^{ax} - l^{-ax};$$

or by expanding the latter member into a series, we have

$$\frac{b}{\beta} - \frac{\beta}{b} = 2\,a\,x \left\{1 + \frac{a^2\,x^2}{6} + \&c.\right\}.$$

If now we adopt for the decrement of temperature, 90 fathoms for every centesimal degree, which is the quantity employed by Leslie, we shall have

$$x = 90\,t;$$

and therefore the preceding equation will become

$$\frac{b}{\beta} - \frac{\beta}{b} = 180\,a\,t \left\{1 + \frac{1}{6}(90\,a\,t)^2 + \&c.\right\}.$$

But

$$180\,a = \frac{180}{4343} = \frac{1}{25} \text{ nearly};$$

and

$$90\,a = .0207 = \frac{2}{100} \text{ nearly}.$$

Hence

$$\begin{aligned}\frac{b}{\beta} - \frac{\beta}{b} &= \frac{1}{25}\,t \left\{1 + \frac{1}{6}\left(\frac{2\,t}{100}\right)^2 + \&c.\right\}\\ &= \frac{1}{25}\,t \left\{1 + \frac{2}{3}\left(\frac{t}{100}\right)^2 + \&c.\right\},\end{aligned}$$

or

$$25\left(\frac{b}{\beta} - \frac{\beta}{b}\right) = t \left\{1 + \frac{2}{3}\left(\frac{t}{100}\right)^2 + \&c.\right\}.$$

But, for small differences of temperature, the series forming the right-hand member of the equation may be regarded as equivalent to unity; and therefore we shall obtain

$$t = 25\left(\frac{b}{\beta} - \frac{\beta}{b}\right),$$

which is the first of Professor Leslie's formulæ.

Further remarks of Mr. Ivory on Mr. Leslie's theory.

(326.) The truth of Mr. Leslie's theory is therefore confirmed, at least for moderate elevations. Mr. Ivory, who was at first disposed to question its accuracy in the case of its application to Gay Lussac's ascent, making its deviation a tenth of the whole,[*] in a later publication[†] seems to regard it with a more favourable eye. The mean elevation, says he, for one degree of depression of the centigrade thermometer, is very nearly 90 English fathoms; and in the great height ascended by Gay Lussac, rather more than four miles and a quarter, the same quantity comes out 95 fathoms. To this great extent the law of a uniform decrease of temperature holds good, without much deviation from the truth. It therefore seems to be the assumption most likely to guide us aright in approximating to the true constitution of the atmosphere.

(327.) Of the second formula furnished by Mr. Leslie, it may be remarked, that nothing can exceed its simplicity and beauty. It may be enunciated in ordinary language as follows: Multiply the constant coefficient 25 into the difference between the density of the air and its reciprocal, and the result will represent the measure of heat due to the change of condition. This result may be either *plus* or *minus*: it may express the heat emitted in the condensation of air, or the heat absorbed during its opposite rarefaction.

Practical example of its use.

(328.) To illustrate, by a practical example, the uses of this formula, let it be required to estimate the heat liberated from air, when its density is tripled. In this case the formula will assume the numerical form of

$$25\left(3 - \frac{1}{3}\right) = 66^\circ\,\frac{2}{3},$$

which is the measure of the heat liberated; and the same quantity is withdrawn, either when the air recovers its former density, or when air of the ordinary state expands into triple its volume. A computation of equal simplicity will enable us to estimate the copious liberation of heat extricated by great and sudden condensations. The pneumatic matches invented by Mollet, which produce their effect by the momentary action of a small syringe, afford a beautiful experimental proof of the theory.

(329.) Professor Leslie was led to the creation of the preceding formulæ, by many delicate and refined experimental investigations connected with the increased capacity of rarefied air. Mr. Atkinson, in pursuing the same inquiry, has adopted another course, and endeavoured to deduce the laws which connect the altitude and temperature together, by an appeal to actual observation. His investigations on this important subject are contained in his *Memoir on the Astronomical Refractions* before quoted.

Views of Mr. Atkinson on the decrement of temperature.

(330.) Mr. Atkinson adopts as a basis for his inquiries, the results of a number of barometrical and thermometrical observations collected by General Roy, and others, with a view of obtaining a more correct rule for determining the altitudes of mountains. These Tables may be seen in the *Transactions of the Astronomical Society*, vol. ii. p. 151, &c., and their results are contained in the next Table. It will be remarked, that all the observations are confined to the North temperate zone.

TABLE LXX.

Skiddaw	20	112.00	28710.0
Totals	128	820.75	213234.5

Deductions from Table.

(331.) Of the third column in this last Table, named Differences of Temperature, it may be remarked, that it contains the sums of the successive differences of

---

[*] *Philosophical Magazine*, vol. lviii. p. 30.

[†] *Philosophical Transactions*, 1823, p. 437.

temperature observed at the highest and lowest stations of observation contained in the Tables referred to in the *Astronomical Transactions;* and the column devoted to the Altitudes, the aggregate amount of the different altitudes between the same points of observation.

By dividing the aggregate amount of these altitudes by the number of observations, we shall obtain the mean altitude of all the observations

$$=\frac{213234.5}{128}=1665.9 \text{ feet.}$$

In like manner, the sum of the differences of temperature divided by the same number of observations, will give $\frac{820.75}{128}=6^\circ.412$ of Fahrenheit, for the *mean depression* of the thermometer due to the *mean height* of the observations.

(332.) By referring also to Table XXXV., we shall find the

	Feet.
Sum of the altitudes in the first column of heights	= 18480
.... second............	= 13816
Total..........	32296

And dividing this total by 22, the number of observations contained in the Table, we shall obtain $\frac{32296}{22}=1468$ feet, the average altitude of the whole; and hence the depression of the thermometer due to the same elevation will, by the same Table, be according to

$$\text{Brewster's first formula } \frac{83^\circ.87+47^\circ.24}{22}=5^\circ.960,$$

$$\text{Brewster's second formula } \frac{72^\circ.09+49^\circ.87}{22}=5^\circ.544,$$

$$\text{Mayer's formula } \frac{80^\circ.22+44^\circ.69}{22}=5^\circ.678,$$

$$\text{and by Daubuisson's formula } \frac{78^\circ.72+43^\circ.30}{22}=5^\circ.546.$$

The mean of these gives 5°.682 for the mean depression of the thermometer at the height of 1468 feet, as deduced from the twenty-nine places recorded in Tables XXXIII., XXXIV., and XXXV.

(333.) From the preceding and other analogous considerations, Mr. Atkinson deduces the five following results:

TABLE LXXI.

Number of the Results.	Different Altitudes in Feet.	Depression of the Mean Temperature.
1	1468	5°.682
2	1666	6.412
3	3624	13.683
4	6597	23.850
5	10386	33.480

And from this last Table may be derived

TABLE LXXII.

Number of the Results.	Average Height due to each Degree of Depression, in Feet.
1	258.360
2	259.825
3	264.854
4	276.604
5	310.215

The gradation of heat is not that of an equable decrease when the altitude uniformly increases.

(334.) By a reference to this last Table it appears, that the law which represents the gradation of heat in the atmosphere, is far from being that of an equable decrease, when the altitude increases uniformly. At the same time it appears, that when the *decrements* of temperature are uniform, the *increments* of altitude constitute an arithmetical series.

(335.) To determine, however, whether this law is in conformity to Nature, let the uniform decrement of temperature be represented by a single degree of Fahrenheit's scale, and the corresponding increments of altitude by the series

$$x,\ x+y,\ x+2y,\ x+3y,\ \&c.$$

wherein the first term x represents the height due to the first degree of diminution of temperature from the level of the sea, and y the common difference appertaining to the whole progression. Let also n and n' denote the number of degrees which the temperature is depressed, at the elevations h and h'. We shall then have

$$x+(x+y)+(x+2y)\ldots.(x+(n-1)y)=h,$$

and

$$x+(x+y)+(x+2y)\ldots.(x+(n'-1)y)=h',$$

or

$$nx+\frac{n^2-n}{2}y=h,$$

and

$$n'x+\frac{(n')^2-n'}{2}y=h'.$$

From these last equations we obtain

$$x=\frac{h}{n}-\frac{n-1}{2}y\ldots..(N),$$

and

$$y=\frac{2\left(\frac{h'}{n'}-\frac{h}{n}\right)}{n'-n}\ldots.(O).$$

Applicati of the for mulæ to mean results befc obtained.

(336.) Applying these formulæ to the five mean results before obtained, and comparing the

			Feet.
5th with the 1st, we obtain	$y=3.73$	and	$x=249.63$
5th....... 2d..........	$y=3.72$	....	$x=249.76$
5th....... 3d..........	$y=4.58$	....	$x=235.81$
4th....... 1st..........	$y=2.01$	....	$x=253.66$
4th....... 2d..........	$y=1.92$	....	$x=254.63$
4th....... 3d..........	$y=2.31$	....	$x=250.21$

which makes the mean value of......... $y=3.045$
and the mean value of................. $x=248.95$

(337.) All the depressions agree, it may be remarked, in giving a positive value to y, although it varies by a comparison of different results. It seems not improbable, however, that this variation arises from the un-

Mr. Atkinson's inferences.

avoidable errors of observation: for if the 4th depression be diminished only 0°.6, and the 5th increased by 0°.75, the values of y, found as above, will be found to approach to uniformity. It may hence be inferred, says Mr. Atkinson, that the law which has been assumed, is either the true law, or nearly so; though it is evident that we are not yet in possession of observations sufficiently numerous and varied, to enable us to determine whether the law has an actual existence or not. The observations at present known are, however, sufficient to bring the uncertainty that may exist respecting the values of x and y, into comparatively narrow limits.

(338.) If we adopt for the mean value of y just deduced, the numeral 3, we shall find, by employing the depressions corresponding to the height of 1468 feet, the value of x equivalent to an altitude of 251.3 feet. Hence the following formula is obtained for the height due to any given depression of the thermometer n:

$$\left\{251.3 + \frac{3}{2}(n-1)\right\} n = h \ldots . (\mathrm{P}).^{*}$$

(339.) By applying this formula to the depressions and altitudes recorded in Table LXX., we shall obtain the results recorded in

TABLE LXXIII.

When the depression of the thermometer is	The height according to observation is	The height by the formula is	Difference in feet.	Difference in degrees of Fahrenheit.

Application of the same system of gradation to the tropical atmosphere.

(340.) Let us next endeavour to inquire if the same system of gradation holds good in the temperature of the tropical atmosphere.

Mr. Atkinson, in entering on this subject, endeavours by the application of certain corrections, to deduce the temperature of the free atmosphere, from the temperatures of the elevated places that have been visited in the tropics. The air which rests on the plains of the Andes, says Humboldt, although it becomes mixed with the great mass of the free atmosphere, presents, nevertheless, a surprising stability of temperature. However enormous be the mass of the Cordilleras, it acts but feebly on the strata of air which are unceasingly renewed. From these, and other considerations, Mr. Atkinson has deduced the following

Scale of Corrections.

Scale of corrections deduced from the observations of Humboldt.

When the plain is of small extent we may subtract....................................	2°.70	from the observed mean temperature.
For a small valley, or a plain of considerable extent	3.42	Ditto.
For large extended plains, or for warm valleys	4.14	Ditto.
For large sheltered valleys at great heights above the sea	4.50	Ditto.

And hence he remarks, that if the correction due to the *situation* of any place in South America, near the Equator, be taken from its observed mean temperature, the remainder will be a close approximation to the mean temperature of the free atmosphere, at the same elevation. In this manner the sixth column of the following Table was computed; and the depression of the thermometer due to the elevation of each place, is evidently found, by subtracting the temperature of the free atmosphere from the mean temperature at the level of the sea in the given latitude. The altitudes, it will be perceived, are comprised between 2000 and 5000 feet.

TABLE LXXIV.

	Mean height = 3888						Mean depression of the thermometer =	14.36

---

* A very neat approximative value for n may be thus obtained.

Since $$\left\{251.3 + \frac{3}{2}(n-1)\right\} n = h,$$

we shall obtain $$n = \frac{h}{251.3 + \frac{3}{2}(n-1)}.$$

But $$\frac{3}{2}(n-1) \text{ being nearly } \frac{3}{2} \times \frac{h}{300} = \frac{h}{200},$$

we shall have $$n = \frac{h}{251 + \frac{h}{200}}.$$

This will enable the reader fully to understand the formula (K), p. 49, and which we before employed in p. 36.

(341.) By a similar method of proceeding, the succeeding Tables have been computed. The altitudes in Table LXXV. are comprised between five thousand and eight thousand feet.

	12)108353							12)360.85
Mean height =	9029						Mean depression of the thermometer =	30.07

(342.) The altitudes also in the succeeding Table are found between ten thousand and twelve thousand feet.

TABLE LXXVII.

Names of Places.	Height in feet.	Latitude.	Observed Mean Temperature of Place.	Correction of Temperature on account of Localities.	Mean Temperature of free Atmosphere at same Height.	Correction for Latitude.	Mean Temperature at Level of the Sea in that Latitude.	Depression of the Thermometer due to the Height.
Plateau de los Pastos	10099	......	54°.50	2°.70	51°.80	....	84°.50	32°.70
Les Paramos	11480	4° 36′ N.	47.30	....	47.30	0°.47	84.03	36.73
	2)21579							2)69.43
Mean height =	10790						Mean depression of the thermometer =	34.715

(343.) In addition to these, Mr. Atkinson adds, that at the altitude of 15748 feet, the inferior limit of perpetual snow, a mean depression of temperature was found equivalent to 49°.62; and by an observation of Humboldt, made at One P. M., in June, a depression of 57°.38 was found on Chimborazo, at the elevation of 19,286 feet.

(344.) The different results thus obtained are inserted in the following Table:

Table of General Results.

Table LXXVIII.

Number of the Results.	Altitudes in Feet.	Corresponding mean depressions of the Thermometer in degrees of Fahrenheit.
1	3724	14°.070
2	6740	23.310
3	9029	30.070
4	10790	34.715
5	15748	49.620
6	19286	57.380

Inferences from it.

(345.) From this Table it may be inferred, that the gradation of heat in the portion of the atmosphere surrounding the torrid zone, actually coincides, or nearly so, with what has been shown to exist in the atmosphere of Europe. And, in order to investigate its condition more accurately, we may, as before, demonstrate, that if the *decrements* of temperature be regarded as uniform, the *increments* of elevation may be very nearly represented by an arithmetical series, whose first term is x, and common difference y.

Application of the formulæ (N) and (O) to the results of the last Table.

Applying therefore the formulæ (N) and (O) deduced from this supposition, to the results contained in the preceding Table, we shall obtain by comparing

Feet.

the 6th with the 1st, $y = 3.30$

6th........2d, $y = 2.76$

6th........3d, $y = 2.62$

5th........1st, $y = 2.96$

5th........2d, $y = 2.14$

4th........1st, $y = 4.47$

which makes the mean value of $y = 3.04$.

Taking, therefore, $y = 3$,

Feet.

the 1st result gives $x = 245.08$

2d............$x = 255.64$

3d............$x = 256.66$

4th...........$x = 260.23$

5th...........$x = 244.37$

6th...........$x = 251.53$

which makes the mean value of $x = 252.25$.

And therefore in a general way we may regard the values of x and y, as 252 and 3 respectively.

Further attempt to deduce the elements x and y.

(346.) But to obtain these values as accurately as the observations will admit, let the true value of $x = 252 + x'$, and that of $y = 3 + y'$. Substituting these in formula (N), and transposing, we obtain

$$252 + x' + \frac{n-1}{2}(3 + y') - \frac{h}{n} = 0,$$

if both the observations and formula be correct. If, however, one or both be incorrect in a small degree, we shall then have

$$252 + x' + \frac{n-1}{2}(3 + y') - \frac{h}{n} = \mathrm{E},$$

Formation of the necessary equations of condition.

in which E represents some unknown error.

(347.) Applying this last formula to each of the six mean results, we shall obtain the following equations of condition, for determining the values of x' and y':

$$x' + 6.535\,y' + 6.92 = \mathrm{E}_1$$
$$x' + 11.155\,y' - 3.68 = \mathrm{E}_2$$
$$x' + 14.535\,y' - 4.66 = \mathrm{E}_3$$
$$x' + 16.860\,y' - 8.25 = \mathrm{E}_4$$
$$x' + 24.310\,y' + 7.64 = \mathrm{E}_5$$
$$x' + 28.190\,y' - 6.46 = \mathrm{E}_6.$$

Application of minimum squares to them.

And hence by the method of minimum squares we find

$$x' = +1.428,$$

and

$$y' = -.06889.$$

Hence we shall have

$$x = 253.4 \text{ feet},$$

and

$$y = 2.9311 \text{ feet}.$$

Values of the elements when particular quantities are omitted.

If the last be omitted, we shall have $x = 253.478$ and $y = 2.927$

..... 5th....................$x = 251.060$ and $y = 3.180$

..... 4th....................$x = 251.796$ and $y = 2.933$

..... 5th and 6th.............$x = 237.330$ and $y = 4.390$

..... 3d and 4th..............$x = 249.380$ and $y = 2.988$.

And since the values of x and y, already adopted for Europe, were 251.3 and 3, it is evident that, so far as the observations in Europe and America can be depended on, the law representing the gradation of heat in the atmosphere, is the same both for the temperate and torrid zones.

Inference respecting the frigid zones.

Reasoning also on general principles we may infer, that it will either be the same, or nearly so in the frigid zones.* The formula (P) therefore before deduced for the temperate zone, may be likewise applied to the torrid zone, and to all the varieties of altitude contained in Table L. The following Table has been added to indicate the degree of confidence that may be placed in the formula.

Table LXXIX.

Europe.				America.

				19286	57.380	57.41	−0.030

---

* We are only acquainted with a single experimental observation made with a view of discovering the decrement of temperature in high latitudes. This experiment was performed by the Rev. George Fisher, and the intrepid navigator Captain Sir Edward Parry, at the Island of Igloolik, in lat. 69° 21′ N., and long. 81° 42′ W.

A paper kite was hoisted, to which was attached an excellent register thermometer, in a horizontal position. Its height above the level of the frozen sea, upon which the experiment was made, was determined by two observers in the same vertical plane, taking its altitude at the same time above the distant horizon; and thence its height was computed. The greatest height observed was 379 feet, at which it was nearly stationary for a quarter of an hour, although it had probably been more than 400 feet above the sea. The experiment was made under very favourable circumstances, the kite being sent up and caught in coming down, without the slightest agitation. "*The indices,*" says Mr. Fisher, "*had not altered their position in the slightest degree*, and they would have indicated any variation of temperature, had it

The differences between the observed and calculated temperatures are quite within the limits of observation; and the formula employed may therefore be regarded as exhibiting, with tolerable accuracy, the relation between the temperature and the height, in the mean state of the atmosphere, up to the greatest altitude at which observations have yet been made.

Humboldt's opinions respecting the decrease of heat in the atmosphere of the torrid zone.

(348.) On the decrease of temperature in the atmosphere of the torrid zone, Humboldt is of opinion, that in its mean state, the heat does not decrease uniformly in an arithmetical progression. This he infers from the observations recorded in the following Table.

TABLE LXXX.

Heights in		Equatorial Zone, from 0° to 10°.		Temperate Zone, from 45° to 47°.	
Metres.	Feet.	Mean Temperature.	Difference.	Mean Temperature.	Difference.
0	0	81°.50			
974	3195	71.24	10°.26	53°.60	
1949	6393	65.12	6.12	41.00	12°.60
2923	9587	57.74	7.38	31.64	9.36
3900	12792	44.60	13.14	23.36	8.28
4872	15965	34.70	9.90		

Alterations in the decrements of temperature at different altitudes.

In the Cordilleras, says Humboldt, (and the fact is extremely curious,) we observe the decrease getting less and less between 1000 and 3000 metres, particularly between 1000 and 2500 metres of elevation, and then increasing anew from 3000 to 4000 metres. The strata, says that distinguished traveller, where the decrease attains its maximum and minimum, are in the ratio of 1 to 2. From the height of the Caraccas to that of Popayan and Loxa, 1000 metres produce a difference of 6°.3. From Quito to the height of Paramos, the same 1000 metres change the mean temperature more than 12°.6. Do these phenomena, inquires Humboldt, depend only on the configuration of the Andes, or are they the effect of the accumulation of clouds in the aerial ocean? In considering that the Andes form an enormous mass, from which rise lofty peaks or domes insulated and covered with snow, we may conceive how, from the point where the mass of the chain diminishes so rapidly, the heat decreases also with rapidity. It is not easy, however, to explain by an analogous cause, why the progressive cooling diminishes between 1000 and 2000 metres. This eminent man supposes the slowness with which the heat decreases in the stratum of air between 1000 and 2000 metres to be the triple effect of the extinction of light, or the absorption of the rays in the clouds, of the formation of rain, and the obstacle which the clouds present to the free passage of radiant heat. The bed of air here referred to by Humboldt, is the region in which are suspended the large clouds which the inhabitants of the plains see above their heads. The decrease of temperature, which is very rapid from the plains to the region of the clouds, becomes less rapid in that region; and if this change is less sensible in the temperate zone, it arises from the effects of radiation being less sensible at the same height, than above the burning plains of the equinoctial zone.

Attempt to explain the cause.

Humboldt' results respecting th decrement of temperature.

(349.) The following Table contains the results of Humboldt's researches on this interesting subject. The measures recorded in the third column indicate the mean result, or the measure of the distribution of heat in the whole column of air.

TABLE LXXXI.

Part of the Globe.	Extreme Altitudes in Metres.	Altitudes corresponding to the Temperatures of the next Columns in Metres.	Temperatures.	
			Cent.	Fahr.
Equinoctial Zone..	0—4900	187	1°	1°.8
Temperate Zone ..	0—2900	174	1°	1°.8

(350.) By observations made during solitary excursions to the tops of some lofty mountains, Humboldt has deduced the results contained in the next Table.*

TABLE LXXXII.

Part of the Globe.	Altitudes corresponding to the Temperatures of the next Columns in Metres.	Temperatures.	
		Cent.	Fahr.
Equinoctial Zone....	190	1°	1°.8
Temperate Zone....	160—172	1°	1.8

(351.) The coincidence in the results of the two last Tables is certainly remarkable; and when we consider that we have compared stationary with insulated observations, and hence confounded the mean state of the atmosphere in the course of a whole year, with the decrease which corresponds to a particular season, or some accidental hour of the day, the agreement is still more singular.

Dr. Youn attempt t deduce tl gradation temperat from the mean refractions.

(352.) Dr. Young, in the VIIIth number of the *Astronomical and Nautical Collections*, published in the *Journal of the Royal Institution*, has also endeavoured to deduce the gradations of temperature in the atmosphere, from the mean refraction; and the result of his inquiry is to give 208 feet for the altitude corresponding to the depression of a single degree of Fahrenheit's thermometer.

---

existed, to less than a quarter of a degree, Fahrenheit." The temperature at the time was — 24° Fahrenheit.

Dr. Young, in alluding to this interesting experiment, remarks, that the law of decrease of temperature must be supposed to be very different in the Arctic regions from that which prevails in more moderate latitudes. The inference, however, is by far too sweeping, resting as it does on a single experiment. We may hope, however, that time will make known more perfectly many of the Physical conditions of the Polar regions.

* Humboldt obtained a series of partial results from the back of the Andes, of which the following is an abstract.

Heights in Metres.	Cent.		Fahr.		Metres.
0—1000	1°	or	1°.8	for	170
1000—2000	1	..	1.8	..	294
2000—3000	1	..	1.8	..	232
3000—4000	1	..	1.8	..	131
4000—5000	1	..	1.8	..	180.

In these numbers, we recognise the influence of the region of clouds upon the decrease of heat.

Remarks respecting the data on which the general investigation rest.

(353.) The experimental data on which all our conclusions on this interesting subject rest, are not entirely unexceptionable. The circumstances are so varied under which many of the experiments have been performed, and such is the changing character of the atmosphere, even in the short intervals of observation, that much remains to be done to perfect the inquiry. Not only do the results of observation vary for the same place, under different conditions of the atmosphere, but many anomalies arise from the various circumstances attending the relative situations of the heights at which the observations are made. If the lowest point, for example, be on a level plain, and the highest exist in the free air, the decrease must be very different from what it would be, if the lowest point were at the bottom, and the highest on the summit of a mountain; or if the observations were made at the lowest and highest points of a great city, at the sea-side, or on the summit of a hill in the interior. Nor is it always that the highest point is of the lowest temperature during the day, the atmosphere exhibiting sometimes, in this respect, a remarkable analogy to what takes place on nights most favourable to the production of dew.*

Anomalous observations made by Roy.

(354.) Among the observations made by General Roy on the temperature of the upper regions of the air, it may not be unimportant to notice the following, on account of their exhibiting anomalous results.

Table LXXXIII.

Stations.	Time of Observation.	Difference of Temperature.
Green Wharf at Woolwich Warren, and the upper story of Shooter's Hill Inn. Difference of height 444 feet.	1774, April 27, 4 P.M. Mean of 4 observations. April 27, 6h 30m P.M. Mean of 2 observations. April 28, 5 A.M. Mean of 5 observations.	6° *warmer* at the higher station. 0½° *warmer*, do. 1¾° *colder*, do.

Base of Hawk-hill Observatory, and bottom of the small rock on Arthur's Seat, 684 feet.	1776, Jan. 31, 10h 45m A.M. July 25, 2 20 P.M.	6° *warmer*, do. 2¾° *colder*, do.
Hawk-hill Garden-door, and bottom of the rock on Arthur's Seat, 730.8 feet.	1775, Dec. 27, 11h 30m A.M. —— 8 40 —— 1776, Feb. 1, 9 30 ——	*No difference.* 3¼° *colder* at the higher station. 2° *warmer*, do.

With greater altitudes the fluctuations diminish.

(355.) As the altitude increases, the fluctuations diminish, but they still exist to a great degree, as will appear from the following Table, containing observations made at Caernarvon Quay, and the top of Snowdon.

Table LXXXIV.

Altitude.	Day of Observation.	Hour of Observation.	Difference of Temperature of two Stations.
3555 feet.	1775, Aug. 7.	6h 7m A.M.	11¼° Colder at the higher station.
	....	9 7 ——	12¾° ditto
	....	0 7 P.M.	7¾° ditto.
	....	2 7 ——	11° ditto.
	14.	8 7 A.M.	12¼° ditto.
	....	0 7 P.M.	16° ditto.

Different results obtained for the *Pic du Midi*.

(356.) In like manner we shall find with reference to the observations made on the *Pic du Midi*, and given in Table LXIX., that the following differences of temperature were found on the different days recorded.

Table LXXXV.

Altitude.	Day of Observation.	Difference of Temperature at the two Stations, the upper being the coldest.
1428.79 feet.	July 26, 1809.	60°.6
	Sept. 15 ——	51.8
	Sept. 4, 1803.	57.9
	Sept. 12 ——	55.6
	Sept. 23 ——	51.3
	Sept. 27 ——	59.2
	Sept. 30 ——	50.9

For Mont Blanc.

(357.) So also for two observations made with reference to Mont Blanc, one at noon, and the other at two P.M., the difference of the temperatures for the former period was 88°.2, and for the latter 84°.6. These variations necessarily produced corresponding changes in the values of the decrements of altitude, that for the first set of observations being 76.55 fathoms, and for the second 82.02 fathoms. But with respect to the Puy de Dome, contained also in Table LXIX., we shall find that for two observations made respectively at noon, and one P.M., the difference of temperature for the former was 44°.6, and for the latter 44°.4. The decrements of temperature hence nearly correspond. Similar observations made at the same place on the 29th of June, 1808, and the 7th of August of the same year, produced in the former case, a difference amounting to 49°.3, and in the latter to 49°.1. These equal differences of temperature produced nearly equal decrements of altitude, but when compared with the former decrements of the same kind afford a difference of nearly 23 fathoms for a single degree of Fahrenheit.

Equality in the observations for the Puy de Dome.

Brisbane's observations for different hours of the day.

(358.) Sir Thomas Brisbane, to whom Astronomy is in particular is under such lasting obligations, pursued the subject of the variations of temperature at a constant difference of altitude for different hours of the day,

---

* "On every clear and still night, the air nearest the earth is colder than that which is more distant from it, to the height at least of 220 feet, this being the greatest to which Mr. Six's experiments relate." Wells, *On Dew*, p. 95. 2d edit.

at Port Macquarie, Van Dieman's Land. His results are contained in the following Table, and were derived from a difference of altitude corresponding to 52 feet.

TABLE LXXXVI.

Period of the Day when the Observations were made.	Difference of Temperature in Fahrenheit's degrees.
Mean difference of temperature at Sunrise.	−6°.00
at 9 A. M.	−9.01
at Noon.	−7.55
at 3 P. M.	−5.50
at Sunset.	−3.50
Mean..	−6°.31
Maximum difference at Sunrise.	−13°.0
at 9 A. M.	−25.0
at Noon.	−18.0
at 3 P. M.	−11.0
at Sunset.	− 9.5
Minimum difference at Sunrise.	0.0
at 9 A. M.	+ 1.5
at Noon.	+ 0.5
at 3 P. M.	+ 0.0
at Sunset.	+ 3.0

These anomalies in the temperature must be attended with corresponding differences in the decrements of altitude.

Observations of Saussure on the effects of the seasons on the decrements of altitude.

(359.) Saussure, in his Meteorological inquiries, deduced the decrements both for summer and winter, assigning to the former season a decrement of 292 feet for a degree of Fahrenheit's thermometer, and to the latter 419 feet. For the whole year he assigned 356 feet.

(360.) The preceding remarks show, that to proceed successfully in this inquiry, a great number of contemporaneous observations should be made, at different seasons of the year and at different times of the day, in order to deduce from them the mean condition of the atmosphere.

Dr. Wilson's suggestion of determining the decrements of temperature by balloons.

(361.) One of the best methods that could be adopted for determining the decrements in question, would be the carrying into execution, on an extended scale, a suggestion originally made by the late Dr. Wilson, Professor of Practical Astronomy in Glasgow. An account of Dr. Wilson's method may be seen in the *Transactions of the Royal Society of Edinburgh*, vol. x. p. 2. and is briefly as follows.

Several paper kites of a large size were raised one above another, upon the same line, with (register) thermometers attached to them. Mr. Wilson began with raising the smallest kite, which, being exactly balanced, soon mounted steadily to its utmost limit, carrying up a very slender line, but of a strength sufficient to command it. In the mean time, the second kite was supported by two assistants, in a sloping direction, with its breast to the wind, and with its tail laid out evenly upon the ground behind, whilst a third person, holding part of its line tight in his hand, stood at a good distance directly in front. Things being thus ordered, the extremity of the line belonging to the kite already in the air was hooked to a loop at the back of the second, which being now let go, mounted very superbly, and in a little time also took up as much line as could be supported with advantage; thereby allowing its companion to soar to an elevation proportionally higher.

Upon launching these kites, and affording them abundance of proper line, the uppermost ascended to an amazing height, disappearing at times among the white summer clouds, whilst all the rest, in a series, formed with it in the air below such a lofty scale, as at once changed a boyish pastime into a highly useful Philosophical experiment.

Lord Minto's application of the same experiment.

(362.) The Earl of Minto[*] has somewhat varied the experiment by employing balloons, having register thermometers attached to them, hung freely in a cylindrical case of glazed pasteboard, open at each end. The thermometer below was suspended in a similar case.[†]

On the Plane of Perpetual Snow.

General considerations.

(363.) The preceding researches respecting the progressive diminution of temperature as we ascend through the air, must conduct us at last to a region of perpetual snow. We have proved, at least approximatively, the existence of a law, common to all the regions of the Earth, by which the decrease of heat in the atmosphere is measured, but which, nevertheless, depends, in the extent of its operation, on the different temperatures of the terrestrial parallels. If we go to the Equator, where the maximum mean temperature is found, and trace the law of its descent in the great volume of the air, until it reaches the limit which Nature assigns to the existence of perpetual snow, we shall arrive at an elevation much greater, than if we ascended from the mean Geographical parallel, or endeavoured to trace its limits above the Polar circle. Thus the great heats of the torrid zone influence the temperature of the air at a much greater elevation above the Ocean, than the temperate regions of Europe, or those cheerless climes of the North, where the dominion of cold holds a more unlimited sway.

No animated beings o vegetabl forms ex above it.

(364.) In setting out from the Equatorial regions, where the magnitudes of the mountain masses fill the traveller with amazement and awe, he is led to contemplate those hoary summits, which in so many latitudes invite his examination;—unfolding the existence of a plane—magnificent from its extent and operations—at and above which, all the dreary powers of winter are called into perpetual action; which, even in the torrid zone, destroys the fairest and most gigantic forms of vegetation, and permits within its vast and boundless domain, the existence of no animated being to disclose, amidst the fearful sublimity, those living functions and powers, which communicate happiness and joy to the more favoured regions of the Earth.[‡]

---

[*] *Edinburgh Journal of Science*, vol. vii. p. 249.

[†] Lord Minto seems to have enclosed his *lower* thermometer in a case of *writing paper*. The circumstances of an experiment will be much altered by the employment of thermometers enclosed in cases of *different materials*. Dr. Wells has given some interesting observations on this head, in his valuable *Essay on Dew*. When the bulb of a thermometer was enclosed in a metallic paper, the temperature indicated by it was found to be greater than the actual temperature of the air; whereas one enclosed in a similar case of white paper, was commonly found, when a difference did exist, to be lower.

[‡] This observation cannot be regarded as rigidly true; although when contrasting the dreary regions of the perpetual snows, with the

Plane of perpetual snows supposed at first to be uniform,

(365.) By the plane of perpetual snows, we are to understand the curved surface which passes through the greatest heights at which the snows are preserved during the entire year. To trace the altitude of this plane above the different terrestrial parallels, has long been an object of interesting inquiry. At first it was imagined, that its range through the atmosphere partook of some character of uniformity; but later and more Philosophic views have proved, that its altitude above the level of the sea, is the result of a great variety of causes, —of all the uncertain conditions of the terrestrial surface,—of the unequal distribution of heat,—of the anomalous effects of mountains and plains, the great oceans alone contributing a partial uniformity to it.

but now known to be most unequal.

General idea of its figure.

(366.) A general idea of its figure may, however, be gathered from fig. 5, in which N E S Q denotes the surface of the Earth, and C D E F the superior limit of the atmosphere. The curve A N B S may be supposed to represent a section of the plane of perpetual snow, attaining, but for peculiar anomalies, its greatest elevation at A E and B Q in the Equatorial regions, and gradually descending towards the Earth's surface, until it at length meets it in some point of the Polar zone.

Its elevation known but at a few points.

(367.) The known points are comparatively few, which mark the elevation of this plane above the ordinary level of the sea; and they ought to be highly valued, notwithstanding the chances of some uncertainty existing in them, when we consider the immense difficulties attendant on their determination. We shall, therefore, take a rapid review of its position on some of the principal mountain chains of the Globe.

First attempts in Equatorial regions to find its elevation.

(368.) It is in the Equatorial regions of the New World that we meet with the most magnificent examples of this splendid plane, as it was in that region the first efforts were made to ascertain its height. The first and earliest attempt was made by the French and Spanish Philosophers, who were employed in the operations connected with the measurement of the great arc of the meridian in the tropical regions. The measures of Bouguer and Condamine appear to disagree, although an inscription engraven on a table of marble, —which, in spite of the destruction of the Order of the Jesuits, has been preserved in one of the Galleries of the College of that order at Quito,—seems to imply that a common measure was agreed on by these celebrated men: *Altitudo acutioris ac lapidei cacuminis nive plerumque operti 2432 hexapedes Parisienses, ut et nivis infimæ permanentis in montibus nivosis.* Ulloa and Don Juan, coadjutors in the same great enterprise, assigned a different value to the altitude of the plane.

Rocky summits of Pichincha.

(369.) The latest investigations of Humboldt on this very important subject, are contained in an admirable Paper, *Sur la limite inférieure des Neiges perpétuelles dans les Montagnes de l'Himâlaya et les Régions Equatoriales*, and published in the *Annales de Chimie*, tom. xiv. p. 5. The Volcano of Pichincha, he says, has four rocky summits, the altitudes of which were determined by direct barometrical measurements, by angles of elevation taken near Quito, and by trigonometrical operations carried on at Cachapamba, on a plane whose elevation is 8576 feet. His results are contained in

TABLE LXXXVII.

Names of the Summits.	Altitude in feet.
Rucupichincha.................	15924
Huahuapichincha	15719
Cono de los Ladrillos............	15354
Tablauma	15278

One only covered with perpetual snow.

(370.) Of these summits, only the first is covered with snow during the whole of the year, the inferior limit descending from 25 to 35 fathoms below its top. The Huahuapichincha, the next in elevation, is nearly always destitute of snow, its peak seeming just to penetrate the mighty plane of frost.*

Perpetual snows of Chimborazo.

(371.) On the great mountain of Chimborazo, Humboldt found the perpetual snows, by a trigonometrical operation carried on in the Plain of Tapia, near the City of Riobamba-Neuvo, to be at an elevation of 15,802 feet above the level of the South Sea. He also remarks, that the diameter of the mountain where the snows commence, seemed, from measures made at different epochs, to be 22,031 feet—a proof of the nearly equal constancy of their elevation in those regions.†

Cotopaxi.

(372.) On the sides of the Volcano of Cotopaxi, the elevation of this plane was found, by a trigonometrical operation performed in the plains of Mulalo, to be 16,231 feet, although from some other considerations, Humboldt is disposed to regard it as 15,924 feet. This volcanic cone is not well adapted for the determination of the perpetual snows. Its form, however, is described by Humboldt to be the most beautiful and regular of the colossal summits of the high Andes. It is a perfect cone, which, covered with an enormous layer of snow, shines with dazzling splendour at the setting of the sun, and detaches itself in the most picturesque manner from the sky. The covering of snow conceals from the eye of the observer even the smallest inequalities of the soil. No point of rock, no stony mass, penetrates the coating of ice, or breaks the uniformity of the figure of the cone. We have given, in figure 6, a representation of this magnificent mountain, because it affords a good example of the well-defined limits of the perpetual snows.

At times entirely deprived of its snows.

(373.) It is worthy of observation, however, that notwithstanding the enormous bulk of this mountain, it is liable at times to be despoiled of its snowy mantle, by the active agency of its internal fires; and Humboldt, with his usual acuteness, has drawn from this circumstance the useful Geological inference, that its sides are therefore thinner than those of the other

---

beautiful fertility of the climates below, an apology may be found for the expression. Wahlenberg, in his observations on the Lapland Alps, observes that the Snow Bunting, *Emberiza Nivalis*, is the only living creature that visits an elevation of 2000 feet above the perpetual snows. It has also been remarked, that the Ansonia butterfly is occasionally found to fly over the very summit of Mont Blanc. Wahlenberg also remarks, that a few plants of *Ranunculus glacialis*, and other similar ones, may now and then be found in the cleft of some dark rock rising through the snow. This happens even to the height of 500 feet above that line. Further up the snow is very rarely moistened, yet some umbilicated lichens, (*Gyrophoræ*,) &c., still occur in the crevices of perpendicular rocks, even to the height of 2000 feet above the line of perpetual snows.

* According to some very accurate measures, the summit of the mountain appears to rise above the plane of perpetual snow only two fathoms.

† See Humboldt, *Rec. d'Observ. Astr.* tom. i. p. 72; and Zach., *De l'Attraction des Montagnes*, vol. i. p. 7.

mountains whose bosoms are the seats of equally active volcanic fires. The disappearance of the snow is regarded by the natives as a certain index of an approaching eruption.*

Mountain of Antisana.

(374.) The Mountain of Antisana is another example given by Humboldt to illustrate the subject of the perpetual snows. On account of its being surrounded, however, at an elevation of 13,429 feet, by a vast plain, exercising great radiating powers, he concludes that the perpetual snows are pushed as a necessary consequence to a higher region in the air. And, although the numerical mean of all the examples recorded, amounts to 15,803 feet, yet Humboldt, making an allowance for the fires of Cotopaxi, and the force of radiation here referred to, is disposed to fix the altitude of the perpetual snows at the Equator at no greater elevation than 15,748 feet, or 4800 metres. The next Table contains the whole of his results.

Altitude of perpetual snows at the Equator.

TABLE LXXXVIII.

Names of the Mountains.	Latitudes.	Altitude of the lower limits of the Perpetual Snows in feet.

Chimborazo	1 28	15802
	Mean....	15803

The altitude of perpetual snows at Equator can only be deduced from the Andes.

(375.) The determination of this Equatorial element, although of the utmost importance in any attempt that may be made to trace theoretically the plane of the perpetual snows, must rest entirely on the observations that have been made in the Andes. It is true that we are not yet acquainted with the altitudes of all the mountains of America to the East of Peru, although we are certain the perpetual snows exist in this continent only in the chain of the Andes, of which the Cordilleras of Mexico are to be regarded as a prolongation towards the North, in the group of Merida, and in that of Santa Martha. Not one of the summits of the chain, it may be remarked, on the coast of Venezuela, of those of Parime, of Chiquittos, and of the Brazil, pass above the limit of perpetual snow; and hence Humboldt has remarked, that these snows are wanting in all the Eastern and non-volcanic region of the New Continent. Of the interior of Africa between Cape Lopez and Melinda we know nothing, although the traditions respecting the junctions of the mountains of Lupata, and Al Komri, render it probable that the Equinoctial regions of Africa yield but little in their altitude to the Andes of Quito. The great size, also, of the elevated plains of the continent of Africa, and the immense accumulations of sand in the meridian of Darfour, must have a tendency to elevate prodigiously the inferior limit of perpetual snow by the influence of radiation; and still, according to the best authorities, the mountains of Al Komri pass above this limit. Through all the remaining range of the Equator, not one solitary mountain is presented, to mark the elevation of the plane whose properties we are endeavouring to trace. The phenomena of the perpetual snows is equally unknown in the Galapagos Isles, and even in Borneo and Sumatra, of which the highest peak, the Gunong Pasaman, reaches only to an elevation of 13,842 feet.

The elevated plains of Africa raise the limit of perpetual snows.

Attempts find elev tion of pe petual snows in other lati tudes.

(376.) The determination of the altitude of the perpetual snows in the Equatorial regions, necessarily led to inquiries respecting its altitude in other latitudes; and their observed approximation towards the surface of the Earth, opened a most fruitful field of inquiry. In the immediate vicinity of the Equator, a small change in the latitude was observed to produce no sensible difference; but as observations became extended towards the Northern border of the torrid zone, that difference became perceptible. It is still, however, in the Cordillera of the Andes—of all the mountain chains being the only one prolonged in the direction of a meridian for the extent of 2000 leagues—that we must seek for further elements of this interesting problem. It is true, indeed, that the Cordillera does not offer a continued chain of snowy summits, as the Alps of Swisserland, and the mountains of Himalaya, but it is, nevertheless, raised into seven enormous groups to the North of the Equator, at a prodigious elevation.

Humbold measurements of perpetual snows on mountain of Mexic

(377.) With respect to observations made at the Northern extremity of the torrid zone, the most perfect are those by Humboldt on the elevated plains of Mexico. On the parallel of the great heights of Anahuac, between 18° 59′ and 19° 12′ of North latitude, six enormous mountains are ranged in the same East and West line. Four of these mountains, *viz.* the Peak of Orizaba, having an altitude of 17,375 feet; that of Popocatepetl, of 17,722 feet; that of Iztaccihuatl, or the White Woman, exceeding 15,028 feet; and the Nevado de Toluco, of 15,169 feet; are perpetually covered with snow. Two others, however, the Cofre de Pérote, having an elevation of 13,417 feet, and the Volcano of Colima, exceeding 10,871 feet, are often destitute of snow the greater part of the year. According to a trigonometrical measure made by Humboldt on the snows of Popocatepetl, in latitude 18° 59′, in the month of November, the inferior limit was found at an elevation of 14,977 feet; but by calculating the barometric observations of M. Sonneschmidt, according to the formula of La Place, the altitude obtained was 15,163 feet. An application of the same formula to some observations of d'Alzate, gave for the altitude of the snows of Iztaccihuatl, in 19° 10′ of North latitude, 15,060 feet. Humboldt by an observation, on which, however, he does not much depend, assigned to this elevation only 14,069 feet. The Nevado de Teluco, in lat. 19° 11′ North, presents, like Rucupichincha, an immense central hollow, surrounded by rocks of a turretted form, and of a very dangerous access. Like Rucupichincha, also, the summit of the Nevado but just enters the limit of the perpetual snows.*

---

* In January, 1803, eight months after Humboldt and Bonpland's visit to Cotopaxi, it threw forth enormous volumes of fire and scoriæ, and the catastrophe was preceded by a total melting of the snow.

* Humboldt carried his barometers to the most elevated summit (Pico del Fraile) where he found the surface of the rock pierced and vitrified by the effect of atmospheric electricity. This phenomenon, according to Mr. Gilbert, is analogous to that of the hollow cylinders

General inferences respecting snows of Mexico.

(378.) From the whole of the observations made and collected by Humboldt in this interesting region, he draws the conclusion, that in the nineteenth degree of latitude, the plane of the perpetual snows is found at an elevation of 15,028 feet, or at the lowest estimate 14,708 feet. On the borders of the torrid zone, therefore, this plane has only lowered 720 feet, or at most 1040 feet; but it should at the same time be remarked, that the *Nevados* of Mexico are encompassed by an arid plain, which radiates heat powerfully, and of which the mean temperature is 62°.6, and in which, during the hottest months, the thermometer ranges by day between 60°.8 and 69°.8, and through the night from 55°.4 to 59°.0. This country is not, like Quito, a narrow valley contained between two chains of the Andes, but a country elevated in one enormous mass, to an elevation of twelve or thirteen hundred toises.

Mountains of Himalaya.

(379.) From the latitude of 19° to the parallel of 30°, we are not acquainted with the altitude of a single snowy peak. Of the mountains of Mexico, not one peak penetrates the plane of the perpetual snows between the parallels of 19° 12′ and 40° North. The Peak of Teneriffe can hardly be said to reach it, and we are not acquainted with the interior of New Holland. A portion of the zone, however, in the Eastern hemisphere, comprised between the latitude of 27½° and 36°, embraces the stupendous range of the Mountains of Himalaya—those holy haunts of superstition, where, enthroned on lofty and snow-capped pinnacles, the divine Mahadeo sits and surveys the fertile plains of Hindústan.*

Earliest estimate of their altitude made by Mr. Colebrooke.

(380.) Some of those extraordinary men, the Jesuit Missionaries, were the first in modern times to scale this stupendous buttress; and although the British conquerors of India had long contemplated the snowy summits from the plains of Hindústan,† yet many years have not elapsed since we were ignorant of all but the general name of this vast mountain range. The earliest estimate of the altitude of one of its "conspicuous peaks" was made by that very able and accomplished scholar Mr. Colebrooke, in the year 1790, when he deduced, from observations made at a station in Bengal, an altitude of 26,000 feet. The subject was afterwards resumed by the same author in the year 1814, in the *Asiatic Researches*, and in which he examined with great acuteness and ability the information then existing; and announced, for the first time, that the Indo-tartaric Mountains surpass the Cordillera of the Andes, before esteemed the highest on the Earth. This, indeed, had long been suspected; or, rather, as Mr. Colebrooke observes, had been very generally believed in India; for Major Rennel had remarked, in one of his able *Memoirs*, that the distance at which these mountains could be viewed from the plains of Bengal exceeded 150 miles; and a simple computation applied to the actual dimensions of the Earth would naturally afford some inference of the kind.

Observations of Captain Webb.

(381.) In November, 1817, Captain Webb, who had been engaged in the important operation of surveying the Ganges to its remotest accessible source, published a Memoir on the same subject, containing the measurements of more than two hundred elevated positions, determined geometrically for inaccessible heights, and by the same mode combined with the barometer, for those stations that were found capable of access. By tracing also the *Gauri* River to the place where it emerges from the snow, at the elevation of 11,543 feet, he furnished the first element afforded by this interesting inquiry on the subject of the perpetual snows. A copious abstract of this part of Captain Webb's labours, will be found in the VIth Volume of the *Journal of the Royal Institution*, drawn up by Mr. Colebrooke, with his accustomed perspicuity, and intended probably as a reply to the objections that had been made to the former measurements of Captain Webb in the XXXIVth Number of the *Quarterly Review*. It is worthy of Historical notice, that the Number of the *Review*, containing the objections to the measurements of Captain Webb, was received by him at the Temple of Kedar-nath,* a spot which had never before been visited by any European. Animated by a truly Philosophic spirit, he determined to recommence his admeasurements, and, if possible, to verify or refute the conclusions of the reviewer on the spot; a task which he well knew his barometers would enable him to effect.

Determination of altitude where the Gauri River emerges from perpetual snows.

Mr. Colebrooke first announced that the inferior limit of snows is higher than theory gives.

(382.) But little, however, had been hitherto advanced in all these discussions, connected with the main object of this division of our Essay. The subject of the perpetual snows had only been glanced at as part of a magnificent picture, until Mr. Colebrooke published, in the VIIth Number of the *Journal of the Royal Institution*, an Essay on the Limit of Constant Congelation in the Himalaya Mountains, derived from the Observations of Captain Webb; and for the first time remarked, that the inferior limit of perpetual snows does not descend so low as theory would lead us to conclude. This was followed up by Humboldt's Memoir on the Mountains of India, and by an Essay in the XLIVth Number of the *Quarterly Review*, on the passage of the Himalaya chain. In the XIVth Volume of the *Annales de Chimie*, Humboldt published the admirable dissertation before alluded to, on the inferior limit of the perpetual snows in the Himalaya Mountains, in which he discussed the latest observations of Captain Webb, and remarked with respect to the anomalies they present, that the more the results seem to be opposed to the conclusions deduced from the snows of the Andes, the more ought they to fix the attention of Philosophers.

Humboldt's investigations on the same subject.

Captain Webb's confirmation of great anomalies discovered by him.

(383.) It will be useful, therefore, to follow a few of the steps of Captain Webb in this interesting inquiry, in order to make our readers acquainted with some of

---

of vitrified earth, which have been recently found in the sands of Germany and other places, and which will be more particularly alluded to hereafter.

* The mountain which is held to be the throne, or residence, of Mahadeo has five principal peaks, called Roodroo Himala, Burrumpooree, Bissinpooree, Ordgurreekauta, and Soorga Rounee. These form a sort of semicircular hollow of very considerable extent, filled with eternal snow. Mr. Baillie Frazer was the first European that ever penetrated to the holiest shrine of Hindú worship which these stupendous mountains contain.

† These mountains appear from the plains of Bengal in the distant horizon, extending in a continued line through more than two points of the compass, and appearing in clear weather like white cliffs, with a very distinctly defined outline.

* Kedar-nath is one of those numerous shrines, which neither difficulties nor dangers, mountain roads, fierce torrents, or steep precipices can deter the pilgrim from visiting, in order to perform those duties which are enjoined by the Hindú Religion,—a Religion which seems to delight, as Captain Webb justly observes, in practically demonstrating to its deluded votaries, that rugged as is the path to that region of beatitude to which in fancy they are continually pressing forward, its ministers endeavour, by every means which human ingenuity can devise, to render it yet more intolerable by wantonly strewing it with additional thorns.

the enormous deviations of the snow line on the mountains in question, from all the theoretical deductions that had been previously made.

Great elevation of Milem without snow.

Also the ridge of mountains to the South of Dauli river.

(384.) The village and Temple of Milem were found by this enterprising surveyor at the respective elevations of 11,405 and 11,682 feet above Calcutta; extensive fields of buck wheat and Tartaric barley occupying the space between the two. A twelvemonth after these observations were made, *viz.* on the 21st of June, 1818, Captain Webb proceeded Southward from Jóshí-mat'h, and from the Dauli River, observed barometrically the altitude of a station on the ridge of mountains to the South of that river. Its altitude he found to be 11,680 feet above the level of Calcutta, yet the place was surrounded by flourishing woods of hoary oak, long-leaved pine, and arborescent rhododendron, and the whole surface clothed with a rich vegetation as high as the knee, extensive beds of strawberries in full flower, and plenty of currant-bushes in blossom all around, in clear spots of rich black mould.

Also the pass of Pilgointi Churhaï.

On the following day Captain Webb reached the summit of the pass Pilgointi Churhaï, and found its elevation to be 12,642 feet above the same level, or more than 12,700 feet above the sea. A thick mist confined the prospect, but no snow was to be seen contiguous to the spot. The surface exhibited a black soil, unless where the bare rock appeared, covered with strawberry plants, butter-cups, dandelions, and a profusion of other flowers. Even a projecting part of a higher mountain was destitute of snow, and, as far as the view extended, it appeared enamelled with flowers. The goatherds of the country are accustomed to lead their flocks to pasture during the months of July and August upon a yet loftier ridge, estimated to be as much above the pass of Pilgointi, as this was above the preceding day's encampment; that is, nearly a thousand feet, and which therefore removes the actual boundary of congelation to a still higher elevation.

Snows not perpetual at 12,000 feet on Southern side, in lat. 30° 40′.

(385.) The Temple of Kedar-nath before alluded to, according to a mean of five barometrical observations, is 11,897 feet above Calcutta, or 12,000 feet above the level of the sea; but no snow remained in the vicinity of the Temple later than the beginning of July; so that under the latitude of 30° 40′, at the last-mentioned elevation, the snows were not perpetual on the *Southern* side of the Himalaya Mountains.

Remarkable example afforded by Nitee Ghaut.

(386.) Another remarkable example is afforded by Captain Webb's observations on the crest of the Nitee Ghaut. On the 21st of August, at 3 P. M., four barometers gave a mean elevation of the quicksilver equal to 16.27 inches, the temperature at the same time being 47°. From a Journal kept by General Hardwicke at Dumdum, about fifty feet above the sea, the mean of five observations, of which that on the 21st of August formed the middle term, gave for the barometric pressure 29.51 inches, and for the average temperature 84°.4. These comparative results, after allowing for the height of Dumdum, gave for the total elevation of the Nitee Ghaut above the sea, 16,814 feet. At this great elevation not a vestige of snow was to be seen on the Ghaut, nor on the projecting shoulder of the mountain ridge, rising about 300 feet on the Western side of the pass; and we may hence conclude from it, that the height of the lower limit of congelation, on the *Northern* side of the Himalaya range, cannot be less than seventeen thousand feet.

Lower limit of congelation on Northern side not less than 17,000 feet.

Great e vation Table of Tartary, d tute of petual snow.

(387.) The great elevation of the Table Land of Tartary is deserving also of much consideration in an inquiry of this nature, influencing, as all extensive plains do, every circumstance of temperature. By observations made on the crest of the Nitee pass, Captain Webb found the Sutledge to flow in a plain elevated 14,924 feet above the level of the sea; yet so far are the great plains known to the Hindús by the name of Undes, or Oondes,* from being buried in eternal snow, as our ordinary theories would lead us to suppose, the banks of the river afford the finest pastures for myriads of quadrupeds throughout the year. The town of Daba, also, which Moorcroft asserted to be only a summer residence, appears to be tenanted in all seasons. In the neighbourhood of this place, and near Doompoo, both considerably higher than the bed of the Sutledge, Captain Webb was informed that the finest crops of a grain called *Ooa* were gathered, from which the natives make their bread.

Captai Gerard found c tinuous snow-b comme ing at 16,300

(388.) Captain Gerard observes, in his surveys published in the Ist volume of the *Transactions of the Royal Asiatic Society of London*, that when proceeding by the Chárang pass, 17,348 feet high, to the valley of Nangaltí, many snow-beds were crossed, and that, at about the height of 16,300 feet, the "continuous snow-beds commenced." In another place, however, he remarks that the mountains in the neighbourhood of *Chárang* are all of blue slate, naked to their tops, and exhibiting decay and barrenness in their most frightful forms. They tower in sharp, detached groups to about 18,000 feet; no vegetation approaching their bases, nor do their elevated summits offer any rest to snow.† Upon the left bank of the *Táglá* river, mountains of an elevation of 16,000 feet are found, on which no snow appears. Upon the right bank, the summits seem to be 18,000 feet, and with but little snow in streaks. The mountains also which enclose the dell of the Táglá river, are between 19,000 and 20,000 feet in elevation, and but just tipped with snow.

Remar altitude perpetu snows Northe and So ern sid Himal chain.

(389.) A proof, likewise, of the disparity between the altitudes of the perpetual snows on the Northern and Southern sides of the Himalaya mountains may be gathered from the following remarks of Captain Gerard. Zamsírí, a mere halting-place for travellers, on the banks of the Shéltí, is 15,600 feet above the level of the sea, a height equal to that of the passes through the outer range of the snowy mountains, and yet, he says, there is nothing to remind the traveller of the Himalaya. Gently sloping hills and tranquil rivulets, with banks of turf and pebbly beds, flocks of pigeons, and herds of deer, present the idea of a much lower elevation. But Nature, continues Captain Gerard, has adapted the vegetation to this extraordinary country; for did it extend no higher than on the Southern face of the Himalaya, Tartary would be uninhabitable both by man or beast. On ascending the *Southern* slope of the snowy range, the extreme height of cultivation is found at 10,000 feet, and even there the crops are frequently cut green. The highest habitation is 9500 feet, and 11,800 feet may be reckoned the upper limit of forests, and 12,000 that of bushes, although, in a few sheltered situations, dwarf-birches,

---

* Signifying the *Region of Wool*. It is from this lofty region the Cashmír manufacturers are chiefly supplied with the material from which their celebrated shawls are made.

† It is possible that their great steepness may prevent the snow from resting on them.

and small bushes are found almost at 13,000 feet. But if we go to the Baspă river, the highest village will be found at an elevation of 11,400 feet, cultivation reaching to the same altitude, and forests extending to 13,000 feet at least. Advancing further, we find villages at the last-mentioned elevation, cultivation 600 feet higher, fine birch-trees at 14,000 feet, and támá bushes at 17,000 feet. Eastward, towards Mánassaróvai, according to the accounts of the Tartars, crops and bushes thrive at a still greater height.

Perpetual snows depend much on influence of localities.

Difficulty of the anomalies presented by snows of Himalaya chain.

(390.) From the preceding observations it is apparent, that excepting the determination of the spot from which the Gauri river emerges from the snow, and the observations made at the Chárang pass, no direct barometrical observations have yet been made at the actual elevation of the perpetual snows on this magnificent range. The determinations that have been made connected with the elevated points and plains on which the perpetual snows are never found, afford only indirect evidence on the subject, but yet are sufficient to awaken the most ardent curiosity respecting the deviations which this region presents, from all our previously received notions respecting the positions of the perpetual snows in the latitudes referred to. Humboldt has truly remarked, that of all the phenomena connected with the distribution of heat, no one is more complicated, or more dependent on the influences of particular localities, than that of the perpetual snows; and it is not too much to say, in the present condition of our knowledge, that we are unable to account satisfactorily for the extraordinary anomalies we have alluded to. That the great elevation of the plane of the perpetual snows, in the regions referred to, is an effect of a very copious radiation of heat from the elevated plains of Tartary, is certain; but, unless we are able to assign a numerical value to this radiating power, we are deprived of every means of tracing its effects on the higher regions of the air. We know, indeed, too little of the nature of terrestrial radiation, to attempt to form an estimate of its influence, when developed on so great a scale as in the plateaus referred to. We know but little of the effects of declivities in modifying the circumstances of temperature; or of the influence that the very nakedness of the soil may exercise on the air which reposes on it; nor can we attempt to measure the play of the currents which descend from the neighbouring summits, or to trace the effects of the humidity of the forests which lie scattered at their base. Added to this, we know that the summers are exceedingly short, commencing about the middle of June, and ending about the middle of August, scarcely ever extending to the close of that month; a circumstance which adds new conditions of difficulty to the whole inquiry. So early as the 10th of August, we are told by Mr. Moorcroft, the thermometer in the morning fell to the freezing point, and his tent was covered two inches thick with snow; and on the 28th, near the Nitee pass, the mercury stood at 28°, ice being formed $2\frac{1}{2}$ inches thick. The fact, also, of the ripening of grain at so great an elevation, seems to favour Mr. Daniell's opinion of the superior energy of the solar rays in the higher regions of the air. We know, indeed, that on the Southern side of the Himalaya chain, at an altitude of eleven or twelve thousand feet, the temperature varies during the hottest part of the day from 60° to 75° in the shade and during the night descends not lower than 50° or 45°; the sun developing its whole power during the day, and a shower of rain but rarely falling.

Effects of grouping of mountains.

Where isothermal lines at the surface have convex summits, perpetual snows are higher.

(391.) Humboldt has likewise remarked, that if all the mountains covered with eternal snow, instead of being connected together in continued chains, or supported by table land of a greater or less extent, formed insulated cones of equal dimensions, it is probable that the limits of the perpetual snow, under different meridians, would preserve a constant elevation above an isothermal line traced at the level of the sea; and did such cones exist, the altitude of the perpetual snows might enable us even to estimate the measure of the summer heat in the plains below. But as the isothermal lines have convex summits in the interior of a large continent, and as the temperature of the summer in such a region exceeds that which otherwise the conditions of latitude would afford, the perpetual snows must attain a corresponding excess of elevation. Besides this effect of the radiation of the summer heat of the plains, there are also other causes operating in the higher regions of the air, which, together with the peculiar conformation of mountains, unequally raise or lower the limit of constant snow above the same isothermal band. Humboldt sometimes met with heats in the middle of the Andes, equivalent to those of the plains, and which he found to be more insupportable, because the air of valleys of that kind is but seldom agitated by the winds.

Final remarks on Himalaya chain.

(392.) Finally, it is to be observed respecting the mountains of India, that they occupy a position in a considerable degree central, and in consequence have what has been denominated a continental climate; that is, summers exceedingly hot, and winters very cold. In a climate of this nature it is also found, that comparatively but little snow falls, when the air is cooled below 10° of temperature. The snows are, therefore, not necessarily thicker, where the winters are more rigorous, or where the atmosphere passes rapidly to its extreme degree of cold. If, says Humboldt, the curves of equal annual temperature, when traced on the plains, have a concave summit in Asia, the lines of equal summer, on the contrary, are raised considerably; and where this is the case, anomalies like the present must exist. And when we consider that the enormous range of mountain and table land, the influences of which on the atmosphere we have been endeavouring to trace, exceeds 800 leagues in length, and 400 leagues in breadth, disclosing in the whole extent of its surface, a quantity exceeding 3,266,500 square British miles, we cannot but expect that a mass, so extraordinary from its magnitude and position, should disclose phenomena connected with climate, the numerical effects of which cannot be estimated in the present condition of Meteorological science.

Snows of Caucasus higher than those of the Pyrenees, although nearly in same latitude.

(393.) The chains of Caucasus and of the Pyrenees occupy nearly the same average latitude, and a comparison of the perpetual snows in the two ranges discloses a very interesting fact. Mount Kasbek, in the first of these chains, is scarcely half a degree more South than the Pyrenees, and yet the perpetual snows are supported on its Northern slope, according to the barometric measurements of Englehardt and Parrot, at an elevation of 10,552 feet, whereas in the range of the Pyrenees, as we shall presently see, Ramond estimated this limit so low as 7674 feet; and if we adopt the higher elevation given by Hum-

Cause of great elevation of snows of Caucasus.

boldt, we shall still find a difference of 250 or 300 fathoms in the small range of half a degree of latitude. The cause of this anomaly is to be attributed to the peculiar position of this mountain chain; partly from its being situated in a narrow isthmus between two seas, but principally from the effects produced on its temperature by the very extensive plain which ranges from its base through Moscow to the Icy Sea. And that an increase in the altitude of the perpetual snows may be reasonably inferred from the latter cause, may be gathered from the great elevation of the isothermal curves in this continent. Humboldt remarks, that at Moscow, in latitude 55° 45′, and on the isothermal line of 40°.1, the temperature of the hottest month rises to 70°.5; whereas at Paris, in latitude 48° 50′, on the isothermal line of 51°.1, the warmth of the hottest month amounts in general but to 65°.3.

Altitude of perpetual snows on Pyrenees.

(394.) The altitude of the perpetual snows on the mountains of the Pyrenees, is differently reported by different authors. By Humboldt their elevation is stated at 1400 fathoms, but according to Ramond, their general range commences at 7674 feet, and presents a snowy band of 500 or 600 fathoms in breadth. These mountains are very abrupt, and numerous snow-fields exist, some of which are of considerable extent; and Ramond has deduced from them a most interesting fact, that the snow-line along the breadth of the mountains constitutes a curve whose convexity is turned towards the Earth, and whose apex is probably at a middle distance between the opposite sides of the range. This flexure in the perpetual snows arises from a twofold cause. The warm air ascending the sides of the mountains has a tendency to elevate the plane of the perpetual snows; whereas the chilling influence of the great fields of snow, causes its middle portion to descend; so that instead of preserving its continued concavity, as A B fig. 7, it presents a convex section, as C D. The observations of Ramond were principally directed to *Mont Perdu*, and he remarks, that snow exists from the great glacier to its summit; but that the thickness gradually diminishes, and becomes very inconsiderable towards the top, on account of its trenched form not admitting of any great accumulation. On the Northern side, the snows obtain, by degrees, an extraordinary consistency; but on the Southern, the soil can be readily distinguished; a fact, however, which Ramond is disposed to attribute less to the action of the solar heat, than to the extreme precipitancy of that part of the mountain pass.*

Flexure in the plane of perpetual snows.

Difference in snows of Northern and Southern sides of Pyrenees.

Snows of the Alps

(395.) Saussure, in his most interesting journey, fixes the limit of perpetual snow in the Alps at 8313 feet, or 9273 feet, or at a mean elevation of 8793 feet. We know, also, that very considerable differences exist in the altitudes of the perpetual snows on the Northern and Southern sides of the Alps. Of Mont Blanc, it may be remarked, that the mantle of snow which covers its top exceeds in elevation 4000 feet, and occupies horizontally an extent of 9000 feet; the total height of the ice and snow, estimated from the source of the Arveron, at the bottom of the glacier of Montanvert, to the summit of the mountain, being not less than 12,000 feet in perpendicular height. According to Von Buch, the altitude of the snow-line between the parallels of 45¼° and 46½°, amounts to 9080 feet; and that in Appenzel it must be 100 fathoms lower than in the Valais and in Savoy, and cannot exceed 8402 feet.

Saussure made an ingenious estimate of the refrigerating influence of the great snow-fields which exist in the Alps, in sinking the line of the perpetual snows, and found it capable of depressing their range 600 feet below its level, even on the lesser mountains of the Alps. Both Ramond and Saussure have remarked the chilling influence of these snow-fields in producing contrary flexures in the snow-lines of the Alps, as in the case of the Pyrenees. These flexures may in some cases be very numerous and varied. Thus, in a group of elevated peaks, as in fig. 8, if vertical planes be supposed to pass from the peak A to the summits denoted by B, C, D, and E, through the curve of the perpetual snows, a series of sections may be presented of an exceedingly diversified character, arising from the unequal radiating powers of the surfaces below. And these inequalities will be found not only to exist on the innumerable surfaces of a great mountain range like the Alps, or the Andes, as rendered visible by the snows with which they are covered, but inequalities somewhat analogous must exist in the atmosphere above those mountains whose summits do not reach the range of perpetual snow. A hot valley will have a tendency to raise it,* whereas a snow-field will exercise an opposite effect. The flexures of the perpetual snows, also, in the atmosphere of a level country like Russia, must be of a much less variable kind than in the mountainous regions of Norway or Swisserland. The plane of the perpetual snows is most uniform over the Ocean.

Saussure's ingenious estimate o their refrigerating i fluence.

Perpetual snows mo uniform o the Ocea

Carpathi mountain

(396.) The Carpathian mountains, also, present some interesting anomalies connected with the snow-line. Occupying a position between the parallels of 48° 55′ and 49° 15′, and extending through a degree and a half of longitude, they exercise, in conjunction with the neighbouring plains, a considerable influence on Meteorological phenomena. Although situated to the North of the Alps, the perpetual snows are found at a much higher elevation than on the mountains of Swisserland. Mont Pilatus, for example, in the latter Country, although only 6927 feet above the sea, is covered with perpetual snow; whereas not one of the peaks of the Carpathian range is found to be so, though the great Lomnitzerspitze attains an altitude of 8464 feet. From different considerations, Wahlenberg† supposes that if this mountain had an elevation of 8526 feet, it would just reach the snow-line. Snow lies, indeed, during the whole year, in some of the gullies and chasms of these mountains, and there is a kind of glacier at Eisthalerspitze, arising from this cause. This anomaly in the elevation of the snow-line is to be attributed to the hot winds from the plains of Hungary, which being by far the most extensive in Europe, and situated considerably to the South, the heat in summer is very great. A confirmation of this anomaly is afforded in the vegetation of the Carpathian range. Corn and

Althoug North of Alps, the snows ar much hig than on mountai of Swiss land.

---

* This interesting geological feature exercises an important influence on the problem of the perpetual snows, nor is the observation to be confined to the mountains of the Pyrenees. The Alps, like them, are steepest to the South, but the mountains of Scandinavia have their most precipitous sides on the North.

* May not large towns have a tendency to raise the plane of snows above its proper elevation, from the currents of warm air almost constantly ascending from them? Howard remarks, that London is always warmer than the neighbouring country at a mean rate by more than a degree and a half.

† Wahlenberg on the Carpathian Mountains. Göttingæ impensis Vandenhöck et Ruprecht 1814.

fruit trees flourish at a greater elevation on the outskirts of these mountains, than in Swisserland, and the ~~region of beeches is much richer in plants than the same~~ region in the range of the Swiss Alps.

Few examples of perpetual snows in Sweden, but many in Norway.

(397.) Of the Scandinavian peninsula it may be remarked, that Sweden, according to Von Buch, presents ~~few examples of mountains~~ upon which the snow rests in summer; but Norway, consisting of a range of mountains extending from one of its extremities to the other, presents many examples of the perpetual snows. Esmark was the first to direct the attention of the Philosophic world to their range and elevation; but it is the later labours of Von Buch, Hagelstam, and Schouw, that have fixed their limits with accuracy.

(398.) According to Hertzberg the altitude of the snow-line on Folgefonden is 5115 feet; and, although in the entire extent of this mountain range there occur no separate eminences, the whole forming one immense mass of snow without division or valley, there nevertheless occur many diversities in the altitude of the perpetual snows, which it may be proper to advert to. The Melderskin and Solen-Nuden present examples of sudden depressions of the snow-line. The absolute elevation of the former mountain is 4860 feet, and of the latter 4796 feet, and the summits of both are covered with everlasting snow. Flakes of snow lie even upon Age-Nuden, although its altitude is only 4587 feet. Von Buch attributes these changes to the influence of the neighbouring sea. The almost constant fog, says he, which shrouds the outermost islands, the canopy of clouds covering the sky, and the thick rains which exclude the influence of the sun from the ground, occasion the temperature of the summer months, during which alone the snow never melts, to be much less than in regions further removed from the sea. As we pass, however, from the snow-field of Folgefonden, the perpetual snows ascend, and after allowing for all the circumstances connected with it, Von Buch is disposed to regard the mean altitude of the snow-line, in the latitude of 61°, at 5542 feet.

Variation in altitude of snows.

(399.) According to Wahlenberg, the altitude of Sulitelma is 5675 feet, and that of the perpetual snows on its sides 3837 feet. In the latitude of 70°, Von Buch assigns to them an elevation of 3517 feet; but between Alten, to which this elevation belongs, and Hammerfest upon the Island of Qualoe, in the neighbourhood of the great Ocean, the snow-line sinks to 2345 feet; affording the remarkable example of a depression of 1172 feet in an interval but little exceeding a degree; whereas between Fillefieldt and Alten, occupying ten degrees of latitude, the perpetual snows sink but 2025 feet.

Remarkable depression of snow-line.

(400.) We have entered in the succeeding Table the later observations of Hagelstam and Schouw* on this subject, and we shall, therefore, merely observe, that, according to the latter, the snow-line is lower on the Western than on the Eastern side of the Scandinavian chain, by 1000 feet in latitude 67°, and 490 in 60°.† This is, perhaps, not exactly what might have been expected from the greater mean coldness of the Eastern side, nor does Professor Schouw explicitly assign the cause. Dr. Brewster, however, thinks it to arise from the greater range of temperature existing on the side most distant from the Ocean subjecting it to a high temperature in summer, which is the principal cause in the reduction of the snow-line, notwithstanding the greater intensity of the winter frost.

Snows lower on the Western than on the Eastern side of the Scandinavian chain.

(397.) The following Table contains a recapitulation of the whole of the preceding results.

---

[*] The observations of Schouw are contained in his *Specimen Geographiæ Physicæ Comparativæ*, a Work which promises to be of the greatest importance to Science.

[†] Dr. Brewster suspects a misprint in the Memoir where the latter number is called 1400, which is not the difference of the heights as printed in the text, unless 4340, the height of the snow-line on the Eastern side, is a mistake as very possibly it may be, for 5340.

With respect to the difference in the altitudes of the snow-line on the Eastern and Western sides of the mountains of Scandinavia, it is worthy of remark, that similar differences are observed with respect to the final limit of trees.

Table LXXXIX.

	Name of the Place.	Latitude.	Altitude of lower limit of Perpetual Snows in feet.	Name of the Observer.	Remarks.
The Andes.	Chimborazo	1°28′ S.	15802	Humboldt.	
	Cotopaxi	0 41 S.	15924	Ditto.	Affected by volcanic fires.
	Corazon	0 32 S.	15719	Ditto.	
	Antisana	0 31 S.	15943	Ditto.	Affected by the radiation of a vast plain.
	Rucupichincha	0 10 S.	15700	Ditto.	
	Huahuapichincha	?	15732	Ditto.	
	General result for the Equator	0 0	15748	Ditto.	
Cordilleras of Mexico.	Popocatepetl	18 59 N.	14977	Ditto.	
	Ditto	18 59	15163	Sonneachmidt.	Deduced from observations by the barometric formula of La Place.
	Iztaccihuatl	19 10	14069	Humboldt.	Doubtful.
	Ditto	19 10	15060	D'Alzate.	Deduced from observations by the barometric formula of La Place.
	From whole of observations made in Mexico	19 0	15028 or 14708	Humboldt.	
Himalaya Mountains in Asia.	Gauri river	30 25	11543	Capt. Webb.	Uncertain whether to be regarded as exact limit of perpetual snow.
	Nitee Ghaut	?	17000	Ditto.	This is the estimated altitude on the Northern side, below which the perpetual snows do not reach.
	Chárang pass	?	16300	Capt. Gerard.	
	Mountains enclosing Dell of Táglá River	?	From 19000 to 20000	Ditto.	Just tipped with snow.
Asia.	Caucasus	42½	10552	Englehardt, and Parrot.	Measured on the Northern slope of the mountains.
European Mountains.	Pyrenees	42¾	8400	Humboldt.	
	Ditto	42¾	7674	Ramond.	
	Alps	45½ to 46	8313 to 9273	Saussure.	
	Ditto	45¾ to 46½	9080	Von Buch.	
	Appenzell	47	8402	Ditto.	Somewhat doubtful.
	Carpathian range	48 55′ to 49 15′	8526	Wahlenberg.	No mountain in this range actually reaches the perpetual snows, though the Lomnitzerspitze has an elevation of 8464 feet, and from the circumstances of temperature attending it, Wahlenberg infers the altitude of the perpetual snows to be but little above it.
	Mountains of Sweden	59	6000	Hagelstam.	
	Mountains of Norway	59 to 60	5800	Ditto.	
	Ditto	59 to 60	5200	Schouw.	
	Folgefonden	60	5115	Hertzberg.	
	Ditto	60	5000	Hagelstam.	
	Melderskin	......	4860	Ditto.	The snow-line is in reality lower than these numbers denote, on account of their representing the altitudes of the mountains themselves. The depression of the snow-line is remarkable.
	Solen-Nuden	......	4796	Ditto.	
	Age-Nuden	......	4587	Ditto.	Flakes of snow lie only on the latter mountain.
	Mountains of Norway	60 to 61	4747	Schouw.	
	Mountains of Sweden	61	5800	Hagelstam.	
	Mountains of Norway	61	5542	Von Buch.	
	Fillefieldt in Norway	61	5600	Hagelstam.	
	Langfieldt in Norway	61 to 62	5410	Ditto.	
	Mountains of Norway	61 to 62	5083	Schouw.	
	Above the Doorefieldt	62 to 63	5300	Hagelstam.	
	Mountains of Norway	62 to 63	5142	Schouw.	
	Mountains of Sweden	63 to 64	5200	Hagelstam.	
	To the West of Fjällrygg in Norway	63 to 64	4800	Ditto.	
	Mountains of Norway	63 to 64	4925	Schouw.	
	Mountains of Sweden	65	4800	Hagelstam.	
	Ditto	67	4400	Ditto.	
	Sulitelma	67	3837	Wahlenberg.	
	Mountains of Norway	67	3600	Schouw.	
	Nordland in Norway	67 to 68	3900	Hagelstam.	On the mountains.
	Ditto	67 to 68	3300	Ditto.	On the coast.
	Alten in Norway	69 to 70	3600	Ditto.	
	Mountains of Norway	70	3517	Von Buch.	
	Ditto	70	3300	Schouw.	
	Hammerfest	71	2345	Von Buch.	
	Mountains of Norway	71	2200	Schouw.	
	North Cape	71 10′	2400	Hagelstam.	

Oscillations in altitude.

(402.) Such are the lower limits[*] assigned to the altitude of this magnificent plane, by the celebrated men whose names are recorded in the Table. If, however, we stop our inquiries at this point, we shall leave many interesting portions of the problem unresolved. The plane of the perpetual snows does not maintain a constant elevation in the same latitude, but varies with the vicissitudes of the seasons, rising during the heat of summer, and sinking by the cold of winter; changing also from one summer to another, as alterations are experienced in the temperatures below.

Andes.

(403.) If we first direct our attention to the Equatorial regions, we shall discover some small oscillations to exist in the altitude of the perpetual snows. To the mountaineers[†] of the Andes, the limit of the perpetual snows presents a phenomenon of a very constant kind; and to their uncultivated minds, the silvery line seems to run through the enormous groups of their mountains, in one continued horizontal plane: the greatness of the distance preventing them from observing those small oscillations of altitude, which the more refined inquiries of the Philosopher have disclosed. This close approximation to uniformity arises from the equality of temperature existing in the different strata of the atmosphere; and accordingly it is found that the utmost amount of the oscillation of the perpetual snows in these regions does not exceed 30 fathoms,[‡] and at the Equator itself rarely amounts to half that quantity. It is often, indeed, insensible, notwithstanding the small differences of temperature which are found to exist between the season of rain and that of great dryness.

Mountains of Mexico.

Himalaya.

(404.) If we pass, however, from the Equatorial regions, we shall discover new conditions presented for investigation. No longer confined to the feeble oscillations we have referred to, we shall find all the attendant phenomena become more irregular. In the mountains of Mexico, the oscillations will be found to amount to 2405 toises, attaining their maximum in January, and their minimum in September;[§] and, although we are not acquainted with the actual extent of the oscillations on the mountains of Himalaya, we may infer from the observations of Captain Hodgson, that they must be considerable. The great cedar pines, those gigantic sons of the snow, says he, fringe the bare rocks, and fix their roots where there appears to be but little soil; and the avalanches bring down whole forests in their overwhelming course, and dash the cedars into splinters.

Striking vicissitudes in temperate zone.

(405.) But much more striking vicissitudes will be found as we advance into the temperate zone. Fields of snow of an enormous width are alternately melted and congealed, creating in the lapse of time those mighty glaciers, which by their varied and gigantic forms impart so much sublimity to the Alps.

Glaciers.

Of the Alps.

(406.) In order that glaciers should exist on a mountain, it must rise considerably above the limit of the perpetual snows. Prodigious masses of ice are also necessary for their formation, and an enormous pressure must act from above, to force the inferior parts of the icy volumes into the valleys below. Hence the frozen masses precipitated by an avalanche, form groups below the lower limit of perpetual snow. In this position they undergo but little change during the lapse of centuries; the alterations produced by the gradual thaw being more than compensated by other masses formed in the cold repositories above, and thence precipitated to the valleys below. Hence it is that travellers have remarked the successive invasions of the Valley of Chamouny, by the avalanches that have descended from Mont Blanc and the adjoining peaks. It is worthy, also, of remark, that the five glaciers which have forced their way into the beautiful valley just mentioned, are separated from each other, by forests, corn-fields, and meadows,—large tracts of ice mingling with the cheerful fruits of cultivation.

Of Norway.

(407.) The finest glaciers in Norway, are those proceeding from the chain of the Justedals Eisberge. They are known to the inhabitants by the name of *Jis-Braeer*, and at times are much dreaded by them on account of the rapidity of their motion, which exceed that of the glaciers of Swisserland.[*] In Krondal, the glaciers are described by Von Buch, as a huge, dazzling, white carpet, fastened on both sides to mighty rocks; and when they have reached the valley, they still continue to push on, like the glaciers of the Rhone. Between the sixtieth and sixty-first degrees of latitude, according to Hagelstam, the perpetual glaciers have a breadth of 4600 feet, or nearly seven-eighths of a mile.[†]

Causes of alteration in altitude of perpetual snows.

(408.) Our limits will not permit us to pursue this chain of inquiry in all its generality, and we must therefore briefly remark, that the variations of temperature occasioned by the ordinary changes of the

---

[*] It may be necessary to observe, that we do not confound the phenomenon of the perpetual snows with that of glaciers. The inferior limit of ice is determined by other causes.

[†] These people have an ancient usage of giving a snow-bath to those who, for the first time, pass from the less elevated plains, through the zone on the declivity of the Cordilleras, which may be accidentally covered with snow; the burlesque ceremony agreeing with the baptism which sailors undergo, who for the first time pass the Equator.

[‡] When Humboldt published his Views of the Cordilleras, and his Atlas of New Spain, many regarded with wonder the designs which represented the icy regions of the Cordilleras of Quito and Mexico. Accustomed to the snowy mountains of the Alps and Pyrenees, and to the vicissitudes which they undergo during the successive seasons of the year, they transferred similar ideas to the mountains of the New World, and were surprised to find those glaciers wanting, which in Europe impart so much grandeur and beauty to Alpine scenery. See *Vues de Cordillères*, pl. 5. 10. 16. 25. 35. 42. 51. *et* 61.; and *Atlas de la Nouvelle Espagne*, pl. 16. *et* 17.; and *Atlas Géographique de l'Amérique Méridionalle*, pl. 1.

[§] We must not confound the perpetual snows with the snows which in winter, sometimes, fall in much lower regions. This ephemeral snow, says Humboldt, is never observed under the Equator at 12,467, or 12,795 feet; but in Mexico it is commonly seen at an elevation of 9843 feet. Snow has been seen in the streets of Mexico at 7471 feet, and at 6159 feet, in the City of Valladolid.

[*] An example of their terrific power may not be uninteresting. In the year 1744, the few persons inhabiting the valleys alluded to in the text, complained that they were not able to pay their taxes, because the *Jis-Braeer* had rushed upon their fields, and completely covered them. This statement was not credited, and Surveyors and Excisemen (*Sorenscriver und Foged*) were sent as Commissioners to measure the distance of the middle of *Milvirsdal* from the foot of the nearest glacier, and it was ordered that the same measurement should take place every three years, to ascertain whether or not these glaciers were advancing. Three years after, the same Commissioners went to repeat their measurement, and were not a little astonished to find neither fields nor houses. The *Jis-Braeer* had advanced prodigiously, the inhabitants were gone, and their possessions buried under the ice. (See Thaarup's *Magazin fur Statistik*, 1802.)

In the *Bibliothèque des Sciences et des Arts*, Professor Pictet informs us, that the Glacier des Bossons has lately (1818) advanced fifty feet, much to the dismay of the neighbouring villagers.

[†] There are many mountains in Norwegian Lapland, whose names terminate in *geikna*, and from all of which glaciers proceed. In Lapland, the name *geikna*, or *jackna*, is applied in the same way as the Icelandic word *jockal;* the Norwegian word *jisbræ;* the Tyrolese word *ferner;* and the Swiss word *gletcher*, (glacier.)

seasons, are not the only causes which have a tendency to produce alterations in the elevation of the plane of the perpetual snows. There must be some differences of altitude due to the diurnal changes of temperature, although the present condition of our knowledge will not permit us to estimate their value. The horizontal winds, also, which mingle the temperatures of different zones, contribute sometimes to augment the circumstances of temperature, and at other times to diminish it, in each case exercising some effect on the altitude of the perpetual snows. The enormous beds of clouds likewise, which are found sometimes to exist in the interval between the plains and the limits of constant snow, cannot but be without their effects. The production of caloric, which, says Humboldt, is the effect of the extinction of light, and which diminishes with the density of the superincumbent strata of air, may not, it is true, be appreciable by our instruments; but the masses of vesicular vapour, and the clouds which present distinct and perfect contours, and which in the tropical regions attain an elevation of 3000 toises, become heated to a sensible degree, and emit radiant caloric to great distances. On the other hand, at a less elevation on the Eastern side of the Cordilleras of Mexico, a thick stratum of clouds augments, during several months, the cold of the superior regions, by intercepting the radiant caloric of the plains. Nor must we omit the consideration, that while the directions of the great mountain chains exercise a very important influence on the figure of the plane of perpetual snows, the grouping together of mountains has, in all cases, an effect on its elevation; tending to diminish the altitude, when their summits penetrate above it.

Figure also influenced by inequalities of temperature of Northern and Southern hemispheres.

(409.) We may also add, in again alluding to the figure of the plane of perpetual snows, that on account of the inequalities of temperature which exist in the Northern and Southern hemispheres, some varieties, both in form and elevation, are due on this account. The elevation of the perpetual snows in the parallel of Cape Horn must differ from that of Edinburgh, since the former ranges freely over the Ocean, and the latter is subject to all the vicissitudes of temperature arising from the unequal radiating powers of large portions of the Continents of Europe, Asia, and America. Whatever circumstances, indeed, occasion diversities in the temperatures of the two hemispheres, cannot be without their effects on the altitude of the perpetual snows.

Supposition of Bouguer that temperature of lower limit of snows is constant.

Shown by Humboldt to be erroneous.

(410.) We must now hasten to advert to another most interesting branch of the inquiry. It had long been believed after Bouguer, that the lower limits of the plane of perpetual snow indicated everywhere a temperature corresponding to the freezing point; but Humboldt has shown, in a Memoir read to the French Institute in 1808, and, again, in his Paper on the Inferior Limit of the Perpetual Snows on the Mountains of Himalaya, that such a supposition is contrary to the truth, and that the perpetual snows do not follow an isothermal plane. Their direction, indeed, follows less the traces of the isothermal lines of the planes, than the inflexions of the lines of equal summer. By uniting many good observations, Humboldt found that at the lower limit of perpetual snow, the mean temperature of the air is as recorded in

TABLE XC.

Latitude, or Place of Observation.	Observed Altitude of Plane of Perpetual Snow, above the level of the Sea, in Feet.	Mean Temperature of lower limit of Plane of Perpetual Snow.
At the Equator	15747	34°.70
In the Temperate Zone............	8856	25.34
In the Frigid Zone, in lat. 68°—69°.	3414	21.20

First theoretical attempt to estimate height of this plane.

(411.) The first theoretical attempt to trace the altitude of the plane of the perpetual snows in different latitudes, was also made by Bouguer. Mayer, although occupied with the subject of terrestrial temperature twenty years later, having deduced, as we have before seen, a formula to represent the same, did not venture to trace the gradations of heat in the atmosphere, and to ascend to the frozen regions above. It was sufficient, indeed, for his reputation, that, occupied with the mighty subject of the lunar Tables, he was yet able to marshal the terrestrial temperatures, and develope a law which should approximate in some tolerable degree to that of the geographical parallels. Kirwan, eager to embrace the whole question, ventured to combine the experimental observations of Bouguer with the theoretical deductions of Mayer, and regarded the elevation of the perpetual snows in every latitude, as proportional to the difference of the mean temperature and the constant temperature of the freezing point.

Kirwan combined the observa tions of Bouguer with the deductions of Mayer.

Playfair's formula fo the same object.

(412.) Professor Playfair, also, by means of Mayer's formula of mean temperature, endeavoured to deduce the altitude of the perpetual snows as follows. Since that formula is represented, says he, by

$$T = 58 + 26 \cos 2\,L,$$

and that at the limit of congelation T becomes 32, the equation may assume the form of

$$32 = 58 + 26 \cos 2\,L - \phi,$$

provided we assign to the function ϕ a proper value.

(413.) The value of this function is necessarily dependent on two conditions, the altitude of the point of congelation, and the decrement of altitude due to the change of a single degree of Fahrenheit. It may hence be denoted by $\frac{h}{\Delta}$, if we represent by the numerator of the fraction the first of the elements alluded to, and by the denominator the second. This assumption will, therefore, cause the preceding equation to be transformed into

$$32 = 58 + 26 \cos 2\,L - \frac{h}{\Delta},$$

and from which we obtain

$$h = 26\,\Delta\,(1 + \cos 2\,L),^{*}$$

and which, according to Playfair, will furnish the altitude of perpetual snow for every latitude.

Leslie's vestigati

(414.) Professor Leslie has likewise been led to the consideration of this problem. Having deduced the

---

[*] Playfair, in his *Outlines of Natural Philosophy*, assigned to the altitude of perpetual snow at the Equator 15,577 feet, as before given by Kirwan, and hence deduced 294 feet for the value of Δ. In doing this, however, the Professor fell into an error respecting the formula of Mayer, by assigning to the constant coefficient of the double latitude, the value of 27 instead of 26; and hence his equation for the altitude of perpetual frost was

$$h = 7644 + 7938 \cos 2\,L,$$

instead of the more convenient form given to it in the text.

formula before alluded to for the decrement of temperature in the air, he was naturally led to that limit, which gives to it the character of congelation. The Professor communicated to his formula two forms, as we have before seen in the functions represented by (L) and (M), and deduced from either the altitude of the perpetual snows.

(415.) If we adopt that which we have denoted by (M), and represent the temperature at the level of the Ocean by t, we shall obtain the equation

$$25\left(\frac{1}{\theta} - \theta\right) = t.$$

This value of t being known for every latitude, or at least being capable of computation by any formula of temperature, we may regard θ as the unknown element to be determined, and hence obtain, by a simple algebraical reduction,

$$\theta = \sqrt{(1 + .0004\,t^2)} - .02\,t \ldots . \text{(Q)},$$

Relative elasticity of the air at the limit of congelation.

which gives in terms of the temperature at the level of the sea, the relative elasticity of the air at the limit of congelation. The question thus becomes reduced to the ordinary methods of determining barometric altitudes, and on this principle the Professor computed the following Table.

Table XCI.

Leslie's Table for altitude of plane of perpetual snow in every latitude.

Latitude.	Height of Plane of Perpetual Snow in English feet.	Latitude.	Height of Plane of Perpetual Snow in English feet.	Latitude.	Height of Plane of Perpetual Snow in English feet.
0°	15207	31°	11253	62°	3365
1	15203	32	11018	63	3145
2	15189	33	10778	64	2930
3	15167	34	10534	65	2722
4	15135	35	10287	66	2520

30	11484	61	3589		

Remarks.

(416.) With respect to the preceding Table it may be remarked, that Professor Leslie has computed the temperatures of the geographical parallels by the formula of Mayer, which not representing exactly the distribution of terrestrial heat, must necessarily have some effect on the computed values for the altitude of the perpetual snows. It proceeds also on the supposition that this plane is one of an isothermal nature, which, we have before remarked, has been proved by Humboldt not to be the case. Hence the differences between the results of the Table, and those recorded from actual observation in Table LXXXIX., are considerable. At the Equator, the formula is only in defect 541 feet, but in the parallel of Mexico the difference, according to one observation, amounts to 1066 feet, and according to another to 1386 feet. With one of the observations made on the Himalaya chain, there is a surprising coincidence between the formula, and the point where the Gauri river emerges from the snow; but at the Nitee Ghaut, the Chárang pass, and the somewhat doubtful results relating to the mountains enclosing the dell of the Táglá river, the differences are of the most surprising kind. With the observations made on the Caucasus, the theory is in defect the enormous quantity of 2213 feet; but with the Pyrenees it is for the first and last time a small quantity in excess. With the Alps it is again considerably minus, and with the estimated range of the perpetual snows above the Carpathian chain, it is in defect upwards of 1900 feet. In Sweden, admitting the observations of Hagelstam to be correct, the difference is still greater; although a somewhat closer approximation is obtained for Folgefonden, in Norway. With the snows on the mountain of Sulitelma, given on the respectable authority of Wahlenberg, the difference amounts to 1512 feet; and at the North Cape, where the last visible traces of the perpetual snows on land are found, the defect still amounts to nearly 800 feet.

Differences between the Table and actual observation.

Graphical illustration of the same.

(417.) These anomalies may, however, be more clearly discerned by means of the graphical illustration denoted by fig. 9, in which the horizontal line E N represents the interval between the Equator and the North Pole, divided so as to correspond with the principal latitudes contained in Table LXXXIX.; and on each vertical line raised at the latitudes referred to, is laid off the altitude of perpetual snow according both to theory and observation. Thus, from E to B denotes the altitude of the perpetual snows at the Equator, as indicated by the Table of Leslie, and from E to G the mean of all the Equatorial observations of Humboldt. A simple extension of the same principle produces the curve of contrary flexure B C D F N, of which the one half is nearly the reverse of the other, for the general range of the perpetual snows according to theory; and the irregular line F G H I K, that which is produced by connecting together the points with which actual observation has furnished us. C is the point where theory so nearly agrees with the measurement found for the Gauri river, and D the solitary example of its being in excess of the actual observations made on the Pyrenees. The towering summit at H is worthy the most attentive consideration. The part of the horizontal line E A refers to the observations of Humboldt made South of the Equator.

(418.) Although the theory is in all cases in defect excepting one solitary instance, it would be unjust to charge upon it the whole amount of the differences that have been found, since errors in the actual observations on the perpetual snows do in all probability exist to

The results of observation cannot in all cases be relied on.

Proof from the decrement of altitude.

some considerable amount. The remarkable circumstance, however, that *all* the differences between theory and observation, excepting one, are of a negative character, is sufficient to awaken a salutary caution respecting its results. That the conclusions of actual observation cannot in all cases be relied on, may be inferred from an examination of the results of Table XC. By computing the decrement of altitude corresponding to a single degree of Fahrenheit's thermometer, for the whole range of elevation from the Earth's surface to the plane of congelation, we shall find the results for the three zones to be of a very anomalous kind. If we adopt for the mean temperatures at the surface, the values recorded in Table XLII., and for the mean temperature of the lower limit of perpetual snow, those contained in Table XC., we shall obtain the following results:

Table XCII.

Latitude, or Place of Observation.	Mean Temperature at the Earth's Surface.	Mean Temperature of lower Limit of Plane of Perpetual Snow.	Decrement of Temperature.	Observed Altitude of Plane of Perpetual Snow above the level of the Sea.	Decrement of Altitude in feet, corresponding to degree of Fahrenheit's Scale.
At the Equator	81°.50	34°.70	46°.80	15748	336
In the Temperate Zone.	57.63	25.34	32.29	8856	274
In the Frigid Zone, in lat. 68°—69°.	29.87	21.20	8.67	3444	396

Causes of the anomalies.

These anomalies may again be attributed to two sources, errors in the altitudes, or in the observed mean temperatures of the plane of perpetual snow in the latitudes referred to; and that it exists with much probability in the latter, may be inferred from the following considerations.

Attempt to compute the mean temperature at the limit of perpetual snow.

(419.) We have before found that the formula represented by (P) denotes, in a convenient manner, the relation between the depression of the thermometer, and the altitude observed; and if we suppose by way of subjecting the three observations in the preceding Table to the same test, that the altitudes are correct, and that the question for consideration is to determine the mean temperature at the altitudes recorded in the same place, let us find from the formula last quoted, that value of n, which represents the depression of temperature due to the elevation. By an ordinary algebraical reduction, this will give

$$n = -83.26 \pm \sqrt{\left(\frac{2h}{3} + 83.26^2\right)},$$

and by adopting as successive values for h, the altitudes recorded in Table XCII., we shall obtain for the values of n, the depressions recorded in the first column of the next Table. By subtracting these from the corresponding mean temperatures at the surface, we shall find in each case the computed mean temperature at the altitude of perpetual snow.

Table XCIII.

Latitude, or Place of Observation.	Computed Values of n.	Computed Mean Temperature at Plane of Perpetual Snow.	Observed Mean Temperature at Plane of Perpetual Snow.	Difference.
At the Equator	48.74	32.76	34.70	+1° 94
In the Temperate Zone	30.04	27.59	25.34	−2.25
In the Frigid Zone in lat. 68°—69°..	12.84	17.03	21.20	+4.17

Inference from it tha it is not an isothermal plane.

Here the errors between the observed and computed values of the mean temperature at the plane of perpetual snow, seem to indicate that considerable anomalies exist in the observations, probably in the temperate and frigid zones. It may also be remarked respecting the formula last employed, that it affords by its application to the principal results contained in Table LXXXIX., a confirmation of Humboldt's remark, that the temperature of the plane of the perpetual snows is not of an isothermal kind. It may likewise be added, that the altitude at which the mean temperature of the freezing point is attained in the great range of the atmosphere, seems according to formula (P) to vanish in about latitude 66° 53′; the great isothermal plane corresponding to 32° of temperature, appearing to meet the Earth's surface in that latitude. This conclusion has been obtained by computing the altitude due to 39° by aid of the formula last quoted, and adopting the mean temperatures recorded in Table XLII.

Probable uncertaint respecting the observ altitudes o the plane perpetual snow.

(420.) There is another uncertainty also respecting the altitudes which have been assigned to the lower limits of the plane of perpetual snow, which must be briefly adverted to. The perpetual snows may be said in a general way to attain their maxima and minima of elevation at the opposite seasons, when the greatest and least temperatures for the year take place at the Earth's surface; and the periods when travellers are most likely to approach them, will not be when they are most broadly developed, but when they are approaching their mean, or, perhaps, their least state; when the warmth of the atmosphere has caused the snowy boundary to rise considerably above the lower limit assigned to it by the minimum temperature of the year. This circumstance may afford room for supposing that the heights assigned to the lower regions of perpetual snow are above what they ought to be; and that hence by applying some correction, which the future progress of Meteorology may disclose, a closer approximation may be found between the results of observation and the deductions of theory; particularly in the temperate and frigid zones, where the discrepancies from this cause may be supposed to be the greatest, in consequence of the greater changes that take place in the altitude of the plane of perpetual frost during the successive seasons of the year.

The whole subject is, as yet, entangled with many difficulties, and will require much laborious research to carry it to perfection. All the anomalies which accompany its progress, must, however, be fairly stated before such desired results can be obtained.*

---

* In the following sections (422.) ought to be numbered (421.), and so on.

Isogeothermal lines.

(422.) At the moment this sheet was going through the press, a Memoir on the mean temperature of the air, and of the ground, in some parts of Eastern Russia, reached us, which was read before the Academy of St. Petersburgh in February 1829. M. Kuppfer introduces to our notice in this able paper, a new species of lines which he denominates *Isogeothermal lines*, and which appears likely to lead to some new and interesting results. Kuppfer deduced these lines from the temperatures of springs, and their projections were found to deviate very widely from the isothermal lines.

(423.) Kuppfer determined the positions of his new system of lines as follows. He supposed a relation to exist between the latitude and the temperature of the ground, capable of being represented by the equation

$$a - b \sin^2 l = t,$$

in which l represents the latitude, t the corresponding temperature, and a, b constant quantities necessary to be determined for different meridians. Having determined these coefficients, he found that the observed and calculated temperatures agreed pretty well, excepting for Cumana, Teneriffe, Konigsberg, and Umeo, places upon which local circumstances appear to impress an anomalous character. The meridians assumed by Kuppfer, reckoned from that of Paris, are contained in the following Table, together with the corresponding values of a and b in degrees of Reaumur.

TABLE XCIV.

Meridians.	Values of a.	Values of b.
0°	21°.3	20°.9
20 E.	24.4	25.6
60 E.	22.9	27.5
80 W.	24.0	33.7

By a ready transformation of the preceding formula into the form

$$\cos 2l = 1 - 2\left(\frac{a - t}{b}\right),$$

Kuppfer has been enabled to calculate for each of the preceding meridians, the particular latitudes where any given temperature prevails, and the results of which are contained in the next Table.

TABLE XCV.

Given Temperature.	Corresponding Latitude under Meridian.			
	0°	20° E.	60° E.	80° W.
0°	——	77° 30′	65° 52′	57° 32′
5	62°.12′	60 31	53 47	48 40
10	47.20	48 36	43 14	40 8
15	33.18	37 18	32 25	31 7
20	14.27	24 30	18 57	19 44

By allowing lines to pass through these points of equal temperature, we shall obtain a perfect idea of the positions of some of the isogeothermal lines, which we have represented in fig. 1. pl. ii. by the dotted lines, the isothermal lines being those of a continuous kind.

On Atmospheric Vapour and its Distribution.

Vapour existing in the atmosphere.

(424.) If the phenomena connected with the distribution of heat have disclosed so many interesting results, in no less a degree does the vapour with which the atmosphere is stored. By vapour, we are to understand a very rare, light, expansible body, capable like air of a reduction of volume by external pressure, and also of resisting any force which may tend to compress it. This vapour exists in every climate, and under every variety of temperature; in the frigid atmosphere of the polar zones, as well as in the burning regions of the Equator; nor is there a particle of air uninfluenced by its presence, at least in the lower atmosphere, unless it be relieved from its agency by artificial means. This moisture, extensively as it is diffused, owes its origin to the waters which cover so large a portion of the globe, and which penetrating by a thousand channels, communicate some of their humidity to the earthy soil; and it is to the active agency of heat, that the rising moisture, the result of evaporation, the laws of which we shall hereafter trace, is compelled to distribute itself throughout the different regions of the great aerial volume.

Owes its origin to the waters which cover the globe.

Problem of its distribution a difficult one.

(425.) It will readily be imagined, that to trace in all their generality the laws which regulate the distribution of vapour, throughout the whole extent of the atmosphere, perpetually changing as are all its conditions of density and temperature, must have long been regarded as a capital problem in Meteorology. There is a wide interval, indeed, between the first rude conceptions of the existence of vapour in the air, and those comparatively perfect processes, which our own times have disclosed, respecting the moisture of the aerial columns; and it would be an interesting employment, did our limits permit, to trace up from its feeble beginnings that magnificent chain of discovery, which, connected with the existence and elastic force of vapour, has imparted so splendid a succession of benefits to Man.

Elastic force of vapour.

(426.) The ordinary purposes of Meteorology require only a knowledge of the elastic force of vapour belonging to a comparatively small range of temperature, and the latest inquiries have added but little to the accuracy which Dalton so long ago imparted to them. Very recently, indeed, we have seen the elastic forces pushed up through the extraordinary range of twenty-four atmospheres, by Prony, Arago, Ampère, Gerard, and Dulong; and we cannot sufficiently admire the ingenuity and talent displayed in so laborious and hazardous an inquiry, which we ardently hope will lead to some really practical means of averting the tremendous calamities attendant on explosions by steam.*

Its practical results capable of being represented by a formula.

(427.) We have already given, in p. 333 of our *Essay on* HEAT, the practical results of Dalton and Ure for the elastic forces; and it affords another beautiful example of the power which analysis possesses, of bringing under its dominion a variable force, which the early cultivators of Physics must have placed in almost hopeless obscurity, among the phenomena of Nature incapable of

---

* For a full account of these admirable experiments, see *Annales de Chimie, Janvier* 1830, or the *Edinburgh Journal of Science*, July 1830, for a copious abstract of the same.

being investigated by the ardent enterprise of Man. Dalton imagined, however, that he could trace in the columns of his elastic forces, the approximative law of the elasticities of steam increasing nearly in geometrical progression, at the same time that the temperatures augmented arithmetically; and Laplace adopting the same principle, represented the elastic force by an exponential whose exponent could be developed in a parabolic series. To the author of the *Mécanique Céleste*, the two first terms of the resulting series appeared sufficient; but Biot proved the necessity of a third; and while the series thus obtained, represented with considerable accuracy the measures of the elastic forces so long as they were confined within the limits of a single atmosphere, yet when the progress of inquiry ventured on loftier developements of the elastic power, the corrected series of Biot also deviated very widely from observation. At the same time it is worthy of observation, that the French Philosophers, with all the advantages which the formulæ of Prony, Laplace, Biot, Ivory, Roche, Auguste, Tregaskis, Creighton, Southern, Tredgold, and Coriolis could impart, found themselves obliged to limit the application of their own formula to elasticities greater than a single atmosphere.* On the one hand, therefore, we see a series accommodated to the elastic forces *below* the ordinary pressure of the atmosphere, deviating very widely from observation when applied to forces *above* it; and on the other, a formula agreeing with wonderful accuracy up to twenty-four atmospheres—its greatest aberration amounting only to four-tenths of a centesimal degree when estimated in terms of the temperature, yet in smaller pressures than one atmosphere, exhibiting a divergence, to adopt the words of the able Report of Dulong, which increases more and more in proportion as we descend.

Remarks on formulæ in general of this nature.

(428.) It will be sufficient for our purpose, however, to adopt the formula of Biot, and the principle of which he has so fully explained in his *Traité de Physique*, tom. i. p. 273. He there shows, that the general term of the series may be represented by

$$F_t = 30.k^t,$$

Formula of Biot.

where F_t denotes the elastic force corresponding to the temperature $100-t$ according to the Centigrade scale, and k is a constant ratio connecting the elastic force at any temperature with that which precedes it. This ratio, it may be necessary again to remark, is not absolutely constant in the experimental results, but without sensible error may be assumed so, to bring all the observations,—within of course the limits of a single atmosphere, under the control of analysis. The series hence employed by Biot is of the general form

$$\log. F_t = \log. 30 + a t + b t^2 + c t^3,$$

and which he has limited to the third dimension of n, on account of the coefficients of the higher powers of n becoming so minute.

To fix the values of the constants, he has recourse to the absolute measures of the elastic forces at the convenient intervals of 0°, 25°, 50°, and 75° of the Centigrade scale, and thus obtains for the general formula the form of

$$\log. F_t = \log. 30 - 0.0153741265\, t - 0.00006743127\, t^2 + 0.00000003385\, t^3 \ldots. (R).$$

(429.) Thus may the elastic force for any temperature within the limits alluded to be computed, by substituting successively proper values for t. If we take the case of $t = 100°$, belonging to the elastic force of vapour at the temperature of melting ice, we shall obtain

$$F_{100} = 0.19918,$$

and we know the actual observation of Dalton gives for the same

$$F_{100} = 0.200.$$

Considering the difficulty of the inquiry, this must be regarded as a very close approximation.

Conversion of this formula into Fahrenheit's scale

(430.) The formula (R) may be converted into degrees of Fahrenheit's scale by a well-known numerical relation, and which will give to it the form of

$$\log. F_f = \log. 30 + \frac{5}{9} a f + \frac{5^2}{9^2} b f^2 + \frac{5^3}{9^3} c f^3;$$

or by substituting the numerical values of the coefficients, and restoring t to preserve uniformity of notation, we shall have

$$\log. F_t = \log. 30 - 0.0085411814\, t - 0.00002081212\, t^2 + 0.0000000058\, t^3 \ldots (S),$$

in which t denotes degrees of Fahrenheit.

(431.) We regret that our limits will not permit us to pursue this branch of our subject further; but we strongly recommend to the reader's attention the whole of the XIIIth Chapter of the Ist Book of Biot's *Traité de Physique*, or the XIIth Chapter of the IId Book of the same author's *Précis Elémentaire de Physique*, if it be desirable to pursue the subject free from its more scientific details.

Weight of vapour in given volume, at a given density and temperature.

Method of Gay Lussac's.

(432.) The preceding formulæ enable us to discover the elastic force of vapour existing in the atmosphere at any temperature. Let us, therefore, next inquire, what is the absolute weight of vapour contained in a given volume, under given circumstances of density and temperature. To accomplish this object, Gay Lussac employed small globules of glass of a nearly spherical form, as B, B, fig. 2. One of these being accurately weighed, had a portion of water introduced into it, the contained air being expelled, and the narrow neck hermetically sealed. The weight of the ball in this new state, compared with its primitive weight, gave the exact weight of water contained in it. The globule being thus introduced into the glass vessel V V, previously filled with mercury, was surrounded by the vessel M M, containing water; and heat being applied to it, necessarily caused the globule to break, and the resulting vapour to ascend to the summit of V V. Subtracting now the altitude of the mercurial column above the external level, from the ordinary barometric column existing at the same instant, must necessarily give the measure of the elastic force of vapour produced.

(433.) Such is Gay Lussac's accurate method of performing this important experiment, and Biot has illustrated it by some equally beautiful investigations

---

* The formula adopted by Arago, Dulong, and their learned associates is $e = (1 + 0.7153\, t)_5$, where e is the elasticity in atmospheres of $0^m.76$, and t the temperature setting out from 100°. It is worthy of remark, that the late learned Dr. Young was the first who represented the elasticities by a certain power of the temperature augmented by a constant number. M. Coriolis adopted 5.355 for the exponent as deduced from Dalton's experiments below 212° of Fahrenheit; and it is remarkable that his formula

$$e = \left(\frac{1 + 0.01878\, t}{2\,878}\right)^{5.355}$$

differs very little from that above given.

Biot's investigations of the same.

of an analytical kind, and which we regret our limits will not permit us fully to follow. He denotes the weight of water in grammes, contained in one of the glass globules by P, and by v the capacity in litres of one of the equal divisions of the receiver, of which N is their number. The resulting volume of vapour might thus be truly represented by $\mathrm{N}\,v$, did not the receiver itself undergo some change in consequence of the altered circumstances of temperature. Representing, therefore, the cubic dilatation of glass by k, the actual volume of vapour will become

$$\mathrm{N}\,v\,(1+100\,k).$$

But this volume, it should be further remarked, is not subject to the whole atmospheric pressure, and if we, therefore, represent the height of the ordinary barometric column by p, and that of the internal mercurial column by h, reducing the whole volume to what it would become under the standard pressure of $0^{\mathrm{m}}.76$, we shall obtain for the volume of a single *gramme* of vapour, at the temperature of the boiling point, the formula

$$\frac{\mathrm{N}\,v\,(1+100\,k)\,(p-h)}{\mathrm{P}.\;0^{\mathrm{m}}.76}\;\ldots\ldots\;(\mathrm{T}).$$

Numerical example.

(434.) This formula Biot illustrates by an appropriate example, the weight of water contained in the globule being $0^{\mathrm{g}}.6$, the number of divisions occupied by the vapour 220, and the capacity of one of them 0.00499316 *litres*. The barometric column also at the same time being $0^{\mathrm{m}}.7555$ at a temperature of 15°, and the mercury within the vessel $0^{\mathrm{m}}.052$ above the external level. By reducing these mercurial columns to the common temperature of zero, and allowing for the dilatation of mercury for each degree of the centesimal scale $\frac{1}{5412}$ of its bulk, we shall finally obtain the following elements,

$$\begin{array}{lll}
\log.\,\mathrm{N} & = 2.3424227 & \\
\log.\,v & = \bar{3}.6983755 & \\
\log.\,(p-h) & = \bar{1}.8465660 & \\
\hline
\log.\,\mathrm{N}\,v\,(p-h) & = \bar{1}.8873642 & \\
\log.\,p.0^{\mathrm{m}}.76 & = \bar{1}.6589649 & \\
\hline
 & \ 0.2283993 & = 1^{\mathrm{l}}.6920 \\
\log.\,100\,k & = \bar{3}.4194865 & \\
\hline
 & \ \bar{3}.6478858 & = \underline{0.0044} \\
 & & \ 1^{\mathrm{l}}.6964
\end{array}
\qquad
\begin{array}{ll}
\log.\,p & = \bar{1}.7781513 \\
\log.\,0^{\mathrm{m}}.76 & = \bar{1}.8608136 \\
\hline
\log.\,p.0^{\mathrm{m}}.76 & \ \bar{1}.6589649
\end{array}$$

from which it appears that a quantity of moisture, equivalent in weight to a *gramme*, is contained in a volume of vapour whose capacity is equal to 1.6964 *litres*, at the temperature of the boiling point, and under an atmospheric pressure of 0.76 *metres* of mercury. We know, moreover, that a *gramme* of water taken at the temperature of the maximum of condensation, occupies precisely a cubic *centimetre*, of which the *litre* contains a thousand; and that hence a cubic *centimetre* of water of this degree of temperature, when reduced into vapour, will fill a space equivalent to 1696.4 cubic *centimetres*. It may also be added, that a *litre* of this vapour, under the pressure above mentioned, and of the temperature of 100°, weighs $\frac{1}{1.6964} = 0.589483$ *grammes*. By reducing these results into English measures, we shall find that a cubic foot of vapour at the temperature of the boiling point, and under an atmospheric pressure of 29.9216 inches, weighs 257.7778 grains.

Weight of a cubic foot of vapour at the boiling point.

Dr. Anderson's method of finding the same at any other temperature.

(435.) But the objects of Meteorology require that a corresponding result should be found for any other temperature. Accordingly Dr. Anderson, in his very able article on HYGROMETRY, published in the *Edinburgh Encyclopedia*, has modified with some advantage, the formula given by Biot for this purpose. If we denote with the author of the Paper alluded to, the weight in *grammes* of a *litre* of vapour at the temperature t by P′, the corresponding elastic force by F_t, the weight in *grammes* of a *litre* of vapour at the boiling point by P; and adopting moreover the principle of Gay Lussac, that vapours so long as they remain in the aeriform state, expand by increase of temperature precisely in the same manner as the permanently elastic fluids, and that they suffer corresponding changes of volume by alterations of pressure, and also that air uniformly expands three-eighths of its bulk from the freezing to the boiling point of the Centigrade scale, we shall obtain by making the requisite substitutions

$$\mathrm{P}' = \frac{1.375\,\mathrm{P}\,\mathrm{F}_t}{0.76\,(1+.00375\,t)},$$

or by substituting for P its value 0.589483 *grammes*, and further reducing,

$$\mathrm{P}' = \frac{1.066499\,\mathrm{F}_t}{1+.00375\,t}.$$

(436.) If again we are desirous of altering the temperatures into degrees of Fahrenheit's scale and the pressure of 0.76 *metres*, or 29.92196 inches, into the pressure of 30 inches, to which that scale of temperature is adapted, we shall obtain after the necessary corrections*

$$\mathrm{P}' = \frac{.0068544\,\mathrm{F}_t}{1+.002086\,(t-32)}\;\ldots\ldots\;(\mathrm{U}),$$

and which, therefore, furnishes the desired weight in known terms of the temperature and elastic force.

Numerical example.

To illustrate this useful formula by a single example, let it be required to determine the weight of a cubic inch of vapour at the temperature of 54°. In this case the value of t being 54°, and F_{54} computed by means of the formula (R) becoming .42779, we shall obtain

$$\mathrm{P}'' = \frac{.0068544 \times .42779}{1.045892} = .00280358 \text{ grains.}$$

And by a similar method may the weight of a cubic inch of moisture be computed for any other temperature.

Dr. Anderson's experiments to determine the accuracy of the formula.

(437.) But it may be useful, however refined and perfect the system of computation, to discover how far the processes of actual experiment will confirm it. Dr. Anderson accordingly made a large volume of saturated air to pass slowly in a small stream through a sufficient quantity of sulphuric acid, or dry muriate of lime, cut off from all communication with the atmosphere; and then observing the increase of weight which these substances acquired in consequence of the air transmitted through them. A complete description of his apparatus may be seen in his Paper

---

* An exposition of these important reductions, which we regret we have no room for in the text, may be seen at pages 275 and 276 of Biot's *Traité de Physique*, tom. i.

before quoted, our limits only permitting us to record the results in

TABLE XCVI.

Tabular results.

Volume of Air subjected to Experiment in Cubic Inches.	Temperature in Degrees of Fahrenheit.	Barometric pressure.	Total Quantity of Moisture deposited in Grains.	Grains of Moisture in a Cubic Inch.

Remarkable coincidence of the experiments with the formula.

It is gratifying to observe how closely the results of the experiment coincide with the numerical values of the formula, affording at once a strong confirmation of Dalton's researches on the elastic force of vapour, and of the relations which Gay Lussac has established between a volume of dry atmospheric air, and of the quantity of vapour contained in the space which that air occupies.

Union of vapour and atmospheric air.

(438.) Let us next inquire into some of the conditions relating to the union of vapour and atmospheric air. On this subject we may remark, as a general law existing among the dry gases, that if among any number of elastic fluids incapable of being blended together at a given temperature, which separately sustain the pressures $p, p', p'', \ldots$ &c., the same volume V of each be taken, and the whole afterwards reduced into a volume of the same magnitude, we shall find the elastic force P of the united volumes exactly equivalent to the sum of the separate elastic forces; that is

Elastic force of united volume equal to sum of separate elasticities.

$$P = p + p' + p'' \ldots\ldots\ldots$$

and we shall now proceed briefly to show that the same remarkable principle holds good in the union of vapour and atmospheric air.

Gay Lussac's experiment to prove this.

(439.) To demonstrate this problem, Gay Lussac employed a cylindrical glass tube A B fig. 3, divided into parts of equal capacity, and having two stop-cocks at R and R′. A little above the lower cock, a bent tube of glass T T′, of a smaller diameter than the cylinder, communicated with its interior at T. The whole apparatus being perfectly dried, the stop-cock at R′ is opened, and mercury well boiled and dried allowed to fill the cylinder, and to ascend to its proper level in the tube. A globe filled with air brought to a complete state of dryness, is then screwed on at R, and a communication opened between the cylinder and globe, by turning the stop-cocks at *r* and R′. If air of the ordinary density be now introduced into the globe, the mercury will not be depressed in the cylinder A B, and hence the stop-cock at R must be turned, to permit a portion of the quicksilver to descend, and thus allow some of the air to occupy its place. As soon as a sufficient quantity of air has been introduced, its expansion is arrested by turning the stop-cock R; and by turning the other stop-cock at R′ at the same time, the dry air introduced into the cylinder A B is prevented from escaping.

(440.) To introduce the water we are desirous of changing into vapour, another stop-cock R″ is applied, surmounted by a very small metallic vase V, in which the liquid is placed. This cock is not pierced through its centre as stop-cocks ordinarily are, but a small hemispherical depression O below the surface of the interior cone is made to contain a drop of the fluid. If the stop-cock be then turned half a revolution, the watery drop will be brought into the interior of A B, and thus as many drops may be introduced as will produce the desired effects on the volume of air submitted to observation.

(441.) The introduction of the first drop of water must evidently augment the elastic force of the air, and cause the mercury in the tube T T′ to ascend. The effect is sudden but not instantaneous, as it would be if the liquid had been introduced into a vacuum; and by which we perceive that the pressure of the air opposes a resistance to the formation of vapour. If a single drop of the liquid be not sufficient to form all the vapour necessary for the given space and temperature, another may be added to increase the elastic force. After a certain number of drops, however, have been introduced, the addition of any greater quantity will produce no effect, the excess remaining above the surface of the mercury without being reduced into vapour. Biot, with his usual ingenuity, supposes a case in which some drops in excess have been added. By closing the cock R, and denoting the divisions of the tube occupied by the mingled volumes of air and vapour by N′, the elastic force of the two will be found equal to the pressure p of the atmosphere, as at the commencement of the experiment, the gas occupying, however, only N divisions. Its elastic force is thus diminished, and, since in its original condition it was equivalent to p, it must in its new state be represented by $\frac{p\,N}{N'}$. Denoting therefore the elastic force of the vapour by f, at the existing temperature, the measure of the whole elastic force will become

$$f + \frac{p\,N}{N'}.$$

And since this is equal to the pressure p, which is supposed to remain constant, we shall have

$$f + \frac{p\,N}{N'} = p,$$

and from which we have

$$f = p \, . \, \frac{(N' - N)}{N'}.$$

(442.) If now, when the experiment is performed, the actual values of N, N′ and p be observed, the same value for f will be found, as the elastic force of vapour in a vacuum would have afforded at the same temperature. Hence the vapour in its state of union with air preserves its own proper tension, and thus confirms the beautiful law announced, that in the simple mechanical union of vapour with air, each portion of the mixture maintains its own elastic force dependent on the volume it is made to occupy.

In mecha cal union vapour a air, each part mai tains its own elas force.

(443.) The preceding formula gives us the value of the elastic force in functions of the whole atmospheric pressure, and the volumes occupied by the air in its original state, and when united to vapour. By a simple conversion, it may be made subservient, by aid of the

Further plication this principle.

beautiful law just demonstrated, to another important purpose. That law enables us to conclude, that the elastic force of vapour in union with air, exercises its own elastic force, precisely as if no air were present; and hence the absolute value of f, under any circumstances of temperature and pressure, may be calculated by aid of the formula (R). The value of f thus becoming known, it is evident the formula before alluded to will enable us to discover the actual volume which a mixture of vapour and dry air must occupy under the same conditions: for a simple transformation of the formula gives us

Method of determining the actual volume of a mixture of vapour and dry air.

$$N' = \frac{p}{p-f} . N,$$

in which all the elements of the right-hand member are known.

Numerical examples.

(444.) To apply this formula numerically, let it be required to determine the actual increase which a given volume of dry air undergoes, when saturated with vapour at the temperature of 100° of Fahrenheit, and under a pressure of 30 inches of quicksilver. Applying this temperature to the formula (R), we have $f = 1.85241$; and regarding the volume represented by N as unity, we shall obtain

$$N' = \frac{30}{30 - 1.85241} = 1\frac{1}{15} \text{ nearly},$$

and from which it follows, that dry air at the temperature of 100°, when saturated with vapour, is expanded one-fifteenth of its primitive volume.

If we inquire what must be the elastic force of vapour, in order that the dry air with which it is mingled may have its volume doubled under the same pressure of 30 inches, we shall have

$$2 = \frac{30}{30-f},$$

and from which we obtain $f = 15$, a measure of the elastic force corresponding to a temperature of about 180°. If we inquire in what case the volume will be quadrupled, we shall find it at a temperature of about 198°.

If we suppose $p = f$, the value of N′ becomes infinite. For when the elastic force of vapour is equal to the whole pressure of the atmosphere, the air mingled with the vapour no longer bears any pressure, and consequently dilates as it would do in a vacuum, provided always that in proportion as it dilates, the vapour continues to form and extend with it.

Another method of obtaining the same results.

(445.) The law which the preceding apparatus has disclosed, may however be obtained without bringing the mercury to the same level in both its branches. To accomplish this, let us suppose after the reduction of the liquid to vapour, that the mingled volume occupies any number of divisions N′, and that the level of the quicksilver in the lateral tube may exceed its height in the cylinder by the quantity h. In this case, the elastic force of the air dilated into the space N′, will still be expressed by $\frac{pN}{N'}$; and by adding to it the tension f of the vapour, we shall obtain $f + \frac{pN}{N'}$ for the elastic force of the two. This elastic force will not, however, be equal to p as before, but to $p + h$, and hence we shall have

$$f + \frac{pN}{N'} = p + h,$$

and from which

$$N' = \frac{pN}{p - f + h}.$$

This value of N′ will always be greater than N, because $h - f$ must in all cases be a negative quantity. The entire coincidence of this formula with experiment, furnishes a new confirmation of the law whose truth we are endeavouring to demonstrate.

Further modification of the same.

(446.) In the preceding experiments we have supposed as much liquid to have been employed, as is sufficient to furnish all the vapour admissible into the space occupied by the air; but let us now suppose that we only introduce a single drop, and that this quantity is not sufficient to saturate all the space capable of being filled with vapour. After reducing this drop to vapour, let the mingled volume be brought back to the pressure of the atmosphere, by allowing some of the mercury to flow out by the inferior cock. The mixture will then occupy some volume N′, and the mercury in the two branches will thus be reduced to the same level. Let more of the quicksilver be now allowed to run out, so that the mingled volume of vapour and air may occupy any number of divisions N″ greater than N′. The mercury in the smaller branch will thus be found depressed below its level in the cylinder by a quantity h, the elastic force of the mixture being thereby reduced to $p - h$. But if the variation of the corresponding volume during this change of the elastic force be observed, we shall find it to be the same as if it had been perfectly dry gas; and hence we shall obtain generally

$$\frac{N''}{N'} = \frac{p}{p-h},$$

the volumes being inversely as the total elastic forces.

(447.) To discover the kind of variation this result supposes in the elastic force of vapour, let us represent it by f' in its new state of dilatation, its value in the case where the mixture occupied the space N′ having been f. The air contained in the mixture will thus sustain by itself only the pressure $p - f$; and since it occupies at present the space N″, its elastic force will become $(p-f)\frac{N'}{N''}$. By joining this to the unknown elastic force f' exercised by the vapour, the sum must be equivalent to $p - h$, and hence we shall have

$$f' + (p-f)\frac{N'}{N''} = p - h.$$

But experiment gives $\frac{N''}{N'} = \frac{p}{p-h}$;

consequently $\quad p - h = p\frac{N'}{N''},$

or $\quad f' = f\frac{N'}{N''};$

thus confirming the principle of Dalton, that the elastic force of vapour in all cases varies with the volume, precisely as the gases do. And hence we may further deduce also, that the quantity of vapour capable of existing in air, is precisely the same as would be found in a vacuum of equal capacity, under constant circumstances

Quantity of vapour existing in air, the same as in a vacuum of equal capacity.

of temperature and pressure; and that, therefore, the formula (U) which enables us to compute the weight of a cubic inch of vapour, will enable us also with equal accuracy to find the actual weight of moisture in a cubic inch of air, under the same measure of the elastic force.

(448.) In making a practical application of the formula last quoted, the only thing requisite is a convenient mode of determining the elasticity of the vapour already existing in the air, under any proposed circumstances. Mr. Dalton's simple method of filling a tall cylindrical glass jar with cold spring water, and repeating the observation until dew ceases to form on the external surface, first enabled us to obtain this interesting result; but we shall reserve the practical developements of this part of our inquiry, until we come to treat of Daniell's hygrometer.

Actual phenomena observed in union of vapour with the atmosphere.

(449.) Having thus briefly investigated some of the essential conditions of vapour, let us next inquire into a few of the interesting relations it presents, in its union with the great and perpetually changing body of the atmosphere. Every volume of air, from whatever region it may be brought, is more or less charged with vapour. There are indeed two atmospheres which encompass the earth on every side, one of air, and the other of moisture. The union of these by Nature is mechanical only, and each is governed by its own peculiar laws. The atmosphere of air, as we have already seen, possesses permanent elasticity, expanding arithmetically by equal increments of heat, and decreasing in density and temperature as it recedes from the surface. The atmosphere of vapour is also an elastic fluid undergoing condensation by cold, and at the same time evolving caloric, augmenting its force geometrically by equal increments of heat, and permeating the former, and moving in its interstices, like water when in the process of filtration it passes through sand.

Limits set by Nature to aqueous vapour.

Temperature the cause.

(450.) To supply the atmosphere with vapour, the power of evaporation is in almost constant operation, and we might suppose that an agent possessing so great an activity, would in time exhaust the store, boundless as it is, by which that moisture is supplied. But Nature has fixed limits beyond which the aqueous element cannot pass, so as to prevent an undue accumulation of moisture on the one hand, and a state of long continued dryness on the other. These limits are assigned by temperature, and which, whatever may be its apparently capricious changes, is confined, in every climate, within definite bounds. The same heat, therefore, which warms and vivifies the air, and renders the earth an agreeable abode to Man, controls with admirable wisdom the rising moisture.

(451.) This power of the air to acquire moisture is, however, modified by every alteration of temperature, any increase thereof augmenting its store, and every decrease of heat producing a proportional diminution. The greatest and least degrees of heat, whether it be that of a day or a year, must therefore afford some phenomena which influence the condition of atmospheric vapour. In the case of the minimum temperature of a given latitude, and a state of entire saturation of the air, no addition can possibly be made to the vapour it supports, so long as that temperature is maintained. Any augmentation of heat, however, from whatever cause it may proceed, is at once accompanied by an increased power of supporting moisture, and new accessions of vapour may be added to it. The minimum temperature of any period, therefore, whether it be that of a day, a month, or a year, must set a limit to the accession of watery vapour in the air; and thus in every region, the equatorial, the temperate, or the polar, a strong and impassable barrier has been fixed by Nature to the continued accumulation of moisture in the air. And that there is an equally impassable limit on the other hand—that of extreme dryness, also existing, is evident, when we consider, that as every diminution of temperature tends to saturation, so every increment of heat must produce a tendency to dryness; and that as the maximum temperature of the day has itself a limit, and therefore governs this last condition of the atmosphere, so the depression of temperature which immediately follows, by at once increasing the humidity of all the atoms of air which undergo that change, must remove at once the possibility of any long continuance of comparative dryness. There are some occasional anomalies, however, in the extreme conditions of humidity and dryness to which Saussure has briefly alluded in his *Essais sur l'Hygrométrie*, and which sometimes embarrass the inquirer.

Minimum temperatu prevents accumulation of vapour.

Maximum temperatu being fini prevents entire dryness.

(452.) This dependence of moisture on the circumstances of temperature will help us to trace some of the phenomena of its distribution. There is a gradation of heat, as we have before found, from the Equator to the Poles, and also from the surface of the globe upwards, into the loftier regions of the air. Generally speaking, the lowest stratum of the atmosphere, in whatever latitude it is found, must be most abundantly stored with the watery vapour, on account of its being nearest the source from whence that moisture is supplied. If an equality of temperature existed therefore at the surface, a cubic foot of air, in whatever latitude it were taken, would contain, when completely saturated, the same quantity of moisture. But since the temperature diminishes with the latitude, a given volume of air in a state of perfect saturation must contain less and less moisture as we approach the Poles.

Lowest a mospheric stratum most abu dantly stored wi moisture.

Moisture diminish with the latitude.

Moisture diminish as we ascend.

(453.) From a similar cause, the moisture of the atmospheric columns must diminish as we ascend vertically above the Earth; and hence that the whole store of moisture contained in a vertical equatorial column of air, must exceed the quantity found in a polar column of equal diameter and in the same state of perfect saturation. There are many difficulties, indeed, in the way of proving experimentally the decreasing humidity of the air, and one of the most interesting Meteorological observations that can be made in the neighbourhood of a mountain is to determine the exact condition of vapour in the atmospheric strata at different elevations. To resolve the question perfectly, such observations should be made at the same instant at the two extremities of the same vertical line. This, however, is hardly possible to be done, and we must hence select such times and places of observation as are not widely separated from each other. Saussure made many among the Alps with this view, from the valley of Chamouni through several successive elevations, and in a general way found the law to hold good. He met with some instances, however, in which the absolute quantity of vapour was greater in the more elevated regions of the air. Thus by comparing the 75th and 76th Meteorological observation of his *Voyage dans les Alpes*, we shall find that his hygrometer advanced 10°.1 towards humidity, by ascending to a height of 291 toises above his first station, the thermometer of

Anomalies observed by Saussure.

Reaumur at the same time sinking only 1°.6. The second observation, it should be remarked, was made in the midst of the glacier of Hautema, and it is therefore probable the ice and snow with which it was covered supplied this extraordinary humidity. And this opinion is confirmed by another observation which he made on a projecting rock seven toises less elevated, and where he found the humidity 14°.7 less than at the lowest station, agreeing, therefore, with the general principle before advanced. In another observation, however, Saussure is not disposed to attribute all this difference to the ice. Another example is also given by the same indefatigable and accurate observer. In the middle of the glacier of Miage, his hygrometer indicated a humidity of 81°.1, but on the *Col de la Seigne*, 186 toises above the glacier, it indicated 100°, though the decrement of temperature 8°.3 according to Saussure's table, ought to have indicated only a humidity of 89°.9. It sometimes happens, therefore, that vapour is more abundant on the summit of a hill than in the valleys at its base; but as the exceptions are not numerous, and may be explained by the influence of peculiar localities, we may in general conclude, that the absolute quantity of vapour in the air diminishes as we ascend. It should be borne in mind in considering this part of the subject, that the anomalies we have before proved to exist in the temperature of the air at different elevations, must necessarily impart a like irregularity to its humidity.

Vapour sometimes more abundant on the top of a hill than in the valley below.

It is possible to compute the vapour in any atmospheric column, and also in the whole atmosphere

(454.) It would be possible to compute approximatively the actual weight of vapour contained in any of the atmospheric columns, and if necessary the whole quantity of moisture contained in the atmosphere. The experiments of Biot and Arago have determined that the weights of equal volumes of vapour and air at the temperature of the boiling point, and when both are subject to the same pressure of .76 *metres*, are as .589481 to .9454476, or as 5 to 8 nearly; and since both are affected in their bulk in the same manner, by every alteration of temperature and pressure, the same invariable relation may be supposed to be preserved, so long as the vapour retains its elastic form. In some inquiries of this sort it has been assumed, that the mean point of deposition for the globe in general, is about 6° below the average temperature,—though this assumption, from the limited nature of the observations from which it is deduced, cannot be received without caution; and if we adopt in addition another hypothesis, by supposing the same invariable difference of temperature to be maintained, throughout all the atmospheric strata, we may make an approximation to the whole quantity of moisture contained in the atmospheric columns, by means of the formula

$$\frac{5}{8} f \times \frac{407.4}{30},$$

wherein f denotes the elastic force of vapour at a temperature six degrees below the mean temperature of the place of observation, and the numerator 407.4 the height in inches of a column of water equivalent in weight to the mean condition of a corresponding column of the air, and the numerical value of which formula, will give the mean height in inches of a column of water, equal to the whole moisture contained in a column of the atmosphere, standing on the same base. In this way we may compute, that if the atmospheric columns at the Equator were to discharge their whole watery store, the moisture precipitated would cover the surface of the earth only to the small depth of 7½ inches, and in the mean parallel of 45° only about 3⅓ inches. Supposing the whole atmosphere, from a state of absolute dampness, were to discharge its entire watery store, it would only form an uniform sheet of about 4½ inches in depth. To furnish a sufficient supply of rain therefore, as Leslie remarks, it was necessary the air should undergo very frequent changes from dryness to humidity in the course of the year. Supposing the mean quantity of water existing in a state of vapour in an atmospheric column, having a square inch for its base, to amount to about 4 cubic inches, we may infer, that the quantity actually existing in the whole atmosphere amounts to about 12,500 cubic miles.

Depth of water if atmosphere were to discharge its whole watery store.

Such conclusions, however, must be truly regarded as approximations.

(455.) Such results, however, must be truly regarded as approximations, and adopted only to enable us to catch a glimpse of the mysterious phenomena of Nature. We know too little of the humidity of the lower regions of the atmosphere, to speak with certainty of any of the phenomena connected with the higher. We know too little of the phenomena which may be said to be continually within our grasp, to permit us, without the exercise of the greatest caution, to apply them even as humble approximations to those lofty regions of the air, which as yet have defied the aspiring ambition of man. Of this, however, we are certain, that the higher regions of the atmosphere are comparatively drier than those below. Colonel Beaufoy, in his interesting ascent of Mont Blanc, remarks, "that the air itself was thirsty, its extreme dryness," said he, "had robbed my body of its moisture."

Moisture not equally distributed in volumes of same temperature.

Case of Plymouth and Prague.

(456.) The vapour actually existing at any time in the air is far however from being equally distributed in those volumes of it which possess the same degree of temperature. A given volume of it, at the temperature of 50°, in a portion of the atmospheric column reared above Plymouth, may possess a very different degree of humidity from a volume of a like temperature above Prague. The former, from its peculiar locality, may be in a state of high saturation, whereas the other, in the heart of a great continent, and governed by a wind from a different quarter, may be comparatively dry. It is not equality of temperature alone that we must seek for, in applying practically the elements of the problem now under review, but the quantity of moisture coexisting with it. To-day, the air of Moscow may afford a greater proportion of moisture than the warmer atmosphere of Ispahan, and to-morrow the relation may be entirely reversed. Contending winds not only influence the temperature and pressure of the air, but its humidity also; and the peasant of our own country is familiarized with their different effects. One breeze may bring to him gentle and fertilizing showers, and another may burn up the produce of his farm.

Moscow and Ispahan.

Different quantities of moisture in same atmospheric column.

(457.) But we need not go to the atmospheric columns of different Countries to seek for diversities of moisture, since like anomalies are sometimes to be found in different strata of the same column. Saussure remarked that his hygrometer, near the surface of the earth, often proved the air to be removed 30 or 40 degrees from extreme saturation, when the presence of clouds in the upper sky demonstrated the entire humidity of that region. That eminent observer often remarked this phenomenon when he ascended a mountain whose summit was enveloped in a cloud. On the other hand he as frequently observed, that when mists covered

Effects of clouds.

Of mists.

the plains, and a bright sun gilded the summits of his noble mountains, the limit of extreme humidity was to be found below, and air far removed from saturation above. Bands of clouds were sometimes also found to swim between masses of air necessarily less humid than the clouds themselves. Of the effects of clouds in augmenting the humidity of the atmosphere, he has one conclusive observation. When on the summit of Mont Brevan, 1306 toises above the sea, his hygrometer, at a moment when the sky was free from clouds, indicated a degree of moisture corresponding to 86°.8; but when the summit of the mountain was soon after enveloped in a cloud, the humidity increased to 94°.6.

Actual example of humidity of a cloud.

Elastic force of vapour does not diminish uniformly as we ascend.

(458.) Mr. Daniell has also deduced, both from theory and the actual experiments of Captain Sabine, that the elasticity of vapour does not diminish in an uniform manner, according to the decrease of temperature and density of the air, but the dew-point remains stationary to a great height, and then suddenly falls to a large amount. At Sierra Leone, the dew-point at the level of the sea was found to be 70°, and at the same hour upon the summit of the Sugar Loaf mountain, 2520 feet above, it was found exactly the same. At Jamaica also, by the sea-side, the temperature of the air was 80°, and the point of deposition 73°; while on the mountains, at an elevation of 4080 feet, they were both 68°.5. At a station not 500 feet higher, by an experiment twice repeated, the point of deposition was found to be 49°, and the temperature of the air 65°. Mr. Green the aeronaut also found, when ascending from Portsea, that at an elevation of 9890 feet, the dew-point was 64°, the same as at the surface of the earth; but at 11,060 feet it fell to 32°, making a difference of thirty-two degrees in a little more than 1100 feet; affording a decisive example, as Mr. Daniell observes, of an immense bed of vapour rising in its circumambient medium, unaffected by decrease of density or temperature, till checked by its point of precipitation; and also of an incumbent bed of not much more than one-third the density, regulated, no doubt, as the last, by its own point of deposition in loftier regions. Such phenomena afford strong experimental evidence of the mechanical mixture of the aqueous particles in the atmosphere, and admit of no explanation by any law analogous to that of chemical solution.

Examples.

Proofs which they afford of the mechanical mixture of vapour with air.

Want of practical observations.

(459.) We have before lamented the want of correct observations to assist us in our inquiries respecting temperature; and with equal reason may we deplore the absence of accurate and extended results to illustrate the much more varied conditions of humidity. The thermometer has existed for a long period in an accurate form to assist the Philosopher in every inquiry respecting heat, but an hygrometer which should disclose the *absolute* circumstances of atmospheric vapour has been but recently known. Mr. Daniell's beautiful instrument, and which we shall hereafter describe, enables us to trace with the greatest exactness all the conditions of humidity; but the limited observations hitherto made with it, afford but little information respecting that general distribution of vapour, which we are here desirous of tracing. As the observations made by the thermometer have enabled us to trace the numberless aberrations of temperature, and to distribute them in isothermal lines, so, had this hygrometer existed a century ago and been diligently applied, might we have traced some of the singular mutations of the great ocean of vapour which surrounds us, and have deduced perhaps from the mean results lines of equal humidity.

Lines of equal humidity.

Desiderat respecting the humidity of the atmosphe

(460.) It is a great practical problem therefore now opened to the ardent enterprise of Meteorologists, to discover, if possible—and what will not united labour and Philosophical enterprise effect,—some accurate relations respecting the distribution of moisture; to trace some of the varying conditions of humidity, which, for ever working in the great aerial volume around, is one of the main springs of the uncertain motions of the air, and of those changes of the weather, which are not only so much blended with our personal health and comfort, but with all the important processes of agriculture. At the present moment we can do little more than say, that of this wide-spreading ocean of vapour, we can merely estimate its elastic force and quantity at a given time, and in a general way trace an analogy between the course of its changes, and the progress of the mean temperature of the year. We know not where to look for the data which will enable us to contrast Philosophically the humidity of different climates, to measure the influence of mountains and valleys in modifying the conditions of vapour, the sea which exercises its own peculiar laws, and the islands and continents which diversify in so great a degree all the phenomena of humidity.

What we present know respecting humidity of the atmosphere

Not able contrast humidity different climates.

Connecti of the humidity of th atmosphe with lan and sea winds.

(461.) It is a useful problem, unquestionably, to determine the mean temperature of a place; but it is a problem of no less interest to discover its mean humidity. In Great Britain the winds which transport the vapour may be divided generally into two classes: the land winds blowing from off the great continent of Europe, and which comprise the North-East, East, and South-East; and the sea winds passing over the waters which surround us on every side, the North, North-West, West, South-West and South. In the former we might expect to find the course of the mean temperature exactly followed, because the sources which supply the vapour must be comparatively shallow streams and reservoirs of water, whose temperature readily adapts itself to that of the surrounding air; but in the unfathomable depths of the great ocean which affords humidity to the latter, the peculiar law by which the density of water is governed, must at particular periods maintain a temperature above that of the declining season, whilst at others, the increasing heat of the latter must outstrip the progress of the former.

(462.) Here then is a single problem, the elements of which must vary with every locality. Swisserland, surrounded on all sides by mountains, must present different phenomena from Great Britain, surrounded on all sides by the sea. For London, Mr. Daniell has found that the vapour of the land winds declines in force from September to January, when it reaches its minimum, and from that lowest point gradually rises to a maximum in August, thus following the course of the mean temperature of the air. In the sea winds, however, the vapour declines from September to November, when an equality appears nearly to take place in the humidity of the two winds; but in December, the vapour from the land descends below that of the sea, and the same difference continues to January. In February the former rises two degrees, and the latter remains stationary. A difference of four degrees continues through March, and which is diminished to three degrees in April and May. In June they again attain their former equality, because the temperature corresponding to the maximum density, cannot be lowered

Mr. Da niell's servati on hun of the peculi winds London till the whole mass of waters has passed this limit; and in the deep seas this must necessarily be a process of some duration. The shallow waters on the contrary, over which the land winds pass, must soon acquire the temperature of the ambient air, and continue to decline with it in heat. Upon the return of Spring a contrary effect takes place. The Ocean must again repass the temperature corresponding to the maximum density, before the waters can again obtain the higher temperature of the surrounding air. A necessary consequence of such an arrangement of things must be, an increase of humidity in December and January, and a rapid diminution in the four succeeding months, a phenomenon found to agree with actual observation. Such is the contrast exhibited by the prevailing land and sea winds peculiar to London. How very different would be the phenomena of the winds peculiar to Moscow!

The numerical results from which Mr. Daniell has deduced these interesting conclusions are exhibited in the following Table.

Table XCVII.

Of the Difference of the Dew Point in the Land and Sea Winds.

Months.	Land Winds. N.E. E. S.E.	Sea Winds. N. N.W.W. S.W. S.
September	53°	53°
October	45	46
November	41	42
December	31	37
January	29	35
February	31	35
March	34	38
April	45	42
May	47	44
June	54	54
July	52	55
August	56	57

Influence of the Polar ice on the humidity of London.

(463.) The peculiar locality of Great Britain may also be supposed in another way to modify the production of vapour, by its having to the North, at one season of the year, enormous masses of ice, which during their formation evolve caloric, and, in the process of liquefaction, occasion its absorption. Dividing the winds into two classes, Northerly and Southerly, Mr. Daniell has been enabled to trace their effects on the moisture of the air, as given in the succeeding Table.

Table XCVIII.

Of the Effect of the Ice in the North Seas upon the Dew Point.

Months.	Southerly. S.W. S. S.E.	Northerly. N.E. N. N.W.
September	58°	48°
October	51	41
November	47	37
December	42	32
January	38	31
February	36	31
March	42	32
April	47	40
May	51	41
June	58	50
July	58	50
August	60	54

By attending to the results of this Table we may first observe a constant difference of the temperature of the Dew point to prevail from September to December, in the two classes of winds; but the Dew point belonging to the Northerly winds, having reached that of the freezing point in the last-mentioned month, continues nearly uniformly to preserve the same temperature, during the succeeding months of January, February, and March, while in the Southerly winds, the declension continues through January and February only. In March the Southerly winds impart an increment of six degrees, but the increase of the Dew point of the Northerly winds does not take place till April, when the addition it receives, amounts to eight degrees, at which point it continues with little variation through the whole month of May, the absorption of heat during the process of thawing, preventing that accession of temperature which is due to the returning influence of the Sun. As soon as this operation, however, has ceased, the vapour rapidly regains its former relative degree of force, imparting considerable increments to both classes of winds in June and July, until their maximum conditions are obtained in August, and are followed of course by a decline of both in September.

Mean results of distribution of aqueous vapour in successive seasons of the year for London.

(464.) We must now take a hasty glance at the few imperfect results we are able to offer respecting the distribution of aqueous vapour during the successive seasons of the year, still, of necessity, limiting our inquiries to the locality of London.

Beginning with January, the time at which the minimum temperature prevails, Mr Daniell found, from a mean of three years' observations, and a triple observation each day, the mean elastic force of the vaporous atmosphere to be also at its lowest point, and represented by 0.234 inches of quicksilver, the mean temperature being at the same time 36°.1. As the mean temperature advances through the month of February to 38°, the force of vapour increases feebly to 0.239 inches. With the month of March, however, the mean temperature is augmented nearly six degrees, the elastic force of the vapour advancing at the same time to .272 inches. In April the mean temperature of the air rises to 49°.9, and the elastic force of vapour to .322 inches. In May, the atmospheric temperature still outstrips the advance of vapour, the former amounting to 54°, and the latter to .354 inches, the air having then nearly attained its greatest state of dryness. During the month of June the advance of the mean temperature and humidity are nearly uniform, the former being 58°.7, and the force of vapour .410 inches. Through July, the moisture augments with rather greater rapidity than the temperature, the elastic force being .468 inches, and the mean temperature 61°. In August, these phenomena continue nearly the same, the force of vapour being .481 inches, and the mean temperature 61°.6. During September, the reduction of temperature is first felt sensibly, its mean sinking to 57°.8, the vapour at the same time declining to .432 inches. In October, the mean temperature falls to 48°.9, and the elastic force to .336. During the dark and dreary month of November, the atmosphere becomes nearly saturated with moisture, the mean temperature falling to 42°.9, and the mean elasticity of vapour to .286 inches. December exhibits nearly the same characteristics, the mean temperature being 39°.3, and the elastic force of vapour .261 inches.

(465.) The preceding abstract forms, as we have

Aberrations from the mean results.

stated, the mean results for the respective months; but what, it may be asked, are the aberrations exhibited during each, by particular winds? a cause which is for ever modifying all the phenomena of vapour. The following maximum and minimum temperatures of the Dew point peculiar to each month, have been deduced by Mr. Daniell.

TABLE XCIX.

Monthly results.

Relation of vapour and mean temperature of the year.

(466.) Mr. Daniell has graphically illustrated some of his interesting results. In fig. 4, we have an example of the monthly progress of the mean temperature and mean Dew point. The full line exhibits the progress of the former, and the dotted line that of the latter, the degree of dryness belonging to each period being accurately represented by the interval between the two curves. We may hence perceive how closely the constituent temperature of the vapour follows the mean temperature of the air, by the general resemblance of the two curves; and also how clearly they exhibit the comparative dryness of the Spring and summer months, and the dampness of the autumn and winter.

Diurnal results.

Relation of vapour and minimum temperature.

(467.) In fig. 5, which has also been derived from Mr. Daniell, this general accordance of the mean temperature and of the Dew point is rendered still more evident, by the variations of the daily mean for forty-five days in September and October 1819. And to exhibit the analysis of this relation more completely, fig. 6 is given from the same respectable source, deduced from observations made four times each day, together with the daily maxima and minima. An accurate inspection of this last figure most clearly demonstrates that there is but little relation between the maximum temperature and the elastic force of the vapour, and that the vapour appears to be governed principally by the daily minima, thus practically confirming the principle before advanced on the authority of Dr. Anderson.

(468.) That the quantity of vapour existing in the atmosphere near the level of the sea, must follow the course of the mean temperature during the successive seasons of the year, may also be inferred from the consideration, that the existence and quantity of vapour in the air, must be governed entirely by its temperature, and that the rate of evaporation is dependent on the same cause. Hence it follows, that whatever influences the temperature, must at the same time affect the quantity of vapour existing in the air; and as through the changes of the year, the mean temperature rises and falls, in a general way it is found that the quantity of vapour in the air must rise and fall with it. In very short intervals, it is true that aberrations may present themselves apparently in opposition to the Principle which has been advanced, but on a great scale it may be clearly and satisfactorily traced.

Changes of pressure of air opposite to pressure of vapour.

(469.) It is also worthy of observation, that if the pressure of the aqueous vapour be separated from that of the aerial, it will in general be found to exhibit changes directly opposed to the latter. This can be best discovered in the daily fluctuations of the atmosphere; and, in the graphical projections which may be made to illustrate the two, it will be found that the undulations of the curve representing the pressure of the whole atmosphere, are directly opposed to those of the vapour, a rise in the line of vapour being generally accompanied by a fall in the barometric curve, and *vice versâ*.

Attempts t connect the indications of an instru ment with the quantity of vapour found in the air.

(470.) Another method, however, of a very different kind has been adopted by some Philosophers to discover the circumstances of atmospheric humidity. Instead of regarding the elastic force of vapour, its density, and the law of its dilatation, as so many independent elements to be found, and by an operation connected with some functions of the density and temperature, to discover thence all the conditions of moisture at any given time or place, an attempt has been made to connect the indications of an instrument with the tensions of vapour at different temperatures, and thence to deduce all the hygrometric conditions of the air. Saussure first endeavoured to establish a relation of this kind, but it is to the later labours of Gay Lussac that we would now especially refer. Of the two methods we certainly prefer the former, but we owe to our readers an explicit account of the latter.

Gay Lussa employed Saussure's hygromete for this pur pose.

Results ob tained by him at the temperature of ten centesima degrees.

(471.) To accomplish this object, the celebrated Chemist alluded to procured one of Saussure's Hygrometers, as accurately and delicately made as the circumstances of its construction would permit; and placed it in a receiver containing some water, or a solution of a Salt of a known Specific Gravity, and then observed the degree which the instrument marked, under the circumstances of saturation in which it was placed. This experiment was repeated under the same conditions of temperature, for different tensions of vapour between the limits of perfect dryness and absolute saturation. In this way the results of the next Table were obtained for the temperature of 10° of the Centigrade scale, the tensions of the liquids employed being expressed in parts of the tension of pure water, which was represented by 100.

TABLE C.

Solutions.	Specific Gravity at the Temperature of 10° of the Centesimal Scale.	Tension of the Solution at 10° of the Centesimal Scale, that of Water being represented by 100.	Degrees of the Hygrometer corresponding to the different Tensions.

Ditto.	1702	2.4	6.1
Ditto.	1848	0.0	0.0

Graphic illustration of the same.

(472.) The relation of these results may, however, be more clearly explained by means of a graphic illustration. For this purpose their author had recourse to a curve whose coordinates x and y should respectively denote the tensions and hygrometric degrees observed. At the origin of this curve, the values of x and y were to be severally zero, because that point of the hygrometric scale answered to extreme dryness; and at the other extremity of the scale, the same coordinates were to be respectively equivalent to 100, because 100 degrees of the hygrometer corresponded to complete saturation. Between these limits, the experimental results obtained by Gay Lussac afforded many intermediate points for the curve, and which upon investigation he found to be a hyperbola, having its concavity turned towards the line represented by x, and its axis inclined in an angle of 45°, forming the diagonal of a square whose base was the abscissa $x = 100$, and altitude the ordinate 100 corresponding to $x = 0$; the hyperbola being thus symmetrically disposed with respect to the two sides of the square. This result we may venture to say could have scarcely been anticipated *à priori*.

Curve whose coordinates are the tensions and hygrometric degrees a hyperbola.

Analytical investigation of the same.

(473.) To investigate these conditions analytically, it will be necessary to transform the original coordinates x and y, into others x' and y', likewise rectangular, but related to the same axis of the hyperbola, and having their origin in some assumed point of it. This new line of abscissæ must thus form an angle of $-45°$ with the former abscissæ; and by naming (x) and (y) as the primitive coordinates of that line, we shall obtain

$$x = (x) + \frac{1}{\sqrt{2}}(y' + x'),$$

and

$$y = (y) + \frac{1}{\sqrt{2}}(y' - x').$$

These equations, however, may be simplified, by representing by unity the abscissa x corresponding to the tension 100, and which assumption will enable us to obtain the expression

$$y = 1 - x;$$

and since the primitive ordinates (x) and (y) are similarly related, we shall in like manner obtain

$$(y) = 1 - (x).$$

The general equations above given will thus assume the forms of

$$x = (x) + \frac{1}{\sqrt{2}}(y' + x'),$$

and

$$y = 1 - (x) + \frac{1}{\sqrt{2}}(y' - x'),$$

and which by addition will further give

$$y' = \frac{x + y - 1}{\sqrt{2}}.$$

Numerical example.

(474.) If we select, by way of application, the third result given in the Table for the muriate of lime, and the density of which is 1397, we shall have according to the limitation before assigned to the abscissæ

$$x = 0.376,$$

and

$$y = 0.613,$$

and which being substituted in the last equation will give

$$y' = \frac{-0.011}{\sqrt{2}} = -0.00777818;$$

and this being so minute a quantity, the point in the curve to which it refers, may, without any sensible error, be regarded as the vertex of the hyperbola. But to avoid any unnecessary error, the origin of the abscissa x' may be assumed at that point of the axis, where the latter is intersected by y'; and then the value of (x) may be found by adding 0.376 to the projection of y' on the axis of x, or in other words, to $y' \cos x$, or 0.0054996, and which will hence give

$$(x) = 0.3814996,$$

thus determining completely the relations of the two systems of coordinates. Hence we shall obtain the two equations

$$x' = (x - 0.3815)\sqrt{2} - y',$$

and

$$y' = \frac{x + y - 1}{\sqrt{2}}.$$

When x and y are both given, we can readily obtain the value of y' as before illustrated; and this being substituted in the former of these last equations, will give the value of x'. According to this method the following Table has been computed.

TABLE CI.

Primitive Coordinates.		New Coordinates.	
x	y	x'	y'
0.000	0.000	+0.167384	−0.707107
0.122	0.253	+0.074953	−0.441942
0.376	0.613	0.000000	−0.007778

Equation of the hyperbola.

(475.) These elements are sufficient to determine the nature of the hyperbola. For since its axis coincides with the line on which the abscissæ x' are reckoned, its equation must be necessarily of the form

$$y'^2 = a + 2bx' + cx'^2,$$

the values of the constant coefficients being determined by the respective values of x' and y' in the Table. Thus we shall obtain

$$a = 0.0000605,$$
$$b = 1.149338,$$

and

$$c = 4.086830.$$

If, moreover, we assume $(x - 0.3815)\sqrt{2} = s$, we shall further have $y' = s - x'$, and this being substituted in the equation for the hyperbola, will give

$$(s - x')^2 = a + 2bx' + cx'^2,$$

the resolution of which quadratic gives

$$x' = -\frac{(s + b) + \sqrt{((s + b)^2 + (s^2 - a)(c - 1))}}{c - 1},$$

and hence

$$y' = \frac{sc + b - \sqrt{((s + b)^2 + (s^2 - a)(c - 1))}}{c - 1}.$$

The value of y' thus found, being substituted in the equation

$$y = 1 - x + y'\sqrt{2},$$

Formula for computing the hygrometric degrees in terms of the observed tensions.

will determine the function y in terms of x, and thus enable us to compute the hygrometric degrees in terms of the observed tensions; and Biot, at page 533 of the Ist volume of his *Traité de Physique*, has furnished us with a table of all the necessary results from zero to one hundred degrees of Saussure's scale; and a simple inspection of which will at once afford the means of discovering the relation between the degrees of the hygrometer, and the density of the vapour to which the instrument is exposed. If we multiply also the weight in grains of the moisture in a cubic inch of vapour of the given temperature, by the relative tension corresponding to the observed degrees of the hygrometer, we shall obtain the weight of moisture in grains in a cubic inch of air.

Inquiry if the relation of the tensions and hygrometric degrees is general for all temperatures.

(476.) Limited as these computations have been to the temperature of ten centesimal degrees, it becomes important to inquire whether the relations of the tensions and the hygrometric degrees will remain the same at any other temperature. We might, indeed, at first view, suppose, that when the index of the instrument marked a hundred degrees, under circumstances of entire saturation at any given temperature, that at any other degree of heat, and with as complete a saturation as that temperature will permit, the same indication of the instrument would take place. There is reason, however, for supposing that such a desirable condition will not hold good;—that the affinity of the hair for moisture is somewhat modified by temperature, and that thus the relation of the coordinates of the hyperbola must change. Ingenious and interesting therefore as the method is by which these results for the observed temperature have been found, we cannot with perfect confidence extend them to other temperatures; nor must we omit stating explicitly, that the *relative* results which this and other instruments of a like kind exhibit, however convenient they may be for some Meteorological purposes where a rigid and Philosophical accuracy is not required, are by no means to be compared with those *absolute* results, which an attention to the conditions of temperature and barometrical pressure afford. We must not, however, enter here on a discussion of the merits of Hygrometers, but hasten to the subject of evaporation.

Absolute results to be preferred to relative.

Evaporation.

Evaporation.

(477.) We come now to the consideration of that process of Nature, which by its incessant activity affords all the moisture with which the atmosphere is stored, and which quickened by every wind, and augmented by every increment of heat, is continually exerting some effort to return the humidity which the rain and the dew may discharge on the Earth.

Remarks connected with its History.

(478.) The History of this department of Physics is replete with interest. Great names have been connected with it, and the subject has been a difficult one to pursue. Men at one time thought that an essential difference existed between the vapour produced above and below the boiling point. In the lower temperatures, it was imagined that moisture was devoid of elasticity, and hence arose the famous theory of Halley that water is dissolved by air. Deluc and Saussure achieved a great step, therefore, when they proved that vapour of every temperature had elasticity; and a step hardly less important was accomplished by Saussure and Pictet, when they found evaporation to be accelerated *in vacuo*. A true and perfect theory of spontaneous evaporation was, however, reserved for **Dalton**, a name which seems to rise in importance the further we proceed.

Water w assume t form of vapour a all tempe atures.

(479.) It is a law of Nature, now absolutely demonstrated, that water has a tendency to assume the elastic form of vapour at all temperatures however low. Our ordinary experience, indeed, must tend to convince us of its truth, since the product of every shower soon disappears, and ice and snow are wasted by its irresistible power. The sea too performs its part on a grand and magnificent scale. Millions of tons are raised by its agency every day, and a copious evaporation is absolutely necessary to diminish the enormous accessions of water which the Ocean continually receives. The silent and unobserved process by which water is compelled to evaporate spontaneously at all temperatures, is one of the most interesting and important in the whole economy of Nature. The growth of plants and the existence of every living creature depends upon it.

No mat rials for compari the evap ration o differen climates Anomal

(480.) We have no materials for tracing experimentally the phenomena of evaporation in different climates, though we know from its general relations to heat, that it must exist in its greatest power in the Equatorial regions, and, diminishing in some way with the latitude, will be found in a state of even comparative activity in the icy regions of the Pole. Anomalies, however, and some of a very remarkable kind, present themselves in these widely extended regions, and the same terrestrial parallel possesses them in different degrees. The Mediterranean Sea, surrounded on all sides by land, is more heated than the Ocean in the same degree of latitude, and the winds which blow over it, being thus rendered drier, promote a more copious evaporation than in the Atlantic itself. The annual evaporation at Whydah has been estimated at 64 inches, but when the Harmattan blows that rate is augmented to 133 inches. With such anomalies therefore, and with so few facts to guide us, it is no wonder that difficulties arise on all sides when we endeavour to trace the laws, which, in spite of such great aberrations, undoubtedly govern evaporation in every climate.

Remar concer the eva ration atom o water placed the ce of a s rical m meter.

(481.) Before we proceed to consider the experimental laws which the sagacity of the Philosopher has already determined, let us attend for a moment to the phenomena disclosed by the evaporation of an atom of water when placed in the centre of a spherical manometer, surrounded on all sides with an infinity of concentric spherical beds of dry air. In such a condition of things, the process of evaporation must at once commence on all sides of the spherical drop, and the stratum of air in immediate contact with it, will be the first to become saturated with vapour. The vapour thus imparted to the first atmospheric stratum, from its occupying a station in immediate contact with another bed of dry air, will at once exert its elastic power and expand according to the mechanical resistance which this second bed permits. In this way, we may imagine moisture to be transmitted from one successive bed to another, but in continually diminishing quantities as the beds are further removed from the centre; and a moment of time may be conceived when the beds of the manometer most removed from the origin of the vapour, are just beginning to receive the first impressions of humidity, whilst the central beds have already acquired all that the circumstances of their temperature will permit. As each particle of vapour, however, tends continually to diffuse itself in the space on which it immediately borders, if the quantity of vapour be less than the circumstances of temperature permit, the process of evaporation cannot cease on the surface of the watery atom at the centre, nor can the humidity imparted from one successive stratum to the other be checked, until the whole mass of air which occupies the manometer, shall have acquired all the moisture which the given temperature demands.

Application of the atmosphere itself.

(482.) In applying to the atmosphere the Principles of this illustration, we shall be able to trace the general Principles of evaporation. The air confined within the manometer may be supposed to be enlarged into the magnificent volume surrounding the Earth, and the surface of water exposed to its free action in a vessel of any kind, may be assimilated to the atom of water placed at its centre. If we suppose as a first example the whole extent of our atmosphere to be of one uniform temperature, and that there already exists in it all the vapour which this temperature will support, no evaporation can possibly take place from the water that is exposed; but if with this condition of uniform temperature, the vapour already existing in the air be below the maximum which that temperature admits, the evaporating process must at once commence, and the water in the vessel being only as a point when compared with the whole extent of the air to which it is exposed, will at length be entirely dispersed, and that without sensibly increasing the tension of the vapour already existing in it. This vapour, indeed, can have no other effect than to modify the rate of evaporation, and which will be more and more rapid as the air happens to be nearer a state of complete dryness.

(483.) To simplify the subject, we have supposed the temperature uniform throughout the whole extent of the atmosphere, but such a supposition, as we have before seen, is far from representing its actual condition. Inequalities of temperature exist on every side, and the unequal distribution of heat will at once produce its effect on the water exposed for evaporation. A volume of air in one position may thus gain a larger share of humidity than another. Inequality of temperature may exist, or one of the volumes may already possess a greater proportion of vapour than the other. The rate of evaporation will thus be changed, and every variety of it may hence be supposed to exist on a surface so infinitely diversified as that of our Earth.

Law of evaporation proportional to the area of the humid surface.

(484.) It may be announced as a general proposition, that the rate of evaporation is always proportional to the area of the humid surface, and, in air entirely quiescent, it appears, that position exerts but very little influence. A sheet of paper, observes Leslie, applied to a plate of glass in a close room, will lose its moisture just at the same rate, whether it be held vertically or horizontally, and whether it occupies the upper or under side of the plate. The quantity evaporated from a wet ball will be the same as from an equal plane, or by a well-known property of the sphere, as from a circle twice its diameter.

Remarks concerning water evaporating from vessels of different magnitudes and forms.

From water also contained in vessels of any magnitude and form, and of equal or unequal depths, the rates of evaporation, at least in tranquil states of the atmosphere, and when the circumstances of temperature and situation are the same, will be proportional to the magnitude of the watery surface exposed to the action of the air. Muschenbroëk, indeed, asserts, that the deepest vessel is always found, after a certain interval of time, to have suffered the greatest waste, and that the quantities evaporated are as the cube roots of the heights, their orifices and other circumstances being the same. He remarks, however, that when the experiment was performed in a room, no sensible difference was perceptible.

Different opinions.

Leslie also asserts, that the deepest vessel evaporates most copiously, and grounds his opinion on the Principle, that the shallowest vessel receives more readily than the other, the chilling impressions which accompany evaporation; and that the larger mass being thus kept invariably warmer than the other, must, as evaporation is always accelerated by heat, afford a more copious supply of moisture than the other. Lambert, however, like Leslie, a refined experimenter as well as a great Mathematician, found from observations continued through several months, in different temperatures and under many varying circumstances of situation, that in vessels of very unequal dimensions both in diameter and altitude, all other things being the same, the quantity evaporated was always proportional to the surface of the water in immediate contact with the air, and that no other exception appeared to the law than the errors necessarily arising from observation. Saussure, it may be added, entertained the same opinion. Whoever has attended experimentally to the subject of evaporation, must have been frequently struck with the anomalous nature of the results which the same course of experiments has disclosed. A sudden gleam of the Sun immediately quickens the evaporating power, and any alteration of wind will likewise modify the course of the results.

(485.) It is necessary, however, to limit the assertion to vessels whose differences of surface are not infinitely great, and whose local conditions are entirely the same. A surface of water contained in a vessel of finite dimensions, and placed in the midst of an open and arid plain, must necessarily undergo a more copious evaporation than if placed in the midst of a great lake, under similar circumstance of heat, of the sky, and of the wind. The reason, also, will be apparent when we consider that the vessel is surrounded by a drier air in the midst of the plain, than when encompassed by the waters of the lake, and must hence undergo a greater evaporation. And this remark may be employed as a useful caution when we endeavour to estimate the amount of evaporation from the sea, by the quantity of vapour raised in a given time from a vessel in a garden.

Principal causes which modify the results of evaporation. Temperature.

(486.) The two great causes, however, which influence evaporation, and modify its results, are the temperature and movements of the atmosphere, into the effects of which we must more particularly inquire. And first with respect to temperature. Every degree of heat seems to produce evaporation from water, nor can the lowest temperature, in a proper condition of the air, entirely destroy this power. Evaporation, indeed, as Dalton remarks, continues to act below the point of congelation as well as above it, and we owe to that profound inquirer, the best experiments we possess respecting the rate at which water evaporates under different degrees of heat. In an atmosphere perfectly dry and calm he obtained the following results.

TABLE CII.

Temperature.	Rate of Evaporation per Minute expressed in Grains.	Elastic Force of Vapour in Inches.
212°	30	30.00
180	15	15.15
164	10	10.41
152	8.5	7.81
144	6	6.37
138	5	5.44

Rate of evaporation proportional to the elasticity of the vapour produced.

Thus the rate of evaporation under the circumstances mentioned is found to be proportional to the elasticity of the vapour produced.

Least evaporation produced when air is perfectly quiescent.

A current of air accelerates it.

The more rapid the current the greater the evaporation, other things being the same.

Mr. Dalton's results.

Effects of currents.

(487.) Concerning the changes which the rate of evaporation undergoes in consequence of the air in contact with the evaporating water being either quiescent, or moving with different velocities over it, it may in the first place be remarked, that air in a state of perfect repose and under constant circumstances of temperature and pressure, produces the least possible degree of evaporation; and that, in such a condition of things, the vapour, as it forms, accumulates over the evaporating surface, and by successively checking the evaporating power, ultimately reduces it to nothing. But a current of air with whatever velocity it may proceed, by bringing new portions of air less saturated with humidity over the evaporating surface, must again renew the evaporating power; and thus the more rapid the current, the more rapidly, *cœteris paribus*, must the water disappear. As a proof of this we may adduce the important experiments of Mr. Dalton, who found, that at the temperature of the boiling point, the least evaporation took place from water, when the evaporating surface was placed in the middle of a room, with the doors and windows closed. Under these circumstances the rate of evaporation was 30 grains per minute. On placing the water in the chimney, with the doors and windows completely shut, the current of air existing in the chimney increased the evaporating power to 35 grains a minute. An increase in the fire, by augmenting the current in the chimney, raised the evaporation from 35 to 40 grains a minute; and by opening the windows of the room, and producing thereby a stronger current in the chimney, the force was increased from 40 to 45 grains per minute. Had the experiments been performed in the open air, and in a very high wind, the rate of evaporation would have been much greater. In air moving with an infinite velocity, as Biot remarks, the rate of evaporation would be infinite also.

Mr. Howard's example of influence of the wind.

An interesting example of the effects of the free action of the wind on the annual rates of evaporation at different heights is given by Mr. Howard. During three years in which the gauge was elevated about forty-three feet from the ground, exposed to the South-East, and subject to the free action of the wind in most directions, the annual average result was 37.85 inches. During other three years in which the instrument was lower and less exposed, the annual rate rose to 33.37 inches; and during another triennial period when the gauge was upon or near the ground, the yearly rates averaged only 20.28 inches.

(488.) In the next Table we have given Mr. Dalton's results at the successive temperatures recorded in it, with different velocities of the atmosphere, but in a perfectly dry state of the air. The three last columns of the Table show the quantity of vapour in grains driven off in a minute from a circular vessel of water six inches in diameter.

TABLE CIII.

Preceding Table formed on supposition that no moisture previously exists in the air.

(489.) But this Table has been constructed on the supposition that no vapour previously exists in the air, a hypothesis which can never be verified in any condition of the atmosphere, since at every season, moisture more or less abounds in it. In cases where the elastic forces are considerable, the influences of this vapour are insensible, but at lower temperatures its amount must by no means be neglected. If we suppose the water of evaporation to have a temperature of 50°, we shall find the force of vapour at that temperature exactly $\frac{1}{80}$th of its force at 212°, and therefore, from what has been before advanced, the rate of evaporation ought to be $\frac{1}{80}$th also. If, however, at the time of observation, an aqueous atmosphere already existed to that amount, or, in other words, the air be completely saturated with moisture, no evaporation can possibly take place, and the amount of vapour must remain unchanged. But if the force of the aqueous atmosphere should be less than that which a complete saturation admits, there will be room for the evaporating power to become active, and a quantity of vapour, dependent on the difference of the temperature of the water and of the vapour already existing in the air, will be raised.

Mr. Dalton measures this moisture.

(490.) To measure the effect of this humidity of the atmosphere, Mr. Dalton endeavoured to discover the exact quantity of vapour existing at the moment of observation. He took a tall cylindrical glass jar, dry on the outside, and filled it with cold water fresh from a well. If dew were immediately formed on the outside, he poured the water out, and allowed it to stand some time to augment its heat, at the same time carefully drying the outside of the glass with a linen cloth. This operation was continued till dew ceased to be formed, when the temperature of the water and the force of vapour were determined. The experiment was performed either in the open air, or at a window, on account of the internal air being generally more humid than that which is without. Spring water being commonly, also, at about 50° of temperature, was made use of for the three hottest months of the year, but, at other seasons, a cold, artificial mixture was employed. To estimate the evaporating power, water was introduced into a tin vessel of a given diameter suspended from the arm of a balance, and the exact loss of weight from evaporation found. Then denoting the whole amount of the elastic force of vapour at the term of saturation corresponding to the observed temperature by f, and the actual force of vapour already existing in the air by f', Mr. Dalton found under all conditions of the atmosphere, whether perfectly quiescent or agitated by the wind, the rate of evaporation to be constantly proportional to

Rate of evaporation proportional to $f-f'$.

$$f-f';$$

or, in other words, that if the whole tension of the vapour at the temperature of the boiling point be denoted by F, and that at this same temperature the weight of water evaporated in a minute in dry air be denoted by m for a given unit of surface, the quantity of vapour to be obtained at any other temperature, but with the same conditions of repose or agitation of the air, will be expressed by the function

$$\frac{m\,(f-f')}{\mathrm{F}}.$$

(491.) The value of the coefficient m will of course be different under different circumstances of the atmosphere. In a calm and tranquil air, as our Table CIII. indicates, its value must be 120; in a moderate breeze 150, and in a high wind 180; so that denoting the results of evaporation under these different conditions by E, E′, and E″, we shall have

Formulæ for estimating the rate of evaporation on different velocities of the air.

$$\left.\begin{aligned} \mathrm{E} &= \frac{120}{30}(f-f') = 4\,(f-f') \\ \mathrm{E}' &= \frac{150}{30}(f-f') = 5\,(f-f') \\ \mathrm{E}'' &= \frac{180}{30}(f-f') = 6\,(f-f') \end{aligned}\right\}\ (\mathrm{V.})$$

(492.) These formulæ will enable us to resolve some interesting Meteorological problems. In the first place by knowing the functions f and f', that is the maximum tension of the aqueous vapour for the observed temperature, and the tension of the vapour existing in the atmospheric beds at the same time, and multiplying their difference by the coefficient depending on the state of the atmosphere as to wind, will at once determine the rate of evaporation. If we take the case when a moderate breeze prevails, and suppose the temperature 70°, and the amount of the observed humidity in the air to be 0.388 inches of the mercurial column, then the whole amount of the elastic force being 0.721 inches, we shall have

Example of rate of evaporation determined.

$$\mathrm{E}' = 5\,(f-f') = 5\,(0.721 - 0.388) = 1.665 \text{ grains},$$

being the rate of evaporation per minute from a circular surface of water six inches diameter and one inch deep, under the circumstances stated.

(493.) This may be regarded as an example of the direct use of one of the formulæ, but they may be all applied to other useful purposes. If we wish to determine the actual tension of the vapour really contained in the atmosphere at the time of observation, and we know by some previous experiment the rate of evaporation, and supposing, moreover, a high wind to prevail, we shall have

$$\mathrm{E}'' = 6\,(f-f'),$$

and from which may be deduced

$$f' = f - \frac{\mathrm{E}''}{6},$$

Example of the actual humidity of the air determined by aid of the rate of evaporation.

and which will therefore give a measure for the actual humidity of the air under the given circumstances of f and E″. If we suppose the first of these elements to be 0.524 inches, and the second 0.324 grains, the temperature, as the value of f indicates, being 60°, we shall obtain from the particular formula we have selected

$$f' = 0.524 - \frac{0.312}{6} = 0.524 - 0.052 = 0.472 \text{ inches},$$

and which may be regarded as an exact and simple means of determining the value of f'.

Whole tension of vapour if necessary.

(494.) We might also discover the whole amount of humidity corresponding to the term of saturation for the observed temperature, by previously obtaining the values of E and f'; but no real advantage would result from it, as we are already in possession of a better method of determining it, and even by a formula which will give us its value at any temperature.

Rate of evaporation influenced by density of the air.

(495.) The rate of evaporation is also influenced by the density of the air, increasing as that density lessens, and exhibiting its greatest degree of power in a vacuum. Mr. Daniell, in an ingenious course of experiments, has traced the relation between the increase of

Mr. Daniell's experiments.

the evaporating power and the diminution of the atmospheric pressure. For this purpose he enclosed in a glass receiver, upon the plate of an air-pump, a vessel with sulphuric Acid, and another with water, and by properly adjusting the surfaces of the two, was enabled to maintain, in the included atmosphere of permanently elastic fluid, an atmosphere of vapour of any required force; or, in the popular mode of expressing the same fact, the air could be kept to any degree of dryness. The density of the air also in such an arrangement could be varied and measured at pleasure. There are three methods of estimating the progress of evaporation in such an atmosphere; the first and most direct is, to find the loss of weight sustained by the water in a given time; the second, to measure by a thermometer, the depression of temperature of the evaporating surface; and the third to ascertain the Dew point, by means of the hygrometer.

His apparatus.

(496.) The receiver which Mr. Daniell made use of in his first experiment was of large capacity and fitted with one of his Hygrometers. A flat dish of 7½ inches diameter was placed under it, the bottom of which was covered with strong sulphuric Acid. The glass bell but just passed over it, so that the base of the included column of air rested everywhere upon the acid. In the centre of the dish was a stand with glass feet, supporting a light glass vessel of 2.7 inches diameter, and 1.3 inches depth. Water to the height of an inch was poured into the latter, the surface of which stood just three inches above that of the acid. A very delicate thermometer rested in the water upon the bottom of the glass, and another was suspended in the air. The sides of the vessel were perpendicular to its bottom, which was perfectly flat. The height of the barometer was 29.6, and the temperature of the water 56°. In twenty minutes from the beginning of the experiment, the Hygrometer was examined, and no deposition of moisture was found at 26°.

Successive experiments.

(497.) This being the greatest degree of cold which could be conveniently produced by the affusion of ether, Mr. Daniell repeated the experiment with a contrivance which admitted the application of a mixture of pounded ice and muriate of lime to the exterior ball of the Hygrometer. In this manner the interior ball was cooled to 0°, without the appearance of any dew. The temperature of the air and water in this instance was 58°, and the atmospheric pressure 30.5.

(498.) From this experiment, therefore, it appears, that in the arrangement above described, the surface of water was not adequate to maintain an atmosphere of the small elasticity of .068 inches. In what degree it was less than this, or whether steam of any weaker degree of elasticity existed, the experiment of course did not determine. We may reckon, however, without any danger of error, that the sulphuric Acid, under these circumstances, maintained the air in a state of almost complete dryness.

(499.) In a second experiment, the same trial was made with atmospheres variously rarefied. No deposition of moisture was in any case perceived, with the utmost depression of temperature it was possible to produce; and the state of dryness was as great in the most highly attenuated air, as in the most dense. In the higher degrees of rarefaction, however, the water became frozen.

(500.) In a third experiment, the water which had been previously exposed to the vacuum of the pump to free it from air, was weighed in a very sensible balance, before it was exposed to the action of the sulphuric Acid under the receiver. Its temperature in this situation was 45°, and the height of the barometer 30.4. In half an hour it was again weighed, and the loss by evaporation found to be 1.24 grains.* It was replaced, and the air rarefied till the gauge stood at 15.2; after the same interval of time the loss was found to be 2.72, but the temperature was reduced to 43°. The loss from evaporation, in equal intervals, with a pressure constantly diminishing one half, was found to be as follows:

Results.

TABLE CIV.

Pressure.	Temperature.		Evaporation in Grains.
	Beginning.	End.	
30.4	45°	45°	1.24
15.2	45	43	2.87
7.6	45	43	5.49
3.8	45	43	8.80
1.9	45	41	14.80
0.95	44	37	24.16
0.47	45	31	39.40

When the exhaustion was pushed to the utmost, the gauge stood at 0.07, and the evaporation in the half hour amounted to 87.22 grains. During this last experiment, the water was frozen in about eight minutes, while the thermometer under the ice denoted a temperature of 37°.

Correctio of these r sults for variation of tempe ature.

(501.) These results require, however, some corrections for the variations of temperature which took place during their progress. The rate ef evaporation having been proved proportional to the elasticity of vapour, we must estimate the latter from the mean of the temperatures before and after the experiments, and calculate the amount for some fixed temperature accordingly. This will afford us a close approximation to the truth, although from the last experiment we may perceive that the method of estimating the temperature of the surface cannot be absolutely correct. The next Table presents us with the former results corrected for the temperature of 45°.

0.47	50.74
0.07	112.32

---

* It will be remarked by referring to our Table CIII. that Mr. Dalton found the full evaporating force of water at the temperature of 45°, to be 1.26 grains per minute, from a vessel of six inches diameter.

Rate of evaporation inversely proportional to elasticity of incumbent air.

Notwithstanding the slight irregularity of the above series, there can be no risk in drawing from it the conclusion, that the rate of evaporation is, *cæteris paribus*, inversely proportional to the elasticity of the incumbent air. This increased evaporation with a diminished density of the air, will account for the high state of saturation in which the air of mountainous Countries is generally found.

Elasticity of vapour from water of constant temperature not changed by differences of pressure.

(502.) Mr. Daniell likewise endeavoured to discover if the elasticity of the vapour as it rose from water, varied in any degree with the pressure of the air, or whether any portion of the increased evaporation depended upon that variation. To determine this he placed the sulphuric Acid in a glass having nearly the same surface as the water, the two being arranged side by side, upon the plate of the air-pump, and covered with the receiver. By many successive experiments it was found, that the elasticity of vapour given off by water having a constant temperature, was not influenced by differences of atmospheric pressure.

Inquiry if temperature of evaporating surface is influenced by changes of density.

(503.) It is also a point worth inquiring in what degree the temperature of an evaporating surface is influenced by differences in the density of the air. To estimate this, Mr. Daniell attached a very delicate mercurial thermometer to a brass wire sliding through a collar of leathers in a ground brass plate. This was fixed, air tight, upon the top of a large glass receiver, which covered a surface of sulphuric Acid of nearly equal dimensions with its base. Upon a tripod of glass, standing in the Acid, was placed a vessel containing a little water, into which the thermometer could be dipped and withdrawn by means of the sliding wire, the bulb of the instrument being covered with filtering paper. At the commencement of the experiment, the barometer stood at 30.2 inches, the temperature of the air being 50°. On withdrawing the thermometer from the water it began rapidly to fall, and in a few minutes reached its maximum of depression. The following Table contains the results, the intervals of observation being twenty minutes each.

TABLE CVI.

Barometer.	Temperature of the Air.	Temperature of the Wet Thermometer.	Difference.
30.2	50°	41°	9°
15.1	49	37	12
7.5	49	34	15
3.7	49.5	31.5	18
1.8	49.5	28.5	21
0.9	49	24.5	24.5
0.4	49	23	26

(504.) Here then in an atmosphere, proved to be in a state of almost complete dryness, we find that at the full atmospheric pressure, the wet surface of the thermometer was reduced 9°. It is worthy of observation how small a quantity of water is necessary to produce this effect. We have before seen that a surface of 2.7 inches diameter, lost only 1.24 grains in half an hour, and which would only have amounted to 1.41 grains, had the temperature been 49°. The surface of the wet thermometer, Mr. Daniell remarks, could not have exceeded one-fiftieth of that of the evaporating vessel, and the maximum effect was produced in ten minutes, or one-third of the time, so that the weight of water evaporated in this case was not more than (.0094 grains) one-hundredth of a grain. It will be seen that the depression increased with the rarefaction of the air, but at a much slower rate. This increase is to be attributed, however, not to the increased rate of evaporation, but to the diminished heating power of the air. MM. Du Long and Petit, in their experiments upon the cooling power of air, determined it to be nearly as the square root of the elasticity; but whether the heat which it is capable of communicating to a cold body, follows the same progression, the experiments which we have here recorded, are not sufficient to determine. We may, however, conclude with certainty from them, that the temperature of an evaporating surface is not affected by the mere quantity of evaporation.

Dr. Bostock's horary rates of evaporation.

(505.) The only series of horary rates we are acquainted with are those of Dr. Bostock contained in the next Table, and are the averages of 149 experiments performed during single hours on different days.

TABLE CVII.

Months.	Rate of Evaporation in Grains per hour.	Months.	Rate of Evaporation in Grains per hour.
January....	0.287	July.......	0.983
February...	0.400	August	0.932
March	0.393	September..	0.555
April	.....	October	0.346
May.......	0.897	November..	0.369
June	0.930	December ..	0.392

Deductions from them.

The whole of Dr. Bostock's experiments embraced the result of 1188 hours, the mean evaporation being 0.501 grains per hour from a vessel of two inches diameter. Of these, 942 referred to the Winter, giving an average of 0.43 grains per hour, and 246 for the Summer, affording a mean of 0.77 grains per hour. The maximum evaporation in an hour amounted to 1.75 grains, and occurred on the 4th of August. The minimum evaporation was found on the 12th of November, when no loss of weight could be traced. The greatest Winter evaporation was found on the 28th of November, amounting to 1.08 grains, and the least Summer evaporation on the 5th of August, the very day succeeding the maximum evaporation;—another example of the sudden and apparently capricious change of the atmosphere.

Horary observations relating to the wind.

Of the horary observations which relate to the wind; Dr. Bostock observes, that the average of fourteen Winter observations, with the wind in a South or West point, gave 0.346 grains per hour. Of the same number of Summer observations, with the wind blowing between the same points, 0.882 grains. Of fourteen Winter observations, with the wind in a North or East point, 0.546 grains per hour; and of the same number of Summer observations, with the wind from the same points, 1.03 grains per hour.

How evaporation is influenced by height of mercurial column.

(506.) To discover in what way the rate of evaporation was affected by the height of the mercurial column, the barometric scale from 29.20 to 30.20 was divided into ten equal parts, and the same number of observations being made under each division, gave the following horary rates of evaporation.

TABLE CVIII.

Height of the Barometer.	Rate of Evaporation per hour in Grains from a Vessel of two inches diameter.
29.3	0.381
29.4	0.451
29.5	0.436
29.6	0.386
29.7	0.760
29.8	0.750
29.9	0.510
30.0	0.545
30.1	0.565
30.2	0.471

High and low barometer less favourable for evaporation.

It would seem from these experiments, though any deduction from them, from their limited nature, must be received with caution, that either a very low or a very high barometer is less favourable to evaporation than an intermediate state; a result, however, which is in some degree favoured by the fact, that the damp or wet weather commonly attendant on a low barometer is unfavourable to evaporation; and that when the barometer is high, the atmosphere may be supposed to be more nearly saturated with moisture, and therefore less disposed to receive any additional quantity.

Horary ol servations with respe to temperature.

(507.) Of the horary observations made with respect to the temperature of evaporation, Dr. Bostock has given the results in

TABLE CIX.

Temperature.	Rate of Evaporation per hour in Grains from a Vessel two inches diameter.
Below 40°	0.470
From 40° to 50°......	0.352
From 50° to 60°......	0.450
From 60° to 70°......	0.878
Above 70°	1.000

The apparent anomaly in the results for the temperature below 40° may be explained on the principle that the greatest degrees of cold are generally accompanied by North or East winds, which in other respects are the most favourable to evaporation.

Monthly observatio for Liverpool, Ken dal, Tottenham, and London.

(508.) Of the monthly observations which have been made to show the progressive rates of evaporation, we have those of Dr. Dobson, Mr. Dalton, Mr. Howard, and Mr. Daniell, which are contained in the several columns of the following Table.

TABLE CX.

Months.	Dr. Dobson's Mean Evaporation for 4 years in inches. Diameter of Evaporating Vessel 12 inches. Locality Liverpool.	Mr. Dalton's Mean Evaporation for 3 years in inches. Diameter of Evaporating Vessel 10 inches. Locality Kendal.	Mr. Howard's Mean Evaporation for 8¼ years in inches. Diameter of Evaporating Vessel 5 inches. Monthly evaporation follows nearly the mean temperature.

(509.) In these monthly results it may be perceived that the rate of evaporation follows in a general, but not uniform manner, the course of the mean temperature. In some years the evaporation receives a check in the Spring, from depressed temperature, but its energy is again restored by a renewal of heat. The frosts of Spring and of the latter months of the year also retard it.

Results Glasgo

(510.) The following Table exhibits the average elasticity of vapour in the atmosphere of Glasgow, and the rate of evaporation for several months of the years 1823, 1824, obtained by Dr. Hugh Colquhoun. We wish such observations could be extended.

---

* In Mr. Howard's results, the evaporating gauge was at different heights from the ground.

TABLE CXI.

Evaporation for the four seasons.

(511.) According to Mr. Howard, the evaporation for the four seasons at Tottenham, with the corresponding mean temperatures, are as follows :

TABLE CXII.

Seasons.	Evaporation in Inches.	Mean Temperature.
Spring	8.856	48°.06
Summer	11.580	60.80
Autumn........	6.444	49.13
Winter	3.587	37.20

It will be seen from these results, that the rates of evaporation are not proportional to their corresponding mean temperatures; the Spring and Summer being in excess, and the Autumn and Winter in defect, arising from the comparative dryness of the air in the former seasons, and its dampness in the latter. It must be borne in mind, however, that Howard's gauge was not always at a constant height above the ground.

Annual rates of evaporation for London, Tottenham, Liverpool, Kendal, and Glasgow.

(512.) The following Table contains a few results of the annual rates of evaporation.

TABLE CXIII.

London	23.974	inches.
Tottenham	30.467	
Liverpool	36.770	
Kendal	25.158	
Glasgow	32.418	

Dr. Thomson is disposed to take 32 inches as the mean annual evaporation for Great Britain. He considers it to be less than this in a great part of Scotland, and a portion of England; but that it exceeds it considerably in the South-East of England, and probably also in East Lothian and Berwickshire.

Experiments on the actual surface of the earth. Hales, Watson, Dalton, and Hoyle.

(513.) But few observations have been made on the rate of evaporation from the actual surface of the Earth. Dr. Hales calculated that moist earth threw off only $6\frac{2}{3}$ inches annually, but this calculation must be far below the truth. Dr. Watson, Bishop of Llandaff, found in a dry season that there evaporated from a grass-plot closely mowed, about 1600 gallons in an acre per day. In the years 1796, 1797, and 1798, Mr. Dalton and Mr. Hoyle undertook an investigation of the subject. They prepared a cylindrical vessel of tinned iron, ten inches in diameter, and three feet deep. Two pipes were inserted into it and turned downwards, for the water to run off from it into bottles. One of the pipes was near the bottom of the vessel, the other was an inch from the top. This vessel was filled up for a few inches with gravel and sand, and the rest with good fresh soil. It was then put into a hole of the ground, and the space around filled up with earth, excepting on one side, for the convenience of attaching bottles to the two pipes. The earth was then moistened with water. For the first year the soil was bare on the top, but during the two succeeding years it was covered with grass. A regular register was then kept of the quantity of water that ran off from the surface of the earth by the upper pipe, and also of the quantity which descended through the column of earth and passed through the lower pipe. A rain-gauge of the same diameter was planted close to the apparatus to find the quantity of rain. The mean result of three years gave 25.158 inches, to which five inches for dew being added, gave for the mean annual evaporation from earth at Manchester 30.158 inches. Mr. Leslie estimates the daily exhalations from a sheltered spot in Winter at 0.018 inches, and in Summer 0.048 inches; but this will only afford 12 inches at a mean rate in the year; and is evidently below the truth. As far as our knowledge at present goes, it appears that the evaporation from water is the greatest, from the grassy surface of the earth, probably, next, and from bare earth the least.

Leslie.

Dalton's experiments on the quantity of water in a given depth of earth.

(514.) Connected with this subject Mr. Dalton undertook some experiments to determine the quantity of water in a given depth of earth, when the soil is at the point of saturation. For this purpose he took a quantity of garden soil that had been soaked with rain a day before, and pressed it into a crucible. It was then exposed to a moderate heat till it appeared of the same moisture as garden soil two inches deep in dry summer weather. Afterwards it was exposed to almost a red heat till it became a perfectly dry powder. In the former case it lost one-twelfth of its weight, and in the latter one-third. When it had lost one-sixth, it did not appear too dry to support vegetation. When it had lost two-ninths, it seemed like the top soil in summer. Hence Mr. Dalton concludes, that every foot of earth in depth so saturated, contains seven inches of water, and that it may part with one-quarter, or even one-half of it, and not be too dry for supporting vegetation.

Evaporation of snow.

(515.) Experiments on the evaporation of snow are by no means numerous, and the Philosophers of Northern Countries would perform an acceptable service by attending in some degree to it. It is carried on in some conditions of the atmosphere with great rapidity and power. Howard mentions a case wherein the vapour arising from a circular area of snow of five inches diameter, amounted to 150 grains from sunset to sunrise in January, and 50 grains more by the following evening, the gauge being exposed to a smart breeze on the housetop. An acre of snow, under such circumstances, would hence evaporate, in the course of twenty-four hours, the enormous quantity of nearly 64,000,000 grains of moisture. Taking only the portion evaporated during the night, a thousand gallons of water were raised from the surface referred to. We may hence see why a moderate fall of snow sometimes entirely disappears

Curious phenomena.

during a succeeding Northerly gale, without the least sign of liquefaction from the surface. It is worthy of observation, also, that in deeper snows, the surface sometimes becomes curiously grooved and channelled by the wind acting unequally on it and thus promoting unequally the evaporating power. This phenomenon is best observed around the trunks of trees and near the interstices of palings, or wherever a stream of air acquires an increased force in a particular direction. Wilson found snow to evaporate at 27°.

Evaporation of ice.

(516.) Of experiments made on the evaporation of ice the principal are those of Mr. Dalton. A given quantity of water was allowed to freeze in a tin vessel of six inches diameter. The vessel and ice were then weighed together, and exposed in the open air for a certain time, and the loss of weight found. The following are his results.

TABLE CXIV.

Time of Observation.		Loss by Evaporation in grains.	In hours	Rate of Evaporation per minute in grains.	Wind.	Temperature of Air.
Nov. 5,	at Night	110	9	0.20	N.E. brisk.	28° to 31°

Of Polar Regions.

Of Glaciers.

According to M. Schuebler the evaporation from ice sometimes exceeds that of water. In the early part of January he found it to be twice as great as from an equal surface of water in the middle of February, during mild, cloudy weather. Gay Lussac has proved the evaporation of ice to go on at two degrees below the zero of Fahrenheit's scale. The great beds of ice in the Polar regions must therefore exert a considerable influence on the humidity of the atmosphere; and the process of evaporation wastes also the glaciers of the Alps, and even the *Mer de Glace* must feel the influence of its power.

Evaporation not always suspended in rain.

Less on those days in which rain falls.

(517.) It has been remarked, that evaporation is not always suspended during rain. Howard has proved this by direct experiment. Its rate, however, is usually much less on those days in which rain falls, and it is liable to a rapid increase immediately after. Howard, also, found, that an excess in the rate of evaporation is sometimes found to precede rain.

Suspended during formation of dew.

(518.) Evaporation must be suspended when dew begins to form, as it would be absurd to suppose the air can both give and receive moisture at the same moment, when in immediate contact with the evaporating surface.

Affected by calm preceding change of wind.

(519.) The calm which often attends a change of wind very sensibly lowers the rate of evaporation. The rate also diminishes on the passing off of a wind which has blown steadily for some days.

Checked by current of moist air.

(520.) Sometimes evaporation is checked by a current of air highly charged with moisture passing over the spot on which the observation is made, even though no rain be the result.

(521.) The most intense cold, yet observed, is insufficient of itself to prevent the formation of vapour.

Greatest evaporatio observed b Howard i a single day.

(522.) The greatest evaporation ever observed by Howard, in a single day, occurred on the 17th of May, 1809, and amounted to 0.39 inches, with the wind from South-East, and a mean temperature of 67°.

Theoretic attempts t estimate quantity evaporatio

(523.) Attempts have been made to estimate theoretically the mean daily evaporation, and, among others, by Dr. Young, who assumes it equal to the tabular number representing the elasticity of the vapour, sometimes exceeding and sometimes falling short of it about one-fourth. Dr. Anderson, also, in virtue of a hypothesis that the mean point of deposition is six degrees below the mean temperature, has contrived a formula for the same purpose, which seems to agree pretty well with observation. By assuming t for the mean temperature, and f_t, ϕ_τ for the elastic forces of vapour corresponding to the temperatures t and τ, the value of τ being $t - 6$, he deduces the formula

Andersoı formula same.

$$E = 365\left(f_t - \phi_\tau\left(1 + \frac{t - \tau}{447.4 + \tau}\right)\right) \dots\dots \text{(W)}$$

for the mean annual evaporation; or the expression

$$e = f_t - \phi_\tau\left(1 + \frac{t - \tau}{447.4 + \tau}\right)$$

for the mean daily evaporation, or nearly

$$e = f_t - \phi_\tau.$$

Exampl

(524.) Suppose, by way of applying this formula, we assume the mean temperature of London to be 50°, we shall then obtain by means of formula (W)

$$E = 365\left(f_t - \phi_\tau\left(1 + \frac{t - \tau}{447.4 + \tau}\right)\right)$$
$$= 365\left(0.37345 - 0.30384\left(1 + \frac{50 - 44}{447.4 + 44}\right)\right)$$
$$= 24.05 \text{ inches.}$$

Remarl able co cidence

And we have before seen, that Mr. Daniell found it from actual observation to be 23.974 inches, which is certainly a remarkable coincidence.

(525.) As a more convenient approximation he further transforms his formula into

$$E = 365\left(f_t - \frac{81}{80}\phi_{t-6}\right),$$

for the mean annual evaporation, or

$$e = \left(f_t - \frac{81}{80}\phi_{t-6}\right)$$

for the mean daily evaporation.

We may hence calculate approximatively the mean annual evaporation for each geographical parallel. Such formulæ, however, in the present condition of our knowledge, must be strictly received as approximations, and as such they are to be very highly valued.

Equa temp in tw feren not s cient mak of ev ratio

(526.) We conclude this interesting subject with the observation, that equality of temperature alone in two different years is not sufficient to allow us to infer that the rates of evaporation in those years are the same. With the same average temperature through all the months of the year, the different velocities of the air will at once introduce diversities of a very considerable kind. Indeed, if equality of temperature alone could determine the rate of evaporation, we might then suppose the equal temperatures found in the Spring and Autumnal months, would afford equal degrees of

Examples.

evaporation, but this we know not to be the case. Howard gives an example in point for March and October 1807, when the temperature of each month was just 42°, but the rates of evaporation were respectively 2.66 and 1.86, the difference being occasioned by the increased humidity of the air in the Autumnal months retarding the evaporating power.

Rain.

Rain.

(527.) The humidity so constantly afforded to the air by the process of evaporation, is returned again to the Earth, principally by the agency of Rain. A variety of theories have been proposed to account for the formation of Rain, for the phenomena disclosed in its descent, and for the many diversities which it presents in the different climates of the Earth; but none seemed to account for it on principles at once simple, satisfactory, and general, before that advanced by Dr. Hutton of Edinburgh. In this theory, Rain was supposed to result from the mingling together of great beds of air of unequal temperatures, differently stored with moisture, and the opinion has been adopted by Dalton, Leslie, and other distinguished men.

Theory of Hutton.

Remarks on saturation of air.

(528.) We have before seen that a volume of air of a given temperature, can be charged with only a limited portion of humidity, and that so long as the temperature remains unchanged, the moisture cannot be augmented. We also know, that air in the act of cooling, approaches to a state of saturation, and is disposed to part with some of its humidity; and on the contrary, that when heat is gained at any time by it, the power of receiving more moisture is at the same time obtained. We moreover know, that while the union of two volumes of unequal temperature must chill the one and warm the other, the former will resign some of its moisture, and the latter be disposed to receive it; and had the order of Nature permitted these opposite conditions of humidity and temperature to be precisely balanced, the united volume might have preserved its moisture unchanged, and no portion of the vapour whatever have been rendered visible. We have seen, however, that while the temperature slowly mounts by uniform arithmetical degrees, the moisture necessary for saturation ascends in a more rapid geometrical form; and that though two saturated volumes of unequal temperatures, may by their union afford a mean degree of heat, a mean degree of moisture cannot result, but some quantity will be found in excess, beyond what the mean temperature requires. This quantity, sometimes more and sometimes less, according to the temperatures of the mingling volumes, must be discharged in the shape of Rain; for the moisture which the air cannot support, ought of necessity to descend.

Temperature and humidity do not increase by the same law.

Consequences of this.

Graphical illustration of Hutton's principle.

(529.) A mode of illustrating this subject graphically was devised by Hutton, as follows. Let the abscisses A B, A B′, fig. 7, denote the temperatures of two equal portions of air, and the ordinates B C, B′ C′, the quantities of humidity belonging to them, the curve C F C′ passing through the extremities of the ordinates, being convex to the axis A B′. If now the extremities C C′ be joined, and B B′ be bisected in D, the perpendicular D E will denote the mean arithmetical measure of the moisture contained in the mingled volumes, and D F the actual quantity which the temperature A D can support in entire saturation, leaving E F for the measure of the moisture precipitated by the union.

Numerical examples.

(530.) A numerical example or two, may, however, more clearly explain this simple but interesting principle. Let it be required to mingle two volumes of air of the temperatures of 40° and 60°, each being saturated with humidity. The force of vapour at these temperatures are known to be respectively 0.263 and 0.524 inches of the mercurial column. The compound mixture will evidently have a mean temperature of 50°, and the mean of the elastic forces is at the same time 0.393 inches of the same column. But if we now inquire whether air at the temperature of 50°, requires an elastic force of this last-mentioned magnitude to saturate it entirely with vapour, we shall find that it does not; and that at the mean temperature here referred to, the measure of entire saturation is really 0.375 inches of quicksilver. The difference of the two columns, or 0.018 inches of mercury, is hence the amount of moisture that must ,be precipitated in some way or other from the compound mass.

Measure of moisture precipitated.

Precipitation not constant for equal differences of temperature.

(531.) To prove, moreover, that this precipitation cannot be constant for equal differences of temperature, let us further take the example of the temperatures 60° and 80°. In this case we shall find the elastic forces to be 0.524 and 1.000; and that at the mean temperature of 70°, the force of vapour is 0.721 inches. But the mean of the two elastic forces is 0.762, thereby proving that a quantity of vapour corresponding to 0.041 inches of the mercurial column, must be discharged the moment the aerial volumes are united.

Objection to the theory.

(532.) An objection may, however, be started, that the quantity of moisture which can at any time be discharged by such an union of masses of air, is by far too small to account for the actual precipitations of humidity which take place; and the example of the mean temperature of the lowest atmospheric stratum may be referred to as a proof, that were it to discharge, as Leslie expresses it, by some internal change of its constitution, its whole store of moisture, not more than five inches of water would be deposited; and that the atmosphere must therefore deposit five or ten times as much humidity in the course of a year, as it can at any one time hold in solution. But it should not be forgotten, that since only a very minute portion of the vapour contained in any of the atmospheric columns is at any time separated from the air, precipitation and evaporation must rapidly succeed each other, and that hence moisture is in some degree restored, as soon as it is discharged. In addition to this it should be also borne in mind, that in the currents which exist at all times in the air, and which bring into union volumes of very different temperatures, we are by no means to calculate on the discharge of *one* atmospheric column alone. The atoms of air which have discharged their watery store over a given spot, pass on, and are succeeded by others resulting from another union, thus adding the humidity which they are capable of discharging, to the Rain which has before descended.

Answered.

Rain should not always result from the union of atmospheric currents. Examples.

(533.) The order of Nature, however, requires, that Rain should not always result from the mingling together of opposite currents, and the theory before us amply confirms it. Two volumes of the temperatures of 50° and 60° may be blended, one of which contains vapour denoted by 0.2 inches of mercury, and the other by 0.3, the mean being 0.25; whereas the quantity necessary for entire saturation, at the mean temperature of 55°, is 0.443. In such a case it is obvious no precipitation can take place. One volume, again, may have a temperature of 52°, and be in a state of entire saturation, its elastic force being 0.401; but the volume to be united to it, with a temperature of 70°, containing moisture equivalent only to 0.589. The mean amount of moisture will therefore be 0.495, whereas the humidity necessary to produce saturation, at the mean temperature of 61°, is 0.542, so that no precipitation can take place. But in cases where the mingling volumes are both entirely saturated, however small may be the difference of their temperatures, some condensation dependent on that difference must take place. It is evident, indeed, that combinations of this kind may be endless, the absence of precipitation, as well as the amount of it when it takes place, depending on circumstances so varied and uncertain, as to afford, on the one hand, a shower so gentle as hardly to bear the designation of Rain, and on the other to supply the torrents which occasionally deluge the Tropics. Not only the existing state of moisture in the mingling columns must be subject to innumerable changes, but their different degrees of heat must be altered also; the elevation of their mean temperature too, as well as the extent of combination which takes place among all the moving volumes, must impress necessarily on the whole of the phenomena the greatest diversity. So varied, indeed, are all these conditions in the great volume of the atmosphere, that snow may be formed at great elevations, which descending into the lower regions of the air, must reach the ground at length in the shape of Rain. On the other hand Rain may be sometimes formed in the upper regions, and become frozen in its descent. Precipitation may also be actually going on above, without any indications of Rain below, the moisture entirely disappearing by the increased warmth of the lower strata.

Some precipitation must take place however small may be the difference of temperature.

Such combinations infinitely diversified.

Inquiry into the truth of the theory.

(534.) The great test, however, of a theory is its conformity to Nature, the capability it has of accounting for the diversified conditions which appear to attend on the phenomenon of Rain,—its generality,—the regularity which appears to characterise it in one region, and its great uncertainty in others; and, moreover, the exceptions which sometimes appear to take place to its descent altogether.

This theory will account for the generality of Rain.

(535.) We may, in the first place, remark, that it will account for the generality of Rain. The only conditions, as we have before seen, necessary for the formation of Rain, are those of unequal temperature and humidity, both of which must exist in every possible degree on a surface so exceedingly diversified as the Earth's. We have before remarked, in tracing the phenomena of vapour, how very variable is its distribution, from the unequal surfaces of land and water which prevail, the mountains, woods, and deserts, which by modifying the temperature, tend to produce a greater or less saturation of the atmospheric columns; and as we shall hereafter see, the great effects of variable winds in transporting this humidity in every direction, and by numberless currents in every locality and at every altitude, blending together the vapour raised in different climes, and thus producing, according to the theory that has been advanced, sufficient causes for precipitations of rain more or less abundant in every zone. Over all the globe, therefore, Rain should occasionally happen, and with greater diversity as the disturbing forces are more considerable. In places situated near land and water unequally distributed, and where the atmospheric strata are much broken and interrupted, either by their contact with the irregular masses rising from the ground, or by the unequal temperatures which separate the different waters of the Globe, variable Rains should be most abundant.

(536.) Again, in those regions of the Earth in which the movements of the atmosphere are more uniform, we may naturally look for a greater uniformity in the descent of Rain. The great atmospheric currents produced by the trade-winds, must in some region or other produce a mixture of different portions of the fluid mass, and if Rain be the result, we must conclude that the mingled masses of air have been sufficiently saturated with moisture, and of different temperatures. This we know to be the case, there being periodical descents of Rain which harmonize with the causes here assigned to them.

Periodical descents o Rain.

(537.) According to the theory also under consideration, the Islands situated under the line in the Indian Ocean, should form to themselves conditions of periodical condensation, corresponding to the diurnal influence of the Sun, and the nocturnal motions which take place in the air. And this is observed to be the case. The sea and land breezes which every day occur, by the blending together of opposite currents, occasion, in conditions favourable to the condensation of vapour, either always, or at particular seasons, the daily phenomenon of Rain. These conditions, it is true, are not always to be found where the periodical currents exist; but it cannot be unreasonable to suppose that a sufficient supply of aqueous vapour exists in those regions in the air, nor that in the great system of diurnal currents, there may not be some portions mingled together of unequal temperatures.

(538.) In like manner, Dr. Hutton accounts for the periodical rains which occur upon the different coasts of the Peninsula of India. In the great range of the tropical regions of Africa and Asia, the rivers indicate that it rains in the Summer solstice, and that fair weather results from the removal of the heating cause. The air elevated by the intense power of the solar heat, has its place supplied by that which has been transported from the neighbouring seas. But arrived here upon a heated continent, this humid air must be elevated into the higher regions of the atmosphere, and either be transported from thence towards the Poles, there to be gradually condensed as the depression of temperature goes on, or it must fall again in rain on the surface from which it was raised. On the first supposition, no Rain should be found to take place in these regions in the Summer; and the rivers, by which we are alone able to judge of the phenomenon, should be found in their lowest state after that season. But, as all authorities concur in stating the opposite to this to be true, the rivers being then swollen, it follows that the humid atmosphere which has advanced from the sea, must have its vapour condensed upon the heated continent at the time of the Summer solstice. Indeed it is a well-known fact, that the heavy Rains which fall in India, always take place during the shifting of the Monsoon, and while they last the winds are always variable.

(539.) The Summer Sun, however, which proves a cause of Rain in some regions of the Earth, in which neighbouring seas affording a great evaporation exist, in other regions becomes the cause of drought, where the evaporating power is less, or is supplied from a more distant source. A continent less abundantly supplied with vapour than the tropical parts of Africa and Asia, when heated by the full power of the Summer Sun, ought to be more disposed to drought than Rain, unless some transient streams of air, properly charged with moisture, should reach the place, and, by being blended, occasion the descent of Rain. Such a phenomenon, however, could not be regarded as a general season of Rain. On the decline of Summer, the air approaches saturation, and becomes disposed to produce Rain with every mixture resulting from unequal temperatures. Hence a source of Autumnal Rains and Winter snows, which may fall with all the uniformity of tropical Rains, and the effect is manifested in the regular covering of the Northern continental regions with snow, an event which happens with so much constancy, that it may be regarded as analogous to a periodical Rain.

Cases where no Rain exists, explained.

(540.) We have before remarked, that precipitation is not at all times the result of the mingling together of opposite currents, and the Sahara of Africa, the low coasts of Caraccas, Egypt, and a portion of the coast of Peru have been instanced as places where it never rains. According to some authorities, a South-West wind constantly prevails at the latter, although, according to others, it varies between the South-West and South South-West points of the compass. Now a wind constantly uniform, or nearly so, must either produce constant precipitation, or no Rain at all; and since the prevailing wind here alluded to, passes from a colder into a warmer region, and thus becomes more and more removed from the term of saturation, it follows that the constancy of the wind insures the permanence of the result. But although no Rain falls in the lower regions of Peru, the atmospheric currents, as they move on, must at length reach the lofty summits of the Andes, where meeting with a diminished temperature they undergo condensation, and occasion those almost constant precipitations with which those mountainous regions abound.

Rare occurrence of Rain in trade-winds.

(541.) The rare occurrence of Rain in the constant trade-winds, may also be regarded as an indirect confirmation of the theory. The aqueous vapour rising into the higher atmosphere, and flowing to the North and South, without accumulation, on account of the steadiness of the temperature and the uniform direction in which the vapour moves, occasions no formation of Rain. But beyond the boundaries of these winds, precipitations are very abundant. Not only the vapour becomes subject to a rapidly decreasing temperature, but the variable winds are constantly bringing atmospheric masses, possessed of the necessary conditions of humidity, into union with each other.

(542.) That the greater portion of the Earth should be found destitute of Rain, would certainly militate against the theory we have been anxious to explain; but that a few spots, having no diversity of climate, should be found without it, confirms rather than invalidates it. In such instances the conditions necessary for the precipitation of humidity do not exist.

Objections of Howard to Hutton's Theory.

(543.) The theory of Hutton has, however, been in some degree questioned by Mr. Howard; but while this distinguished Meteorologist seems to doubt the possibility of an intimate mixture of large masses of the atmosphere, to the extent which the hypothesis of the Scotch Philosopher requires, and that in Summer different currents may be detected, flowing "quietly" over each other, without any "extraordinary precipitation, or, in some cases, without any turbidness at all, during several subsequent days of fair weather," yet he afterwards admits as "matter of experience, that the contact and opposition of different currents, charged with aqueous vapour and differing in temperature, is largely concerned in the production of our vernal and estival Rains." And with respect to the absence of precipitations in Summer, under the circumstances referred to, we are by no means certain that either the conditions of humidity or temperature, necessary for the formation of Rain, existed at the time; and we have before proved, that not every union of the atmospheric columns will of necessity produce it. Mixture, he thinks, may take place to a certain degree and accelerate precipitation, but he cannot regard it as "a *necessary* previous condition." He considers "the great and universal cause of Rain in our latitudes, to be the *depression of the temperature of vapour alone;*" whereas, in such an Island as Great Britain,—and we would by no means be supposed to limit the assertion to that little spot,—the very seat as it were of variable winds, and consequently of the motion of masses of air unequally stored with vapour, and of unequal temperatures, the theory of Hutton seems most abundantly confirmed;—"frequent showers,"[*] as Howard observes, "without extreme quantities of Rain falling at one time—the climate of the country inclining towards moisture." We may add here, also, what is matter of common notoriety, that steady dry weather is always accompanied by some uniform direction of the wind, whereas in rainy weather the winds are unsteady and variable.

There ought to be a diminution of Rain from the Equator to the Poles.

(544.) Amidst the seeming diversities, however, which characterise the descent of Rain, and which impress on particular localities, qualities which seem to set all investigation at nought, we may, nevertheless, infer from those general inquiries before advanced respecting the distribution of moisture, that the maximum descent of Rain ought to be found in the Equatorial regions, and that apart from all the disturbing causes which more or less influence its formation and descent, there ought to be a diminution in its quantity from those regions to the Poles.

Inquiry into this diminution.

(545.) In a general way we may be said to know the mean quantity of moisture existing in the different atmospheric columns for all the parallels of latitude; and that since the cause of the descent of Rain may be resolved into temperature only, we might determine its whole amount at a given place, provided we knew all the varied circumstances of temperature to which the atmosphere above it is subject. But the present con-

---

[*] Some places have obtained a particular character for Rain, and among others Plymouth. The following rhymes are popular in the West, and though their Author has attributed to each of the great Cardinal winds, the power of bringing Rain, yet the Philosopher, bound by more rigid rules than the Poet, will at once recognise in them a confirmation of the theory of Hutton. At Plymouth, the winds are very variable, but the prevailing one is South-West for by far the major part of the year; and at Penzance, an equally variable climate, and not a degree and a half to the West, the prevailing wind, according to the accurate Tables of Mr. Giddy, the Curator of the Royal Geological Society of Cornwall, is North-West. Here then are two winds, to say nothing of the others, or of the peculiar configuration of the land, which by their union must prove constant sources of Rain to the whole of the peninsula over which they pass. The theory of Hutton, however, does not rest on a single example. Innumerable instances might, if necessary, be found.

The South wind always brings wet weather;
The North wind, wet and cold together.
The West wind always brings us Rain;
The East wind blows it back again.

If the Sun in red should set,
The next day surely will be wet;
If the Sun should set in grey,
The next will be a Rainy day.

dition of our knowledge will not enable us to estimate the temperature of the different atmospheric strata on a given day; and hence all that we can do, must be to compute the probable quantity of Rain, on the supposition that some general circumstances of temperature influence the atmosphere throughout. Under conditions like these, precipitations more or less abundant, according to the mean conditions of vapour existing in the different atmospheric columns, will be the result.

Relation between evaporation and rain and dew.

There must be, moreover, a relation of some kind between the vapour imparted by evaporation to the air, in a given time, and the humidity discharged in the shape of Rain and dew from it; but whatever that relation may be, it hardly follows in the troubled volume of the atmosphere, that it is constant even for the same latitude. There is a mean evaporation, and the air will support in a mean state, a given portion of vapour; and as we have before remarked, that vapour is always very much less than the mean result of evaporation affords. The whole amount of evaporation, therefore, being some multiple of the vapour contained in the air at a given time, we may denote the relation by the equation

$$E = m\phi,$$

where E denotes the whole amount of evaporation, m the quantity of moisture contained at one time in a column of air when entirely saturated, and ϕ a function whose value is dependent on the relation which the element m bears to E.

Anderson's mode of computing the rain in every latitude.

(546.) By making the function ϕ constant for every latitude, Dr. Anderson supposed that we might approximate in some degree to the mean amount of Rain in every latitude, by multiplying the aqueous columns which represent the columns of vapour existing in every latitude by it. In this way he computed the Table he has given in his able Article on Hygrometry before quoted, and in which he makes the Equatorial Rain amount to 73 inches, the rain in the parallel of 45° to 29¾ inches, and that at the Pole 11½ inches nearly. These results, however, as Brewster has remarked, are far from approaching the truth; and that supposing the formula of temperature to be corrected on which the computation is founded, it will even be then further removed from the truth, as the annual amount of Equatorial Rain would then only amount to 64½ inches, whereas, as we shall presently see, it is really much greater.

Another theoretical method.

(547.) A formula, contrived with a similar object in view, has been also given in the Article Physical Geography, contained in the Supplement to the *Encyclopedia Britannica*, in which the author supposes 83 inches to be the amount of the Equatorial Rains, and 8 that of the Polar, the formula thus assuming the shape of

$$83\ (\text{rad.} - \text{sin. lat.}) + 8 \ldots\ldots (X);$$

but this will be found to deviate very widely from the truth within the Tropics.

Humboldt's results for several latitudes.

(548.) Humboldt with more propriety fixes the Rain at the Equator, and in three several latitudes, as in the following Table.

TABLE CXV.

Latitude.	Mean Annual Depth of Rain.
0°	96 inches.
19	80
45	29
60	17

Doubt if tropical Rains are sufficient. Another Table for different latitudes.

But even here it is doubtful whether the amount of the tropical Rains is sufficient,* if the results of the next Table can be relied on.

TABLE CXVI.

Place.	Latitude.	Amount of Rain in inches.
Coast of Malabar. .	{ Mean latitude about 11½° N. }	123.5

Rome	41° 54′ N.	39
England	50° to 55° N.	31
Petersburgh	59° 16′ N.	16
Uleaborg	65° 1′ N.	13½

Remarks on the gr anomalie On the te perature and amo of Rain.

(549.) Such anomalies as these may well inspire us with caution respecting theoretical assumptions framed independent of observations. The relations of temperature, which seem to guide other phenomena with accuracy within some tolerable limits, here absolutely forsake us; and we cannot, with any propriety, connect either the Rain at the same place with its average mean temperature, or, passing from one geographical parallel to another, trace any visible relation between the mean temperatures of those parallels, and the average precipitations of Rain upon them. If we take the results of an excellent series of observations made on the Malabar coast from 1810 to 1823 inclusive, as an example of the prodigious aberrations which the Rain undergoes, while the annual temperature oscillates within very moderate limits, we shall have a striking instance of the truth of the remark. The annual results both of the Rain and of the temperature are contained in the next Table.

Observ tions fo Malaba

TABLE CXVII.

Date.	Annual Amount of Rain in inches.	Annual Mean Temperature.
1810	125.90	80°.16
1811	104.90	80.13

---

* The inhabitants of our temperate climes have a sort of timidity respecting the amount of tropical Rains. Malte-Brun remarks, that "the European born to the North of the Alps, is ready to form a false idea of the character of the zone lying between the fortieth and twenty-fifth degrees of latitude." With how much greater reason might this be said with regard to the whole of the Equatorial regions.

Great aberrations exhibited by this Table.

Here there are deviations between the results of two years amounting to more than 75 inches of Rain, at a time when the difference of the mean temperature of the same years does not amount to a single degree. And so also with deviations from the average mean temperature of the whole, not amounting to two degrees of Fahrenheit's scale, there are differences from the average result of Rain exceeding 45 inches.

Contrasted with the observations of Dalton at Manchester.

(550.) As a contrast, however, to these results for the Malabar coast, let us take the case of Manchester as recorded by Dalton in the following Table, and we shall find that with quite as much uniformity in the mean results of temperature, we have a much higher degree of regularity in those of Rain. The greatest deviation from the mean temperature amounts only to 2.3, and that of the Rain but to 7.689, just a sixth part of that found in the Tropics.

TABLE CXVIII.

Years.	Mean Temperatures.	Mean Results of Rain.
1802	47.4	35.737
1803	47.2	27.472
1804	48.2	29.310
1805	48.0	27.542

1818	49.7	34.566
Mean....	47.6	33.596

Greater probability of arriving at correct conclusions respecting Rain in temperate regions.

There seems a greater probability, therefore, of arriving at correct conclusions respecting the phenomena of Rain in the temperate regions of the world, than in those of the Tropics. Mr. Howard has remarked with regard to the atmosphere of London, that the warm years are uniformly dry, or below the average in Rain, and the cold ones uniformly wet, or above the average; and that there is probably in this region of the Earth a close connection between the mean temperature of many years and the Rain at the Earth's surface which attends them.

Schow's comparison of amount of Rain of Countries North and South of the Alps.

(551.) That the Rain, however, does in some way or other decrease with the latitude is apparent from the comparison of what may be termed neighbouring districts. In Schow's inquiries concerning the two great divisions of Europe situated to the North and South of the Alps, he fixes at 25 inches the mean annual amount of Rain for the former, and 35 inches for the latter, although these numbers must not be taken as measures of the comparative humidities of the two, on account of the effects of snow being omitted in the former. The same excellent authority also adds, that the Rain descends more slowly, and with greater uniformity, in the region to the North of the Alps, that in that to the South. The torrents which burst suddenly from the clouds in that part of Europe, recall, says he, the phenomena of the rainy season in the Tropics. And as a contrast also between our climate and the climates of the Equator, and affording an indirect confirmation of the decrease of Rain with the increase of the latitude, we may add the remark of Malte-Brun, that while here the drops of Rain are only a few lines in diameter, in the torrid zone they reach sometimes almost to an inch.

Difference also in the character of its descent.

Probability that line of maximum Rain will be found North of the Equator.

(552.) It is not impossible but future observations may prove that the greatest amount of Rain is not found at the Equator itself; and as the land appears to influence so considerably all the precipitations of moisture, that the line of maximum Rain will be found in some irregular plane to the North of it.

Relation between tropical rivers and great amount of Rain.

(553.) The magnitudes of what may be called the tropical rivers afford additional evidence of an indirect kind, that the amount of Rain is the greatest in those climes. There must be a relation of some kind or other between the annual fall of Rain and the discharge of rivers.* Mr. Dalton, indeed, deduced from some of his inquiries respecting Rain and evaporation, that in England the Rain and the dew are equivalent to the quantity of water carried off by evaporation and by the rivers; and he infers from it, that as Nature acts upon general laws, it ought to be regarded as the case in every other Country till the contrary is proved. This conditional equation, though deduced from very limited experiments, would seem in a high degree probable. It seems reasonable that the quantity of humidity discharged on a given surface in the shape of Rain or dew, should in some way or other escape from it, either by evaporation or the discharge of rivers; and it is worthy of observation, that Nature seems to have made a provision of some sort for it, in the superior discharge of the rivers we have referred to. We know that the proportional discharge of these rivers, exceeds those of the temperate regions, and hence confirms the indirect evidence we have adverted to.

Dalton's remarks on rivers and Rain of England.

The descent of Rain for same parallel not constant.

(554.) In thus endeavouring to connect the fall of Rain with the latitude, it is by no means intended to infer that the descent is constant through the whole range of the same parallel. In the instance of the Malabar observations before alluded to, the average of which is 123½ inches, we can hardly suppose the same extraordinary fall to prevail throughout the whole of that parallel, in the middle of the Atlantic or of the Pacific, because the average descent

---

* The discharges of rivers, particularly those belonging to the tropical regions, are far, however, from being uniform, nor are the superficial extents of their basins by any means constant. In Rennell's Paper on the Ganges and Burrampooter rivers, *Phil. Trans.* 1781, he remarks, that their courses are continually altering, steep banks being formed on the sides which have concave forms, and shelving sides on those which are convex. The outlet of the Jellinghy river has gradually removed three-quarters of a mile further down the Ganges; and, according to two surveys, made of a part of the adjacent bank of the Ganges, at an interval of nine years, the breadth of a mile and a half had been washed away. A mile in ten or twelve years is, Rennel thinks, the usual rate of encroachment, where the current strikes with the greatest force. Some of the Bengal rivers have indeed totally changed their courses. The Cosa river, equal to the Rhine in magnitude, once ran by Purneah, and joined the Ganges opposite Rajemal. Its junction is now forty-five miles higher up. Gour, the ancient Capital of Bengal, once stood on the banks of the Ganges. These are the powers, as Malte-Brun observes, which, set in motion by the hand of Nature herself, and in whose operations ages are accounted as moments, produce some of the great changes which have taken place on the surface of the Globe.

of Rain on the sea, is in general less than on the land, and certainly so in the case we have cited, influenced as the humidity must be by the surrounding mountains, and the woods which more or less cover them. The same principle is moreover confirmed by the well-known fact, that the fall of Rain on the sea-coast, is much more considerable than in places in other respects similarly circumstanced in the interior. According to some authorities, the moisture of the air decreases in a sort of geometrical series in proportion as it is progressively removed from the sea, losing one-third of its moisture in the first four or five hundred miles, a third of that which remains for another interval of the same kind, and so on; but such a ratio must in a great measure be conjectural. We have a comparison by the indefatigable Cotte, made between the sea-coast and the interior, though not confined to the same parallel, and which unquestionably demonstrates the fact. Gottingen, Paris, and Toulouse, not far from the coast, he remarks, have an average fall of Rain amounting to 21.7 inches; whereas at Prague and Buda, situated in the very heart of Europe, and like the former not much elevated, the annual deposit is only 15 inches.

Descent of Rain on sea less than on land.

Fall of Rain on sea-coast more considerable than in interior.

Decrease of moisture assumed by some from sea-coast to the interior.

Comparative examples.

Mountainous Countries most humid.

Causes.

Example of Keswick and Kendal.

Contrast of Puy and Rochelle.

Of Paris, Geneva, and St. Bernard.

(555.) But while in places placed at a considerable distance from the Ocean, and nearly on the same level with it, a decrease in the annual amount of Rain is generally found to exist, an elevation of the land produces a contrary effect; and accordingly mountainous Countries are in all cases found more humid than those comparatively more level. This may, at first, seem contrary to what has been advanced in a former part of the Paper, namely, that the quantity of moisture actually diminishes in some ratio of the ascent; but from the peculiar influences which mountains exercise on the atmosphere surrounding them, the precipitations of moisture and the magnitude of its amount, become much more frequent and considerable, than can possibly be found in the lower regions of the air. The great mountain chains of the globe, indeed, call into activity the real sources of Rain, in their greatest power. To say nothing of the unequal circumstances of humidity in the different strata of the air, the incessant play of the currents generated by the inequalities of the Earth's surface, must incessantly mingle together volumes of unequal temperatures, and thus create, in the lapse of time, a greater amount of Rain than could be produced in the lower regions of the atmosphere, where more uniform laws prevail. In our own Country, Keswick and Kendal, situated among mountains, have annual amounts of Rain respectively 67.5 inches and 54, while many places in the interior of the Country, not much raised above the Ocean, or even on the sea coast itself, have hardly 25. At Puy, situated near the sources of the Loire, the average fall of Rain is 29.5 inches, while 24.5 only fall at the seaport of Rochelle near its mouth;—affording an interesting example of a comparatively small increase of elevation compensating for a great extent of distance from the sea. The annual fall of Rain at Paris also, amounts but to 20 inches, whereas Geneva discloses a mean result of 42.6 inches; and the Great St. Bernard,* the highest Meteorological station in Europe, has an annual fall of no less than 63.13 inches. If we take also the mean result for Toulon, Marseilles, Aix, Montpellier, Arles, Nismes, Cavaillon, and Avignon, places situated between the parallels of 43° and 44° North, and but little raised above the sea, and compare it with a similar mean derived from Orange, Viviers, Lyons, Villefranche, Bourg, and Geneva, found between the parallels of 44° and 46° North, but situated on higher ground, we shall find the same truth confirmed, the first mean amounting but to 22.6 inches, and the latter to 34.3 inches. So also in a series of places to the North of the Alps; *viz.* Carlsruhe, Manheim, Stuttgard, Wurtzburg, Augsburg, and Regensburg, the mean amount of Rain is 25.1 inches; whereas for Zurich, Bern, Lausanne, Peissenberg, and Tegernsee, raised much higher above the sea, the annual average is 40 inches. If again we descend into the Lombardo-Venetian plains, near the Apennines, the mean of eight places gives 29.5 inches; but in the central plain of Lombardy, the average of seven places is raised to 39 inches, and at the very bases of the Alps, and in the lower valleys, the results of twenty places raise the mean to 58.5 inches. In like manner the mean result of observations West of the Lago di Guarda is 42.1 inches, but to the East of the same, in the rising country connected with the Carnic Alps, the average is increased to 62.6 inches.

Toulon, Marseilles, &c. at the level of th sea, compared with Lyons, Geneva, &c. raised above the sea.

Carlsruhe, Manheim, [illegible] North of the Alp compared with Zurich, Bern &c. at higher levels.

Lombardc Venetian plains compared wit central plain of Lombard and with places at the bases the Alps.

Country West of Lago di Guarda comparec with country of Carnic Alps.

As examples of a single year, where the elevations of the places are known, we may give the following:

Places.	Heights above the Sea.	Quantity of Rain in a single Year.
Venice.	zero	31.8 inches.
Verona.	232 feet.	35.0
Udina.	359	64.7
Tolmezzo	1535	109.2

Examples a single year of effects of altitude.

More Ra at bottom a mounta than at t

Dr. Hebe den's dis covery o excess o Rain at lower lev

His expe ment wi three gauges different heights, a single year.

(556.) But, although more Rain falls in mountainous Countries than in Countries of the plain, it is nevertheless an undoubted fact, that the depth of Rain is greater at the bottom of a mountain than at the top, and generally, that a greater quantity falls close to the ground, than at any height above it. Dr. Heberden was the first to remark this phenomenon, by comparing the results of two Rain-gauges at different levels about a mile from each other, the Rain in one of them constantly exceeding the Rain in the other, not only in the average results of a month, but almost every time it rained. Desirous of tracing the anomaly to its source, he had three gauges constructed precisely similar, and one of them placed on the square part of the roof of Westminster Abbey, and at such a distance from the Western towers as to be but little influenced by them. Another was fixed on the top of a house, considerably lower than the first, and a third on the ground in a garden belonging to the house. A year's observations gave the following results:

Gauge on the roof of the Abbey.... 12.099 inches.
Ditto on the top of the house 18.139
Ditto on the ground............. 22.608

This has since been confirmed in a variety of forms by many observers. The best series of observations, however, are those of the Observatory of Paris, under the direction of the able and indefatigable Arago, one of the rain-gauges being in the court of the Observatory, and

---

* Meteorological observations on high mountains were first suggested by the celebrated Pictet, and their great advantages are unquestionable. The Monks of St. Bernard have thus a rare opportunity of adding to our knowledge of the atmosphere. We were highly gratified to hear of the kind and hospitable reception which the Members of the Society of Natural History of Geneva received at their hands, during the meeting lately held in that lofty region for various Philosophical purposes. M. de la Rive, the successor of Pictet, has published a very interesting account of it.

Meteorology.

the other on the terrace of that noble building, 28 metres higher. The mean of twelve years gives the following results for the two positions; *viz.*

Observations at Paris for several years.

	Centimetres.
For the terrace of the Observatory	50.471
And for the court of the Observatory	56.374

Same law also to be traced in the several months.

(557.) The law appears to hold good, not only in the mean results for a series of years, but also for the different months, as may be seen in the following Table, the maximum for each situation being in July, but the minimum of the terrace in November, and of the court in February.

TABLE CXIX.

Months.	Mean Amount of Rain for the several Months of the Years 1826, 1827, 1828, and 1829, on the Terrace of the Observatory at Paris in centimetres.	Mean Amount of Rain for the several Months of the Years 1826, 1827, 1828, and 1829, in the Court of the Observatory at Paris in centimetres, the difference of level of the two Gauges being 28 metres, or nearly 92 feet.

Meteorology.

Remarks on these results.

Rare exceptions to the law explained.

(559.) In two of the results contained in the preceding Table, *viz.* those on the 28th and 29th of October, it will be perceived, that an equality was found in the upper and lower gauges, but in all the others, the excess was found in the lower gauge. There are instances, however, exceptions to the law now under consideration, in which the upper gauge gains the most, but they are very rare. According to Howard, this will be found to be the case, when the source of Rain is high, and the lower air so dry, that the evaporating power exercising its influence on each drop, must occasion a diminution in the amount of Rain. The cause here assigned must, however, be received with caution, as Philosophers are by no means agreed on the point; and with a similar limitation must the solutions that have been offered of the excess in the lower gauge. Arago,—and he is without doubt a very great authority, remarks, that the supposition advanced by some, of the descending streams of moisture reaching the Earth in parallel directions less removed from the perpendicular, on account of the diminished action of the wind, is far from satisfactory. The idea that the drops of Rain augment in magnitude, by appropriating to themselves some of the humidity belonging to the atmospheric strata comprised between the two rain-gauges, he holds to be fallacious also, and to this it has been likewise objected, that the difference is equally found, when the hygrometer, during Rain, does not mark saturation. Boisgiraud, indeed, accounts for this latter difficulty by observing, that the Rain is generally sufficiently cold, relatively to the atmosphere, to cause a precipitation of vapour from the surface of each atmospheric stratum, and thus to augment the quantity of sensible humidity, even when the hygrometer is far removed from the limit of perfect saturation. And in the same way he explains, how it sometimes happens, that the air is not saturated after a shower of a long continuance. Mr. Gough has remarked, that the quantity of Rain at different heights appears to him to be nearly as the height of the plane of congelation above the gauge.

Philosophers not agreed on cause of this, or of the increase at the lower level.

Remarks on the supposed causes.

Inquiry concerning Rain formed between different heights.

(560.) It appears from the last Table, that about one-fourth of the Rain which fell during the term of observation, was formed within 43 feet of the Earth's surface; and it appears also, that this quantity is subject to very great diversity. In the next Table we have given the monthly differences between the results of the higher and lower gauges for the Paris observations for the years 1826, 1827, 1828, and 1829, and in which it may be remarked that the greatest discordances exist.

TABLE CXXI.

Differences in Centimetres between Results of higher and lower Gauges for the Years

	1826.	1827.	1828.	1829.
January ...	.120	.375	.525	.170
February ..	.585	.300	.595	.240
March.....	.285	1.207	.790	.174
April......	.620	.835	.280	.490
May	.430	1.575	.210	.010
June	.070	.110	.425	.180
July	.255	.190	.205	.140
August....	.384	.130	.600	.345
September .	.305	.235	.130	.495
October ...	.525	.745	.050	.460
November .	.865	.565	.230	.130
December..	.810	1.220	.190	.030

In the case of May for 1827 and 1829, the quantities actually formed in the vertical space between the two gauges, were in the ratio of 157 to 1, whereas the whole quanties of Rain deposited at the two elevations did but little exceed 5 to 1.

Relation between Rain on the ground, and that formed within some definite height above it.

(561.) In the next Table we have given the actual amounts of Rain deposited at the lower station, and likewise the absolute quantities formed in the vertical space between the two stations. The ratio of these is given in the third column of the Table.

TABLE CXXII.

Years.	Annual Amount of Rain in the Court in centimetres.	Annual Quantity of Rain formed in the vertical space of 28 metres.	Ratio of the two.
1826	47.209	6.254	100 to 13
1827	57.585	7.487	100 to 13
1828	62.765	4.230	100 to 7
1829	58.889	2.914	100 to 5
Mean of the twelve years above [illegible]en.	56.374	5.903	100 to 11

Not constant.

Mr. Howard's attempt to deduce a correction for it.

Not satisfactory.

Howard's corrections for the different months.

(562.) From this Table also it may be inferred, as well as from Table CXXI., that the quantity of Rain actually formed within the range of some constant elevation is exceedingly variable, and that, therefore, very considerable caution is necessary, in endeavouring to deduce the quantity of Rain actually deposited on the ground, from the results afforded by a rain-gauge at any altitude above it. Mr. Howard has attempted, by the aid of Table CXX., to deduce a correction of this sort, and to apply it to the Royal Society register from 1797 to 1806, by increasing the average annual amount in the Society's gauge, which is elevated 75 feet, from 19.355 inches, to 25.577 inches, the quantity thus presumed to fall on the ground. The ratio employed was that of 28 to 37, or 100 to 132, making the mean increment of Rain 32 for an altitude of 75 feet; whereas the average increment deduced from the Paris observations, and for a greater difference of altitude, amounted only to 11. Mr. Howard's observations, indeed, were too limited in this respect to afford a correct ratio; and it may be remarked respecting his comparison of the average Rain for each month, that while those deduced from the Royal Society's gauge for the period between 1797 and 1806, were confined to a constant altitude of 75 feet, those of his own from 1807 to 1816, were many of them 43 feet above the ground and uncorrected, and the rest on a common level with it. In addition to this, it is hardly proper to compare together observations made in different localities, unless they possess some principle in common, in the present case, either elevation or time. Mr. Howard has, however, constructed a Table of monthly amounts of Rain, corrected for the surface of the ground, in which the rate of allowance is made to increase from 0.05 of an inch in July, to 0.50 in January, and decreasing again through the remaining months in like proportion; the rate of gradation being 0.10 in Spring and Autumn, and 0.05 in Summer and Winter. He remarks, "that the deficiency in the Rain collected at the higher level, from whatever cause or causes proceeding, is very small in the midst of Summer, and increases as we recede in either direction towards Winter. In the former season, the showers fall mostly from elevated clouds, and the lower atmosphere is generally clear of that misty precipitation, which, in the Winter months, must contribute something considerable towards the product at the ground." Mr. Dalton found that a gauge fifty yards high, afforded in Summer two-thirds, and in Winter one-half as much as a gauge on the level of the ground.

Mr. Dalton's relation of t gauges f different seasons.

Mode of correcting rain-gau for differ heights a desiden tum.

(563.) A method, therefore, by which the results of a rain-gauge fixed at a given elevation, can be reduced to what they would have been, had the gauge been entirely on a level with the ground, is still a desideratum. It must, with very few exceptions, be at all times an increment, but one of a most variable kind, subject to great aberrations in the same locality, and differing also with different localities. The Paris observations are the only ones yet known to us where the observations are registered on a systematic plan; and we may hope to receive from the hands of their distinguished observer, when time shall have enabled him to extend them, the element we so much desire, at least for the locality of Paris. In the mean time we may remark, with what very great caution the results of Rain published in our different Journals ought to be received.

This phe menon of Rain the reverse of that of e poration different heights.

(564.) The phenomenon discovered by Dr. Heberden is, therefore, entirely the reverse of the principle which guides evaporation at different heights. The results of the latter are increased by elevating the surface producing the vapour, but the amount of Rain is almost universally diminished.

Rain not precipita with uni formity

In some gions co fined to p ticular p riods.

In other distribut over a w year.

Example Bombay Opposite periods Malabar and Cor mandel coasts.

Less Ra in first than las months the year.

(565.) The amount of Rain in any parallel, although presenting an average result for some definite period, as a year, is nevertheless not precipitated with uniformity during that time. In some regions the Rains are confined to particular periods, descending almost incessantly with very great violence; whilst in others, they may be said to be distributed over the whole year, exhibiting, however, in its two general divisions of the first and last six months, some considerable excess in the latter. The great amount of Rain that falls at Bombay, descends in June, July, August, September, and October, very little appearing in the other months; whereas on the opposite, or Coromandel coast, such are the peculiar effects of the mountain chain of the Ghauts, the wet and dry seasons occur at opposite periods of the year. Thus the seasons of excessive condensation, and those distinguished for serene and cloudless weather, succeed alternately on either side of the great peninsula of India. But if we advance into the more temperate regions of the Earth, we shall arrive at a different arrangement of things. In every place we shall find Rain precipitated during each month of the year, and at a great many an excess of quantity in the last six months of the year. This last truth may be confirmed by referring to the following Table, the mean of the whole giving a relation of 10 to 14. We perceive even from Liverpool and Lancaster, that the results for the first six months being denoted by 10, those for the remaining months require the proportional number 16.

TABLE CXXIII.

Mean Results of the Quantities of Rain falling the first and last Six Months of the Year at different Places.

Name of Place.	Number of Years' Observations.	Rain first Six Months of the Year in inches.	Rain last Six Months of the Year in inches.	Ratio of the Results for the Two Periods.
Manchester	33	14.383	21.757	10 to 15
Liverpool .	18	13.040	21.081	10 to 16
Chatsworth	16	11.652	16.012	10 to 14
Lancaster .	20	15.361	24.353	10 to 16
Kendal . . .	25	22.764	31.180	10 to 14
Dumfries. .	16	15.655	21.264	10 to 14
Glasgow . .	17	8.483	12.848	10 to 15
London . . .	40	8.539	12.147	10 to 14
Paris	15	8.845	11.031	10 to 12
Viviers . . .	40	15.223	20.989	10 to 14
Mean of all Places.		13.245	19.068	10 to 14

Mr. Dalton's explanation of it.

(566.) With his usual ingenuity, Mr. Dalton has endeavoured to account for the excess in question. In the month of January, he says, the vapour actually contained in the air, amounts to about three inches of water, whereas, in July, it is seven inches; the atmosphere containing thus in the latter month, four inches of water more than in the former. Hence supposing the mixture of the aerial currents in both the intervening periods to be the same, the rain ought to be four inches less in the former part of the year than in the latter, producing a difference of eight inches in the whole, and which for Manchester, the residence of that distinguished man, deviates not very widely from the truth.

Amounts for rainy months at Bombay.

(567.) Of the quantities falling during the successive months, the results are necessarily very variable. The means of twelve years' observations for Bombay afford the following results:

June	24.00 inches
July.	23.95
August.	18.87
September	14.06
October	1.26

the greatest being found in June and July, and declining to a very small amount in October. But in the temperate regions, the precipitations will not only be found much diminished in amount, but their arrangement very different also. A few results are thrown into the next Table.

Rain for different months in temperate Regions.

TABLE CXXIV.

Months.	Dalton's Results for Manchester. Mean of 25 Years in inches.	Howard's Results for London. Mean from 1797 to 1806, in inches.*	Howard's Results for London. Mean from 1807 to 1816, in inches.*	Howard's Results for London. Mean from 1797 to 1816, in inches.*	Mr. Daniell's Results for London. Mean of 3 Years, in inches.	Mr. Giddy's Results for Penzance. Mean of 7 Years, in inches.	Mr. Adie's Results for Edinburgh. Mean of 7 Years in inches.
January . . .	2.258	2.011	1.907	1.959	1.483	3.832	1.59
February . .	2.507	1.320	1.643	1.482	0.746	3.257	1.40
March	2.112	1.057	1.542	1.299	1.440	3.876	1.60
April	1.915	1.666	1.719	1.692	1.786	1.819	2.04
May.	2.698	1.608	2.036	1.822	1.858	3.064	1.71
June	2.206	1.876	1.964	1.920	1.830	2.145	1.62
July.	3.400	2.683	2.592	2.637	2.516	2.963	3.13
August. . . .	3.307	2.117	2.134	2.125	1.453	3.496	3.86
September .	2.984	2.199	1.644	1.921	2.193	3.437	2.05
October . . .	3.734	2.173	2.872	2.522	2.073	5.614	2.40
November .	3.378	3.360	2.637	2.998	2.400	5.186	2.80
December. .	3.369	2.365	2.489	2.427	2.426	6.011	2.22

Their maximum and minimum results.

From this Table it appears that the maximum result of Rain occurs at Manchester in July; in London, according to Howard's first and third means, in November, but in his second mean, in October. Mr. Daniell finds, however, the maximum in July for the metropolis. At Penzance, the greatest result, according to Mr. Giddy, is in December; and at Edinburgh, by Adie, in August. Of the minimum results, April belongs to Manchester and Penzance; March for all the three periods of Howard; and February for both Daniell and Adie.

Propriety of reducing months to uniform lengths.

(568.) A rigid comparison of the months can only however be made by reducing them to uniform lengths. M. Flaugergues has done this with respect to his long-continued observations at Viviers, by regarding the months as equal to 30 days 10.5 hours, and from which he has deduced the following results, the mean annual quantity of Rain being taken as unity.

Proportional results, the annual Rain being supposed unity.

TABLE CXXV.

Months.	Proportional Results.	Months.	Proportional Results.
January . . .	0.0716	July.	0.0544
February . .	0.0541	August. . . .	0.0679
March	0.0557	September .	0.1236
April	0.0802	October . . .	0.1370
May.	0.0847	November .	0.1250
June	0.0765	December .	0.0693

The maximum amount here belongs to October, and the minimum to February. The month of May, the author of the Table remarks, comes nearest the mean result of forty years for the Rain. In projecting the results graphically, M. Flaugergues observed that the

---

* These results were corrected by Howard for the elevation according to the method before explained.

Rain curve had two minima and two maxima, the former corresponding to February and July, and the latter to May and October. It is worthy of remark also how closely the minima approach to each other, and moreover that they belong nearly to the coldest and hottest seasons of the year. The maxima seem somewhat to accord with the mean temperature of the year. By comparing different places, this active observer imagines that the first maximum is the greatest in Countries situated near to the Ocean, and the second in those regions near the basin of the Mediterranean.

Proportional results for the quarters of the year.

(569.) The results deduced by the same observer for the four quarters of the year, taking December, January, and February for Winter, and the remaining months in classes of three for the other seasons, still denoting the whole amount of Rain by unity, are the following:

Winter	0.1937 inches.
Spring	0.2217
Summer	0.2001
Autumn	0.3845

Mr. Howard's absolute results for a like arrangement of the seasons are,

Winter	5.868 inches.
Spring	4.813
Summer	6.682
Autumn	7.441

Comparison of Rain by day and by night.

(570.) On the comparative quantities of Rain falling by day and by night, Howard has remarked that of 45 inches of rain which fell in the space of thirty-one lunar revolutions, a portion of it, amounting to 21.94 inches, had been separated for the day and the night, the former amounting to 8.67 inches, and the latter to 13.27. According to this experiment the rain by day amounts to about two-thirds of that by night, but such a ratio cannot be general. Mr. Daniell has also remarked that a greater amount of Rain falls while the Sun is below, than while it is above the horizon.

Number of rainy days. Least at the Equator. Increase with the latitude.

(571.) The number of rainy days is the least at the Equator, and increases in proportion to the distance from it. According to Cotte, the mean number of rainy days is 78 between the parallels of 12° and 43° North latitude; and that

From 43° to 46° the mean number is	103
46° to 50°	134
50° to 60°	161

Howard's results for rainy days of the months.

(572.) For our own climate, Mr. Howard remarks, that on an average of years, it rains nearly every other day, more or less, and that the proportional number of days on which it rained in the different months are as follows:

TABLE CXXVI.

Months.	Days.	Months.	Days.
January ..	14.4	July	16.1
February ..	15.8	August	16.3
March	12.7	September .	12.3
April	14.0	October ...	16.2
May	15.8	November .	15.0
June	11.8	December .	17.7

Number of rainy days in the year at Viviers increases.

(573.) The mean of forty years' observation at Viviers, gives 98 rainy days in the year; but by dividing this long period into four decades as follows, it is found that the number of rainy days sensibly increases.

Decades.	Rainy Days.
1778—1787	830
1788—1797	947
1798—1807	1062
1808—1817	1082

Remarks on rainy days at same place.

The Tables from which these results have been obtained, inform us also, that the sum of the rainy days of Winter and Spring at this place, is nearly equal to those of Summer and Autumn; and moreover that the number of rainy days during Autumn and Winter, is to the number of rainy days during Summer and Spring, as nine to seven. By projecting also the monthly results for the days of Rain, the resulting curve was found to have two minima and two maxima; the first minimum belonging to February, the first maximum to April, the second minimum to August, and the second maximum to December. An additional remark of Mr. Flaugergues is also worth recording, that during the forty years of observation, the days of the year on which it has rained the oftenest are October 31st, on which it rained twenty-three times, and Nov. 4th twenty-one times.

Mr.Giddy results for rainy day &c. for Penzance

Mr. Giddy's observations for Penzance contain, however, the most minute information on this subject, and which we have therefore thrown into the next Table. We ardently hope that he may continue them.

TABLE CXXVII.

(574.) Mr. Howard remarks that about one year in five may be said to be subject to a dry extreme, and one in ten to a wet.

Relation of particular winds and rain. Howard's results, for London.

(575.) There is a connection of some kind between particular winds and the amount of Rain in most localities. Some winds are proverbially wet, and others distinguished as dry. According to Mr. Howard, a wind between North and East, in London, is connected with our driest season, about the vernal equinox; and a wind between South and West, with the wet season following the autumnal. The following are his results for ten years.

TABLE CXXVIII.

Years.	N.—E.	E.—S.	S.—W.	W.—N.	Var.	Annual Amount of Rain in inches corrected for the Altitude.
	Days.	Days.	Days.	Days.	Days.

Means..	74	54	105	100	32	25.18

Remarks on them.

This Table presents some relations between the winds and the annual amounts of Rain. In the driest year of the whole, observes Mr. Howard, *viz.* 1807, the class N.—E. is nearly double the class of E.—S.; and in 1815, the next distinguished for its dryness, a similar relation prevails. In 1808, which is the next in the order of humidity, the former is rather more than double the latter.

In 1816, on the contrary, being the wettest year, the class of E.—S. winds exceeds those of N.—E.; in 1814, it has two-thirds the amount of the latter; in 1812, three-fourths; and in 1810, the remaining wet year, the amount approaches to within a ninth of the N.—E. And with regard to the Westerly winds, the class W.—N. falls off gradually during the three years following 1807, while the annual Rain augments from year to year; and in four of the remaining years, its number is above the average in the dry years, and below it in the wet ones.

Mr. Giddy's results for Penzance.

(576.) Penzance is a place remarkable for the diversity of its individual results, as regards the relations of the winds to Rain, and its peculiar locality would seem to account for it. The County of Cornwall diminishing from the line of its junction with Devon, leaves, at last, Penzance in a locality which may be almost said to be surrounded by the sea. On the South, the deep indentation of Mount's Bay carries into it, without any opposition, all the humidity that the long expanse of water which stretches from its shores can afford; and on the other points, the land can produce but little effect in diminishing the humidity of the air. The atmosphere, however, which rolls from the Western Atlantic on the bold promontory of the Land's End, must necessarily be higher charged with moisture, than that which, coming from the Continent of Europe, may have its humidity in some degree increased by the waters of the English Channel. Accordingly we shall find, by omitting the very rare cases appertaining to the Northerly and Southerly winds in the next Table, that the Rain belonging to the winds of a decidedly Westerly character, exceeds that of the Easterly winds, in a ratio of nearly three to one; the amount of rain for the former winds during the seven years' observations being 216.6 inches and the latter 77.4 inches.

Comparison of Easterly and Westerly winds.

M. Binder's results for Giengen.

(577.) In the next Table we have the results observed by M. Binder, at Giengen in Wirtemberg, during six years, the numbers indicating the cubic inches of Rain falling during each year, on a square Paris foot, under the influence of the winds indicated.

TABLE CXXX.

Winds.	1823.	1824.	1825.	1826.	1827.	1828.	Amount of the six years.	Proportion for 1000 cubic inches.
N.	60	344	118	53	141	46	762	33.3
N.E.	164	196	119	145	249	47	920	40.2
E.	97	172	52	13	68	70	472	20.7
S.E.	0	15	47	78	62	29	232	10.1
S.	235	230	146	131	226	87	1055	46.1
S.W.	697	1171	885	386	1275	892	5300	231.7
W.	2058	2310	1215	1349	2109	1848	10888	476.0
N.W.	319	778	375	541	924	307	3244	141.8

The Westerly wind presents here the maximum of Rain for the six years, and the next in amount to it is the South-West. The least amounts of Rain are those of the South-East and East winds. The mean direction of the winds producing the greatest quantity of Rain, will thus be for Giengen 85° 23′, or a Westerly wind having a deviation of 4° 37′ towards the South-West.

On the extent of Rain.

(578.) It would be an interesting inquiry could we determine the extent of Rain at a given time. Every shower must have its boundaries with respect to the surface which it covers, but there seems no method by which we can discover them. The dimensions of our Island are but small, and doubtless there are times when the Rain covers a much larger space. Mr. Howard has recorded the remark that the Rain of the 4th of October, 1813, having put a period to a fair season of some weeks' continuance, he availed himself of a journey made immediately after, to endeavour to ascertain how far it had extended. During that day, he says, it rained incessantly the whole distance from London to York, as likewise further North quite to the Tyne, and across the Island from Cheshire to Northumberland. It having been, he adds, a very wet day on the South coast, there can be no doubt that the whole of England, at least, was on this occasion irrigated at once, by the introduction of a current from the Atlantic, which mingling with the South-Easterly breeze that before prevailed, produced the great deposition of water which then took place.

Howard's remarks.

Limits of showers.

(579.) The observer may, however, sometimes clearly trace the limits of showers. Mr. Howard mentions that in travelling at different times between London and Folkstone, in the month of July 1812, the showers seemed to avoid in great measure the high chalky tracts, and to follow the course of the rivers and moist valleys. Sometimes, he says, the reverse distribution takes place. In his remarks on the great drought which prevailed for some time in England in August and September 1815, he observes that for three weeks of the time it rained almost every day in Wales. So also in 1816, while the middle of Europe was suffering from excessive wet,—all the country from the sources of the Rhine among the Alps, to its embouchure in the German Ocean, and through a space three times as broad from East to West, being submerged in water, dikes being broken, bridges blown up, the crops spoiled or carried off by torrents, and the vintage ruined by the want of the sun to bring out and ripen the fruit; the North for a time, and to a certain extent, was parched with drought; and public prayers appear to have been ordered about the same time at Dantzig and Riga for Rain, and at Paris for sunshine.

During great drought in England, it rained for three weeks in Wales

Opposite states of North and South of Europe in the same respect.

Excessive Rains.

(580.) There are many instances on record of excessive rains for the parallels on which they fall. This happens two ways, either by a general augmentation of the Rain for the month or year, or by great precipitations in a shorter time. Thus, in the latter half of June and the former half of July 1810, Mr. Howard mentions the amount of Rain to be 5.13 inches, whereas the general average for the time could hardly have exceeded 2.3 inches; and many other examples are recorded in his Meteorological Tables. At Kendal, in 1782, there fell 83.5 inches of Rain, the average result being 54 inches. And with respect to sudden precipitations of Rain, Howard has an instance of 0.89 inches falling between four and half past seven A. M. on the 8th of August. On the 8th of May also, an inch and a half fell in twelve hours. At Perth, on the 3d of August, 1829, four-fifths of an inch descended in half an hour. But the most extraordinary examples are those which occurred on the Continent of Europe in 1827, and recorded in the XXXVIth volume of the *Annales de Chimie*. Arago remarks of them, that the annals of Meteorology offer nothing so remarkable, either in France or in any other Country, not excepting the Equatorial regions. On the 20th of May there fell at Geneva in the short interval of three hours, 6.4 inches of water. At Montpellier there descended in five days, from the 23d to the 27th of September inclusive, 16.7 inches of Rain; and at the Chemical Manufactory of M. Bérard, near the same city, the amount of precipitation in forty-eight hours, from the 24th to the 26th of the month last quoted, the rain was 12.6 inches. Again at Joyeuse, in the Department of Ardêche, according to the register of M. Tardy de la Brossy, the maximum of Rain in a single day in the course of twenty-three years, was found on the 9th of August, 1807, and amounted to what then appeared the enormous quantity of 9.868 inches; but on the 9th of October, 1827, in the space of twenty-two hours only, there descended at the same place 31.173 inches of Rain. We record the original words of Arago for the entire satisfaction of our readers.

Examples for months of a year.

For short periods.

Prodigious falls on the Continent in 1827, exceeding even the Tropical Rains.

Le 9 *Octobre*, 1827, *dans l'intervalle de vingt-deux heures, il est tombé, dans la même ville de Joyeuse*, 29 *pouces* 3 *lignes d'eau:* (vingt-neuf pouces trois lignes:) *j'écris*, continues that distinguished man, *le résultat en toutes lettres afin qu'on ne croie pas à une faute d'impression.*

In eleven days of the same month of October, there likewise descended at the same place 38.37 inches of Rain, a quantity double of that which usually falls in Paris in a year. At Bombay it was noticed as a remarkable occurrence in 1826, that 32 inches of Rain fell in the twelve first days of the rainy season; whereas this quantity but little exceeds that which fell at Joyeuse in a single day. The maximum results of Rain in twenty-four hours on the coast of Malabar for several years, together with the commencement of the Monsoons, are given in the next Table.

Maximum results of Rain in twenty-four hours, during Monsoons on Malabar coast.

TABLE CXXXI.

Years.	Maximum Quantities of Water in 24 hours, in inches.	Commencement of the Monsoons.
1810	4.80	May 20th.
1811	4.50	May 31st.
1812	4.85	May 31st.
1813	4.60	May 27th.
1814	3.90	June 15th.
1815	5.40	May 27th.
1816	3.75	June 18th.
1817	4.55	May 26th.
1818	6.63	June 5th.
1819	7.60	May 9th.
1820	5.38	May 26th.
1821	4.66	June 16th.
1822	4.89	June 2d.
1823	6.46	June 6th.

The discordance between the greatest of these results and that for Joyeuse is most remarkable. Captain Roussin relates that 151 inches of Rain fell at Cayenne in the month of February.

Diversities of Rain in localities not far from each other. Examples.

(581.) It may be proper also to advert to the phenomenon of the diversity of Rain in localities not far distant from each other. In the district of Doombera in Ceylon, one side of a lofty mountain ridge is covered with clouds and mists, and drenched with Rains, at a time when the other is parched with drought, and scorched by an unclouded sun. The little town of Cumanacoa, also, is about 100 toises above the level of the sea, and seven leagues from the port of Cumana. At the latter place it seldom or never rains, while at the former there is a regular rainy season of seven months' duration. Rain again falls but seldom on the Western shores of any of the Sandwich Islands, though showers are frequent on the Eastern or windward sides, and on the mountains they occur almost daily. Between Bombay and the Southern part of the Malabar coast, places not five hundred miles from each other, very great differences are found to prevail, both in individual years and in the amounts of the annual means. In the following Table we have recorded a few results of each.

Great differences for Bombay and Southern part of Malabar coast.

TABLE CXXXII.

Years.	Amount of Rain at Bombay in inches.	Amount of Rain on the Coast of Malabar in inches.
1817	103.79	136.70
1818	81.14	169.19
1819	77.10	135.47
1820	77.34	147.18
1821	82.99	98.44
1822	112.61	145.60
1813	61.70	121.67
Means	85.24	136.32

Here the average annual amount of Rain differs sixty per cent. within so small a Geographical interval; and in two of the years, *viz.* 1818 and 1823, it is even doubled, and in the other years the differences are enormously large.

Inquiry respecting Paris and Versailles.

There is a popular belief also that it rains in Versailles much more considerably than it does at Paris, although the two places are so near each other. Arago, however, with his usual caution, remarks, that before we endeavour to explain why such a difference exists, it would be first proper to inquire if it really exists at all. He gives us the results of two years' observations for each place, and although it would seem to be completely verified in the first, yet it is directly contradicted in the second. More observations therefore are necessary to decide the question. This is an example also to prove the necessity of inquiring into all Meteorological conclusions which have no other foundation than popular belief.

Years.	Rain at Paris in centimetres.	Rain at Versailles in centimetres.
1825	51.93	57.65
1826	47.21	46.15.

Rain constant at Paris, but increasing at Viviers, although many forests have been cut down.

(582.) It is a curious phenomenon, and worthy the attention of the active Meteorologist, that while the quantity of Rain seems constant in some localities, it appears not to be so in others. At Paris, Arago observes that it has not varied in any sensible degree for 130 years. M. Flaugergues found however on the contrary that the Rain has augmented at Viviers, although since his observations, commenced in 1778, most of the forests which covered the Department of Ardêche have been destroyed. The following are his results.

TABLE CXXXIII.

Decades of Years.	Quantity of Rain fallen during each Decade in French Measure.			Mean annual Quantity of Rain in French Measure.	
	Feet.	in.	lines.	In.	lines.
1778—1787	25	11	2	31	1 10/30
1788—1797	27	8	2 2/3	33	2 20/30
1798—1807	28	5	11 2/3	34	2 11/30
1808—1817	31	1	11 2/3	37	4 23/30

Increasing also at Milan.

(583.) It appears also from observations made at Milan, that the Rain has been constantly augmenting there, from 1764, to the epoch at which the calculations were published by Carlini in the *Ephémérides de Milan* for 1816, or as given in the succeeding Table.

TABLE CXXXIV.

Period.	Mean Amount of Rain.	
	In.	lines.
From 1764 to 1781	32	11
1773 to 1790	32	17
1782 to 1799	34	11
1791 to 1808	35	18
1800 to 1814	38	9

The same conclusion is confirmed by M. de Césaris, whose results are as follows:

Mean quantity of Rain from 1764 to 1790 = 91 centimetres :
Mean quantity of Rain from 1791 to 1817 = 101 centimetres :

Confirmed by M. de Césaris.

His cause for it.

Arago's doubts.

Wide aberrations.

and which he accounts for by the numberless channels from year to year formed, for the purposes of irrigation, in the plains of Lombardy. Arago, however, without denying the cause assigned by the Milanese Astronomer for the increase, thinks it may be necessary to inquire if a period of twenty-seven years is sufficient to afford a general result,* in order to be freed from the effects of accidental variations; and he grounds his opinion on the great discordances existing among the individual results from which the means were deduced. In the first period above adverted to, the mean annual amount of Rain varied from 26 French inches to 47.5 of the same measure; and in the last interval also of twenty-seven years, the annual extremes presented the wide divergence of 24.7 and 58.9 inches of the same scale.

More attention due to this subject.

Effects of woods.

Progressive.

Rain decreasing at Marseilles.

(584.) The whole of the phenomena, however, connected with this branch of our subject, merit a more extended examination; and some attention is due to the fact before adverted to, respecting the destruction of woods. M. Moreau de Jonnes, author of a Prize Essay, proposed by the Philosophical Society of Brussels, on the alterations produced in the physical state of Countries by the destruction of forests, asserts that a progressive diminution of Rain has taken place in the South of France, in consequence of the destruction of mountain woods; and the remark seems confirmed by the following results for Marseilles.

TABLE CXXXV.

Period.	Mean Quantity of Rain in centimetres.	Mean Number of Days of Rain.
From 1772 to 1782	59	57
1795 to 1805	53	54
1806 to 1815	38	55
1815 to 1820	37	—

Arago however regards the different results between Viviers and Marseilles as accidental.

Arago, however, observes, on comparing the Tables of Viviers and Marseilles together, the distance of these places not being very great from each other, that the differences they present ought to be regarded as accidental.

Intensity of diurnal Rain at Viviers not constant.

Intensity in Decades.

(585.) It is a curious remark of Flaugergues, that the intensity of the diurnal Rain is not constant. If we divide, says he, the total quantity of Rain which fell during the forty years' observations, *viz.* 16,312 lines by 3921, the number of rainy days during that time, we shall obtain 4.16 lines, for the mean amount of Rain falling in a day. And if, in a similar manner, we divide the quantities of Rain that fell during each decade, by the number of rainy days in that decade, we shall obtain the mean quantity of Rain which fell during a day in the several intervals assumed. The results are contained in

TABLE CXXXVI.

Decades of Years.	Intensity of the Diurnal Rain in lines.
17[illegible]8—1787	4.499
1788—1797	4.210
1798—1807	3.864
1808—1817	4.148

Here the intensity of the diurnal Rain has diminished during the first three decades, but augmented in the last.

Mean intensity of diurnal Rain.

(586.) In like manner, by dividing the quantities of Rain which fell each successive month by the number of rainy days corresponding to that month, he obtained the mean intensity of diurnal Rain during each successive month, as in

TABLE CXXXVII.

Months.	Intensity of Rain in lines.	Months.	Intensity of Rain in lines.
January....	3.447	July......	3.946
February..	2.912	August....	5.690
March	2.938	September .	6.647
April	3.551	October ...	5.481
May......	4.199	November .	4.641
June......	4.059	December..	2.869

A maxi mum in Septem

Thus the intensity of Rain seems to be the greatest in September, or during that month the greatest quantity of Rain falls in the shortest time. It is during this month, or in October, that the great inundations of the torrent of Escoutay take place.

In Sum a heav shower causes duction temper ture.

In Wi it caus an ele tion.

(587.) In Summer it is generally observed, that a heavy shower of Rain causes a reduction of temperature; but in Winter an increase is found to follow its descent. In the former season the Earth is necessarily heated, and the precipitated vapour coming from a colder region of the sky above it, a portion of the caloric at the surface must pass into the water that has descended, and thus occasion a reduction of sensible heat. Added to this, evaporation must sometimes take place, and thus add to the decrease of temperature. In Winter, on the contrary, so soon as the condensation takes place, the caloric disengaged has a sensible effect on the low temperature of the surface, and produces that augmentation of the sensible heat which is commonly perceived.

Air tr parent fore a of Ra

(588.) Previous to a fall of Rain, the transparency of the air is very great. M. De Luc has investigated this subject in a Paper read before the Helvetic Society of Natural Sciences in July 1825. Rain is sometimes found positively and at other times negatively electrified, and sometimes non-electric.

Relat Rain phase the M

(589.) Meteorologists have likewise connected the phenomena of Rain with the different phases of the Moon, and there is perhaps no remark more common, than that changes from wet to dry, and from dry to wet, generally occur during its changes. Mr. Howard has

---

* Twenty-seven years may seem, to the ordinary inquirer, a term sufficiently long to determine an average result. But Arago looks at things widely, and with the comprehensive view of a Philosopher. Where uniform causes prevail, short intervals will enable us to determine a mean; but where the aberrations are great, and they are spread over a long interval of time, a longer period becomes necessary. The future progress of Meteorology may enable us to contemplate this subject of the mean with more accuracy and generality.

Meteorology.

traced this with some success, but it still demands a more extended inquiry. According to him, when the Moon has great South declination, there falls but a moderate quantity of Rain with us; and that while she is crossing the Equator towards these latitudes, our Rain increases. The greatest depth of Rain falls with us in the week in which she has the greatest North declination; and during her return to the South, the Rain becomes reduced to its minimum state. And this holds good in very nearly the same proportions, both in extremely wet and dry seasons.

Relation of Rain to the Moon's declination.

Relation between phases of Moon and number of rainy days.

(590.) There exists also, according to M. Flaugergues, a constant relation between the phases of the Moon and the number of rainy days. From observations made by him, during a period of nineteen years, he obtained the following results.

Table CXXXVIII.

	Phases of the Moon.					
	New Moon.	First Quarter.	Full Moon.	Last Quarter.	Moon in Perigee.	Moon in Apogee.
Number of rainy days coinciding with the days of the Moon's phases....	77	82	79	60	93	78

And he adds, that the number of rainy days which coincide with the days of the Moon's phases, and of the perigee and apogee, follow the same progress as the mean heights of the barometer corresponding to these phases, but in an inverse order. Thus the number of days at new Moon on which it rained, is less than the number on which it rained at full Moon; and the mean height of the barometer on the day of the Moon's conjunction, is, on the contrary, greater than on the day of her opposition. In like manner, the number of rainy days belonging to the first quarter much exceed those of the last quarter, and so conversely the mean height of the barometer is much less in the first quarter than in the last. And lastly, the number of rainy days coinciding with the days on which the Moon was in perigee, is much greater than the days corresponding to her apogee; and so on the contrary, the mean height of the barometer at the former season, is much less than at the latter.

The diminution of the atmospheric pressure, caused by the attraction of the Moon, must be regarded as among the causes that determine the fall of Rain.

(591.) The following Table contains the results of Rain for different places, arranged according to their progressive numerical amount.

Table CXXXIX.*

Names of Places.	Number of Years.	Annual Amount of Rain.
Uleaborg	?	13.5
Petersburgh	?	16.0
Upsal	?	16.7
Mean rain for lat. 60° (Humboldt)		17.0
West Bridgford	?	17.0
Wittenberg	?	17.0
Petersburgh, another result	?	17.2
Lund	?	18.5
Diss, Norfolk	?	18.7
Upminster	?	19.5
Paris	15	19.9
Carlisle	1	20.2
Berlin	?	20.6
London (Dalton)	40	20.7
Widdrington, North	1	21.2
Glasgow	17	21.3
Edinburgh	?	22.0
Dublin	?	22.2
London (Daniell)	3	22.2
South Lambeth	9	22.7
Mean of Toulon, Marseilles, Aix, Montpellier, Arles, Nismes, Cavaillon, and Avignon, between 43° and 44° North, at the level of the sea (Schow)		22.6
Near Oundle, Northampton	14	23.0
Lisle	?	24.0
Lyndon, Rutland	21	24.3
Rochelle	?	24.5
Edinburgh	3	24.5
Utrecht	?	24.7
Haarlem		24.7
Youngsbury, Hertfordshire	5	25.0
Kimbolton	?	25.0
Mean of Carlsruhe, Manheim, Stuttgard, Wurtsburg, Augsburg, and Regensburg (Schow)		25.1
London (Howard)	23	25.2
Norwich	13	25.5
Vallerie, five leagues N. E. of Rochelle	18	25.6
Rochelle, another result	17	25.8
Fyfield, Hampshire	7	25.9
Edinburgh (Adie) another result	7	26.4
Ferriby, Yorkshire	?	26.6
Chichester	?	26.8
Epping	7	27.0
Ulm	?	27.0
Algiers	?	27.0
Barrowby, Yorkshire	6	27.5
Strasburg	20	27.6
Chatsworth	16	27.7
Hague	?	28.4
Delft	?	28.6
Harderwyk	?	28.6
Mean rain for lat. 19° (Humboldt)		29.0
Bristol	3	29.2
Bridgewater	?	29.3
Gordon Castle	?	29.3
Abo	?	29.3
Puy, near the source of the Loire	?	29.5
Lombardo-Venetian plains, near the Apennines, a mean of eight places (Schow)		29.5
Leyden	?	30.2
Madeira	?	31.0
Minehead, Somerset	?	31.3
England, Dalton's mean, taking first a mean of the Counties		31.3

---

* The mark ? inserted so often in the above Table, merely denotes the number of years to be unknown, and not that the amounts of rain are *known* to be doubtful, although we cannot place entire confidence in more than a few results of the Table. It will be observed that the means which rest on the respectable authorities of Humboldt and Schow, have not those doubtful marks attached to them; but though the number of years from which they are derived be not known, a high degree of reliance may be placed in them. In one or two instances, the same place has different results assigned to it, the consequence, perhaps, of different localities, or of different modes of reducing the results. What a vast field of inquiry remains to be explored in this interesting branch of our subject, and what unwearied industry and precautions will be necessary to improve it!

TABLE CXXXIX. *continued.*

Names of Places.	Number of Years.	Annual Amount of Rain.
Venice	1	31.8
Mean of sixteen places in Great Britain (*Ency. Britt.*)		32.5
Zurich	?	33.1
Exeter	?	33.2
Liverpool	18	34.1
Mean fall of rain, from lat. 44° to 46°, *viz.* at Orange, Viviers, Lyons, Villefranche, Bourg, and Geneva, (Schow)		34.3
Padua	?	34.5
Cotte's mean of 147 places in Europe		34.7
Verona	1	35.0
Mean of 32 places in Great Britain, mostly rainy, (Dalton)		35.2
Sienna	?	35.2
Viviers	40	36.2
Venice, another result	?	36.1
Manchester	33	36.1
Dumfries	16	36.9
Isle of Man	6	37.0
Selbourne, Hampshire	?	37.2
Dover	5	37.5
Rome	?	39.0
Central plain of Lombardy, mean of seven places, (Schow)		39.0
Lyons	?	39.4
Lancaster	20	39.7
Mean result for Zurich, Bern, Lausanne, Peissenberg, and Tegernsee, (Schow)		40.0
Kirkmichael, Dumfries	?	40.3
Ludgvan	?	41.0
Dordrecht	?	41.0
Townley, Lancashire	15	41.5
Country to the West of the Lago di Guarda, (Schow)		42.1
Geneva	?	42.6

Garsdale, Westmoreland	3	52.3
Kendal	25	53.9
Fellfoot, Westmoreland	3	55.7
Kendal, another result, (Marshall)	9	56.2
Mean of twenty places in the lower valleys at the very bases of the Alps, (Schow)		58.5
Crawshawbooth, Lancashire	2	60.0
Country to the East of the Lago di Guarda, (Schow)		62.6
Great St. Bernard	?	63.1
Vera Cruz	?	63.8
Udina	1	64.7
Keswick	7	67.5
Mean rain for lat. 19° (Humboldt)		80.0
Calcutta	?	81.0
Bombay	12	82.0
Ceylon	1	84.3
Carfagnano in the Apennines	?	92.0
Equator, (Humboldt)	?	96.0
Adam's Peak, Ceylon	1	100.0
Tolmezzo	1	109.2
Cape Francois	?	120.0
Coast of Malabar	14	123.5
Granada	?	126.0
Leogane, St. Domingo	?	150.0

Snow.

Snow.

(592.) The precipitations of moisture so often resulting from the union of atmospheric volumes of unequal humidity and temperature, cannot, however, at all times descend in the form of Rain. The region of the air in which they take place is subject, like the surface of the Earth itself, to different vicissitudes of temperature; and in the season of Winter, when a diminished radiation causes the atmosphere frequently to sink below the freezing point of water, the particles of moisture must, in some stage or other of their descent, become frozen, and form flakes of Snow, having great diversities of density, and displaying innumerable varieties of the most beautiful forms, and at length reaching the ground in those states, when the temperature necessary for their first formation continues down to the ground.

Density of Snow not constant.

Experiments of M. Quetelet.

(593.) The density of Snow is far from being constant, and M. Quetelet has endeavoured to show that there is a relation between it and the form. By representing by unity the volume of water produced from the melting of a constant mass of Snow, he found the maximum of density to exist when the Snow remained on the ground in one uniform mass, its numerical value being $\frac{1}{2.5}$, at a temperature of 34°.5. The least condition of density varied between $\frac{1}{10}$ and $\frac{1}{12}$, the temperature ranging from 29°.7 to 18°.5, the forms of the Snow being very small stars. Unformed flakes had a density of about $\frac{1}{5.6}$ at a temperature of 33°.1; and fine Snow, having no determinate forms, was found with a density of $\frac{1}{4}$ and $\frac{1}{7.5}$, the temperature varying from 32° to 30°.2.

Beautiful forms of Snow.

(594.) Snow presents the most beautiful variety of forms, and when examined by the microscope is found to be composed of an immense number of separate and transparent crystals of ice. In the Polar regions, where a diminished temperature calls into the highest activity the crystalline power, their variety seems endless; and while a general character pervades the whole, the groupings produced by combination, disclose arrangements uniting at once the most perfect forms of regularity and beauty. Dr. Nettis of Middleburgh, in 1740, was the first to describe some that fell in the intensely cold Winter of that year. They were found to be hard, entire, and pellucid; and some particles received on a pencil, were placed on a plane glass plate, under the object glass of a fine microscope. Great care was taken that the smallest particles might not be dissolved, either by the breath or the warmth of the hand. In one day and night he found twenty or more particles differently formed; and on several other days he enjoyed opportunities of delineating eighty admirable figures of Snow, many of which we have given in the figures comprised from 1 to 29 of plate iii. The size of these varied from $\frac{1}{20}$th to $\frac{1}{3}$th of an inch. Figs. 30, 31, and 32, are examples of anomalous figures of Snow, and of which he observed an almost infinite variety.

Forms.

(595.) We owe, however, to Mr. Scoresby the most exact and accurate delineations of the forms of Snow, which he obtained during his successive Polar voyages. This indefatigable observer did not content himself with mere outline descriptions, but measured the magnitudes of the particles he examined, classified their different modifications, and noted the barometrical and thermometrical conditions of the air, as well as the general aspect of the weather during the time of observation. Mr. Scoresby's varieties are arranged under the five following forms:

Reduced to five general classes.

1. Lamellar.
2. A lamellar or spherical nucleus, with spinous ramifications in different places.
3. Fine spiculæ, or six-sided prisms.
4. Hexagonal pyramids.
5. Spiculæ, having one or both extremities affixed to the centre of a lamellar crystal.

(596.) Of the first of these divisions, the varieties were found to be very numerous, and abundantly formed at all temperatures sufficiently low to call into activity the crystallizing force. Their structure is highly delicate, and very thin and transparent. It may be divided into several distinct species.

(597.) *Stelliform*, having six points radiating from a common centre, with parallel, collateral ramifications in the same plane. This species is represented in fig. 33, and is the most general form met with. It varies in size from the smallest point to about one-third of an inch in diameter. It occurs in the greatest abundance when the temperature approaches the freezing point.

(598.) *Regular hexagon.* This occurs in moderate as well as at the lowest temperatures; but its structure becomes more delicate and thin, and its size is diminished, as the temperature itself is lowered. In some cases it assumes the form of transparent plates, as in fig. 34; whilst in others, figures of the most beautiful regularity are formed within the perimeter, by different white lines. The size of this species is from the smallest visible atom to about one-tenth of an inch in diameter. Some of these forms are delineated in figs. 35, 36, 37, 38, and 39.

(599.) *Aggregation of hexagons.* This beautiful species admits of endless variety, and is formed chiefly at low temperatures. A few are delineated in figs. 40, 41, 42, 43, 44, 45, 46, 47, and 48.

(600.) *Combinations of hexagons with radii or spines and projecting angles.* This species is by far the most numerous, and affords some of the most interesting specimens. Figs. 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, and 67, afford examples of it. The parallel lines in these figures, are not intended as shadings, but actually occurred in the crystals though with this difference, that the lines which appear black in the diagrams, were white in the originals. Figs. 68 and 69 afford examples of crystals having twelve spines, and seem like aberrations from the general law which governs crystallizations of this kind; but as Mr. Scoresby justly observes, they may rather be regarded as accidental varieties, produced probably by the correct application of two similar crystals upon each other.

(601.) Of the second general division, it would be difficult to convey an exact representation by means of a figure. It seems, however, to consist of two or three species, the fundamental figure of which is either of the species before described, and from the lateral and terminal planes of which arise small spines, similar to the collateral ramifications of fig. 53. These spines spring from one or both of the lateral planes or principal surfaces, or from both lateral and terminal planes, maintaining a constant angle of 60° with the plane from which they rise. The diameter of the crystal sometimes exceeds the fourth of an inch, and Mr. Scoresby found it most frequently to form at a temperature of 20° or 25°. In some cases, a spherical nucleus is to be traced, from which spring radii in all directions. In the former, the central figure is transparent, but in the latter consists of a small, rough, white concretion, its diameter seldom reaching a quarter of an inch. The spines or radii are similar in both. This latter species is formed at about the freezing point, and sometimes in temperatures rather lower.

(602.) The third class contains examples of very delicate and crystalline forms, and also of forms quite white and rough. The finest specimens resemble white hair, cut into lengths, not exceeding a quarter of an inch, but so small and clear as not easily to admit of an exact determination of their figure. Another variety, occasionally the third of an inch in length, exhibits a fibrous or prismatic structure. When the temperature is about 28 degrees, the finer specimens occur, and the coarser at about the degree of the freezing point. The latter are very common during fog showers, and appear to be composed of aggregations of the frozen particles of the fog, and to have their origin in the lower parts of the atmosphere.

Fourth class.

(603.) The fourth class seems to be very rare, Mr. Scoresby having observed it but on one occasion. It apparently consisted,—for in a delicate examination of this sort more than one instance is necessary,—of a triangular pyramid, but whether its base was triangular or hexagonal, similar to fig. 67, he could not determine. The pyramids were about the thirtieth of an inch in height, and fell with some other curious figures during a gale of wind from the North. They are represented in figs. 68 and 69.

Singular forms of the last class.

(604.) The last species was seen by Mr. Scoresby only twice. It resembles, he says, a pair of wheels, united by an axle-tree, the wheels consisting of hexagonal or other lamellar crystals, and the axle of a slender prism. Figs. 70 and 72 represent examples of this Snow crystal. Fig. 71 is another, having three laminæ, and two prisms about one-sixth of an inch long; and fig. 73 is an instance of one tabular crystal and a prism. This last and the two former varied from one-thirtieth to one-tenth of an inch in length. The temperature, when the very singular form of fig. 45 occurred, was in one instance 22°, and in the other 20°.

Remarks on magnitudes of illustrative figures.

(605.) The figures we have given to illustrate these curious and very interesting forms, Mr. Scoresby informs us are magnified from 30 to about 400 times. The fractional numbers succeeding each crystal, denote the diameter in parts of an inch. The largest crystal represented was one-third of an inch, and the smallest one-thirty-fifth.

The most perfect figures fall at low temperatures.

Remarks on the varieties of form.

(606.) The figures actually recorded here were all perfect specimens seen by Mr. Scoresby; but many instances occurred during his long investigation of the subject, of mutilated and irregular forms, some wanting two or three radii, and others having radii of different sizes and shapes. At low temperatures, however, the greatest proportion of crystals that fall are probably perfect Geometrical figures. The constant regard to equality, in the form and size of the six radii of the stellates, the minute accuracy of the different parts of the hexagons, the beauty and precision of the internal lines of the compound figures, with the proper arrangement of any attendant ramifications, together with the general completion of the regular figures belonging to such diversified forms, compose one of the most interesting among the many admirable examples with which Crystallography abounds.

Seldom met with in temperate regions.

Snow in Swisserland.

(607.) But these delicate and beautiful forms are principally confined to the Polar regions, and only in very rare instances are some of the less complicated crystals to be met with in the temperate climates of the Earth. In Swisserland, the descent of Snow in crystallized stellar pallets, with feathery filaments arranged along the rays, was regarded in January 1829 as an uncommon phenomenon. M. Huber-Burnand, who particularly watched its descent, gave to it the name of

Varieties.

Polar Snow, from its corresponding to the description given of such, and which name it retained. Five or six inches of it fell in three successive days, and was found to be extremely light, very dry, and without adhesiveness. Instead of presenting a swan like whiteness, it had more the silvery appearance of feathers of the colymbus, in consequence of the high polish of its crystalline facets. When dropped freely into a basin, measured, and then melted, it gave one-forty-fifth its volume of water. On some foggy days, another kind fell, which was called *Elementary Snow*, and was supposed to be formed near the Earth. Its form was that of fine powder, but without any regular crystallized form. The temperature ranged during these formations ten or fifteen degrees below the freezing point.

Experiment of Monge to illustrate the formation of Snow.

(608.) Monge the Geometrician has alluded* to the ordinary crystallization of sal ammoniac in delicate feathery crystals, as affording a beautiful illustration of the formation of Snow. If we fill, says he, a deep glass to which heat has been applied with a saturated solution of sal ammoniac in a warm state, and allow it to cool in a tranquil air, the surface of the Liquid will be covered with very minute crystals. These will sink as soon as they are formed, and descend slowly, on account of their Specific Gravity but little exceeding that of the Liquid. During their descent they will receive other aggregations, and at length reach the bottom of the vessel in large white flakes. The rapid progress of crystallization is entirely owing to the affinity of the particles. The first crystal which descends forms as it were a nucleus for all the other particles which have a tendency to unite to it. But no experiment can do adequate justice to the exact Geometry and delicate mechanism of Nature.

Natural Snow-balls of globular forms.

(609.) There are other crystalline forms of Snow, which however merit attention. Sometimes when a strong wind sweeps over a surface of Snow, portions of it are raised by its power, and passing on with the breeze under a diminished temperature, become crystallized, and by attrition assume globular forms. In some instances their size is so much increased by the continual accession of Snow, as at length entirely to resist the action of the wind, and to remain at rest. An example occurred to Mr. Howard, in January 1814, of several thousands of balls being formed under circumstances of this kind.

Seen by Howard.

By Sherriff, and formed by wind.

(610.) Mr. Sherriff records an instance of balls being found by him, in February 1830, in East Lothian, varying from a foot to a foot and a half in diameter, which had left hollow tracts in the Snow, ranging from East to West, the wind at the same time blowing from the latter quarter. In one village in particular, with a complete exposure to the West, they were exceedingly numerous, and not above a yard and a half from each other.

By Cleveland.

(611.) An example occurred to Professor Cleveland, so late in the year as 1st of April, in North America, of Snow-balls varying in size from one to fifteen inches diameter, the smaller being nearly spherical, and the larger somewhat spheroidal. The larger balls were formed by having been rolled through a considerable distance by the wind, their paths upon the Snow being in general distinctly visible. The smaller balls however, the Professor asserts, were decidedly formed in the atmosphere, as they occurred in woods and small enclosures. The texture of all these balls was homogeneous, being composed of minute prisms of Snow irregularly aggregated. Those observed by Mr. Sherriff were entirely destitute of crystalline forms. In some cases it is said that aggregations of Snow have occurred in decidedly cylindrical forms, hollow at each end to almost the centre; but the accounts that have been published of them do not seem satisfactory.

Smaller balls forme in atmosphere.

Cylindrica forms, hollow at eac end doubtful.

Peculiar character imparted t scenery by Snow.

(612.) After a copious fall of Snow, an attentive observer may find in the scenery, to which it imparts so peculiar a character, much to exercise and delight his mind. "The pensile drifts," says Mr. Howard, "resting on a narrow base, invite contemplation, at the time they may be regarded as just objects of fear." Sometimes when the Sun shines clearly, and the temperature is too low to permit any deposition of moisture, the level surface may be found sprinkled with small polished plates of ice, which refract the light in colours as brilliant and varied as those of dew. At such times, also, there are to be found on the borders of frozen pools, and on small bodies which happen to be fixed in the ice and project from the surface, groups of feathery crystals of a curious and delicate structure. From the moment almost that snow alights on the ground, it begins to undergo certain changes, which usually end in a more solid crystallization than it originally possessed. The peculiar adhesive quality of Snow at particular times, results from its needly crystalline texture, aided by a degree of attendant moisture, which afterwards freezes in the mass. Snow sometimes exhibits beautiful blue and pink shades at sunset.

Surface of Snow sprinkled with small polished plates of ice.

Snow changes soon as it reaches th ground.

Cause of adhesive quality of Snow.

Different colours o Snow.

(613.) Snow has been seen in the Polar regions of red, orange, and salmon colour. This occurs both on the fixed and floating ice, and appears in some cases to result from vegetable, and in others from animal matter, suspended in the sea, and deposited upon the ice around.

Luminou Snow storms.

(614.) Snow storms sometimes present a luminous appearance, and are then objects of great interest. One occurred in March 1818, to a party on Lochawe in Argyleshire, which imparted to the glassy surface of the lake, the boat, their clothes, and all the surrounding scenery, a luminous appearance, like a huge sheet of fire. Nor were the exposed parts of their bodies singular in this respect, for to the eye they all seemed to burn, although of course without any feeling of warmth. When they applied their hands to any of the melting Snow, the luminous substance adhered to them, as well as the moisture, and this property was retained by the Snow for twelve or fifteen minutes.

Thermo meter sc times ri during t descent Snow.

(615.) During the descent of Snow, the thermometer will sometimes gradually rise. Howard gives an example of an unusual fall at Plaistow, during which the thermometer at 10 A. M. stood at 19°, at 3 P. M. 22°, and at 9 P. M. 26°.

Compar tive des of Snov and Ra

(616.) All other things being the same, Professor Leslie supposes that a flake of Snow, taken as nine times more expanded than water, descends thrice as slow.

Actual mation Snow i huts of lar reg

(617.) In the Arctic regions, it has been observed by an able writer in the *Edinburgh Review*, that the wretched settlers, covered with a load of bear skins, remain crowded and immured in their huts, every chink of which they carefully stop against the piercing external cold. Soon, however, the whole of the inside becomes

---

* *Annales de Chimie*, vol. v. p. 1.

Observed also at Tornea by Maupertuis in a room.

At St. Petersburgh also in a crowded assembly.

lined with a thick crust of ice; but if they happen for an instant to open a window, the moisture of the confined air is immediately precipitated in the form of a shower of Snow. Maupertuis, who was engaged in the great operation of measuring a degree of the meridian within the Arctic Circle, also remarks, that at Tornea, upon the opening of a door, the external air immediately converts the warm vapour of the chamber into Snow, *de gros tourbillons blancs.* Robison, the celebrated Natural Philosopher of Edinburgh, likewise remarked to Hutton the Geologist, as a beautiful example illustrating the truth of his theory, that in a crowded assembly at Petersburgh, when the company were suffering from the closeness of the room, a gentleman broke a window for relief, and the air rushing in, formed a visible condensation of snowy matter, having a revolving motion.

Frequent falls of Snow in Arctic regions in months of April, May, and June.

(618.) In the Polar regions, where every thing connected with Snow is exhibited on the grandest scale, Mr. Scoresby informs us it snows nine days out of ten, in the months of April, May, and June. With Southerly winds near the borders of the ice, or where moist air blowing from the sea meets with a cold breeze from the ice, the heaviest falls of Snow occur. In this case, a depth of two or three inches sometimes descends in an hour. Such heavy falls, it is said, frequently precede sudden storms. There seems no data to assist us in approximating to the annual average amount of Snow for the latitudes in which it falls.

Electricity of Snow.

(619.) Snow has generally been found electrified, and according to the observations of Schübler, it is oftener positive than negative, in the ratio of four to one.

Hail.

Hail has not attracted so much attention in this Country as on the Continent.

(620.) The phenomenon of Hail does not appear to have attracted so much attention in our own Country as on the Continent, where it has been made the subject of several most interesting Memoirs; and even at the very moment this Essay is passing through the press, the Academy of Sciences at Paris has announced it as another Prize question, and with conditions also of the most general and rigorous kind. In Great Britain our attention has been more occupied with rain, and we have happily not to lament the desolations produced by those tremendous Hail storms, which from time immemorial have ravaged the beautiful Provinces of France. Some places, from frequent catastrophes of this kind, have obtained the designation of Hail Countries. England, on the contrary, may with more propriety be denominated a Rain Country.

Formation of Hail a great paradox in Meteorology.

(621.) There is undoubtedly much in the origin and formation of Hail to awaken curiosity. Volta indeed regarded the formation of small flakes of ice—the kernels of future Hail-stones, in the month of July, during the hottest hours of the day—as one of the greatest paradoxes in Meteorology; and though we cannot hope, in the brief limits to which we are confined, to trace all the phenomena connected with it to their source, or produce observations, as the conditions of the learned Academy require, made in the very region of Hail, we may nevertheless remark, that the theory of Hutton, as just applied to the phenomena of Rain and Snow, seems better adapted on the whole to account for the formation of Hail, than any of the other theories that have been proposed.

Theory of Hutton seems adequate to account for it.

Precipitated moisture influenced by temperature of medium through which it passes.

A low temperature capable of producing Hail.

(622.) We have before remarked that moisture may be precipitated from the mingling together of masses of air of unequal temperatures, and unequal degrees of humidity; but the state in which the precipitated moisture reaches the Earth, must depend on the temperature of the medium in which it is formed, and on that through which it has to pass. We have already seen how moisture precipitated in this way produces rain; and how, under the influence of a lower temperature, it comes to us in the form of snow; and it would seem reasonable to attribute to a further decrease of heat, the power of still further crystallizing the descending atoms, and thus to give to them the decided character of Hail. The only difficulty in the way of an entire reception of the theory is, the comparative scarcity of Hail showers in the Winter season, the lowness of the clouds from which Hail in general results, and the magnitude of the masses in which it occasionally reaches the ground.

Phenomena which seem to indicate a common origin for rain, snow, and Hail.

Hard snow-balls and flakes of snow at same time.

(623.) There are however certain phenomena which have been remarked respecting the descents of rain, snow, and Hail, which would seem to imply a common origin for each, differences of temperature alone seeming adequate to explain their different formations. Howard has observed more than one instance of a huge nimbus, affording hard snow-balls and distinct flakes of snow at the same time; and Hail and rain are by no means an uncommon result of the same cloud. The magnitude of a cloud may indeed be such, or clouds at different elevations may be supposed to exist, which in an upper region shall afford Hail, in a lower region snow, and in a still lower region rain, differences of temperature existing in the supposed range, fully adequate to the production of these different phenomena. The same is also confirmed,—such are the capricious conditions of temperature in the air,—by rain actually forming in an upper region of the sky, and, descending into a colder stratum of the atmosphere, becoming converted into decided globules of Hail. Howard has an example of this in what he denominates a freezing shower, on the 19th of January, 1809. It consisted of hollow spherules of ice, filled with water, of transparent globules of Hail, and of drops of water at the point of freezing, which became solid on coming into contact with the bodies they fell on. The same observer also records, that on the 19th of July, 1803, a kind of icicle descended from the clouds, which was succeeded by large Hail, and finally by rain.

Freezing shower.

Large Hail succeeded by rain.

Rain succeeded by Hail.

Hail succeeded by rain.

(624.) A fine example, illustrating the junction of clouds, and of the resulting phenomena of rain and Hail, was observed at Tarragona on the 15th of September, 1828. Some large clouds were seen to advance with a South-East wind, at 7 A. M., discharging torrents of rain. Another great mass of cloud, driven by a Westerly wind, met the former with the greatest violence, producing thunder. As soon as the rain had ceased, an immense abundance of Hail descended, at first very small, but sensibly increasing to a very great size. Another example also occurred in North America about noon, on the 4th of June, 1814. A dark cloud appeared in the South-West, exhibiting an electrical appearance, some light clouds moving at the same time from the North-East, and apparently meeting the former. The united masses, after their junction, seemed to rise, and at length to attain an extraordinary height, their appearance inducing Dr. Crookshank, the observer, to predict Hail, and which presently fell in masses from 13 to 15 inches in circumference. Copious rain succeeded their descent. Arago likewise remarks, that Hail generally precedes storms of rain, and sometimes accompanies them; why then cannot they have a common origin, difference of temperature only modifying their states?

Hail may be formed either by day or by night according to the theory of Hutton.

(625.) A strong argument in favour of this application of Hutton may also be derived from the circumstance, that Hail may be formed either by day or by night in every climate, although its descent is most frequent in the former season. The theory of Volta[*] required the absolute presence of the Sun to act on the clouds, and by producing evaporation from the vesicular vapours which compose them, to form Hail as a result; whereas we know that very great Hail storms have occurred during the absence of the Sun; and the theory of Von Buch, which is founded on the effects of ascending currents of air, is open to a like objection.

Theory of Volta.

Objection to it.

Changes of wind frequent in Hail storms.

(626.) Examples of change of wind, and of the action of opposite currents, so necessary for the production of rain, are also frequent during Hail storms. In one which occurred to Mr. Howard in May 1809, the wind was first East, then South, afterwards West, again East, and finally West. Beccaria also recognises the same principle. "While clouds," says he, "are agitated with the most rapid motions, rain generally falls in the greatest plenty; and if the agitation be very great, it generally hails."

(627.) The descent of Hail in some Countries,

---

[*] It may not be uninteresting to give a brief account of the theory of Volta in a note. That celebrated man grounded his theory of Hail on evaporation, and on the familiar electrical experiment known by the name of the *danse des pantins*, which consists of two metallic discs placed horizontally one above the other, the upper disc being suspended from the prime conductor of the machine, and the lower communicating with the ground, either immediately, or by the aid of a chain. A few pith balls placed on the lower disc, will, when the upper disc is electrified, shoot from the former to the latter surface, and back again; the oscillating motion being continued until the different electrical states of the two surfaces are at length equalized and rendered similar. Volta, in applying the results of this electrical toy to the great phenomena of Nature, supposed the black, stormy clouds which produce Hail, to be substituted for the metallic discs; and the small grains of Hail existing between them, exhibiting, by the electrical agencies of the clouds, motions like the pith balls in the *danse des pantins*.

There is certainly no difficulty in supposing, as Arago observes, two or more strata of unequally elevated clouds to exist at the same time, since we often see masses so disposed by the action of contending winds. When a storm seems beginning, small, greyish, detached clouds, sometimes immovable and sometimes disturbed, often appear under others of a different and much more extended form; and Volta has proved that the electrical transitions from a positive to a negative state, occur ten or twelve times, or even more, in a single minute.

But how, it may be asked, is the first embryo of Hail formed between the two clouds? The clouds, says Volta, are formed of hollow vesicles, the external surfaces of which are fluid. The myriads of these which form the upper surface of a cloud, must undergo, towards the South, a strong evaporation, both on account of the intensity of the solar rays, and the dryness of the air in which they swim. The elastic vapour thus produced by the solar heat, must first saturate the dry air through which it passes, and at length, by the low temperature of some superior stratum, become again reduced into a vesicular state, forming another cloud, differing in its electrical condition from the first. The upper cloud will have positive electricity, on account of that species of electricity being developed during the precipitation of vapour, the lower having changed its character to negative in consequence of the evaporation it has undergone. A diminished temperature at length may produce between the clouds icy particles, or Hail in a nascent state, which the opposite electrical states of the upper and lower clouds will cause to oscillate, until, by gathering matter from the surrounding moisture, they become at length enveloped in compact and opaque ice, and attain a size which, overpowering the electric forces, are compelled by Gravity to descend.

But this theory, apparently so simple, and at one time so popular on the Continent, has had objections opposed to it of a very formidable kind. Volta, indeed, having supposed that the first rudiments of Hail could only be produced by the action of the solar rays on the upper surfaces of clouds, found himself obliged to admit, that a Hail-stone which fell at three or four in the morning, before the Sun could possibly have acted upon the surface of a cloud, had oscillated at least ten or twelve hours between the surfaces of the oppositely electrified clouds; and Bellani, in some of the examples he has cited in opposition to the theory, has even adduced the instance of a storm in July 1806, which commenced before the rising of the Sun, and produced a prodigious quantity of Hail, when the preceding evening had displayed no indications whatever of a coming storm, throughout the whole extent of the visible horizon.

The experiment of the *danse des pantins*, continues Arago, furnishes moreover arguments more specious than solid. The electrified metallic plates, between which the pith balls oscillate, can neither be displaced nor divided. The particles, on the contrary, composing the clouds, are endowed either in their whole mass, or in their separate parts, with an extreme mobility. May it not therefore be aked how they alone remain immovable, and how they escape from the influence of those electrical forces which communicate the oscillatory motion to the interposed Hail-stones? Ought not the energetic action of these forces to bring into union the masses of clouds themselves?

It is also true that the experiment of the *danse des pantins* requires at least that one of the two electrified plates should be solid; for by substituting a sheet of water for the lower, as Bellani has done, the oscillatory motion takes place no longer: the balls, at the end of their first descent, penetrating the Liquid and rising no more. The clouds must present analogous phenomena: they cannot repel the Hail-stones until they have *touched* them; so that the gravitating force of succeeding Hail-stones, acting on those which have just come into contact with a cloud, must occasion some at least to penetrate it. A natural result of any long-continued system of oscillations must therefore be, the descent of Hail for many hours; whereas, on the contrary, Hail-storms are sudden and never continue long.

Arago, with his accustomed acuteness, has remarked in his commentary on Volta's theory, that did this oscillatory motion really exist in the atmosphere, it is somewhat remarkable that no one has ever perceived it. Hail clouds are commonly low, and travellers, continues that excellent and learned man, must have been oftentimes on mountains, within the range of the interval wherein these oscillations are performed; and added to which, the Hail-stones, in their ascent, must at least be sometimes brought into situations, where their *descending* courses never could have transported them; such as the lower parts of the roofs of cabins, or of very prominent rocks. But no such appearances have ever been remarked. Bellani, also, has made the important remark, that if electrified clouds sometimes possess the power of causing masses of ice of eight or ten ounces to oscillate between them, ought not the electrical energies of the clouds and the Earth sometimes to cause dust, gravel, and even stones, to be raised in calm weather? thus rendering, as he says, the atmosphere hardly fit for respiration, and producing to man more formidable evils than even Hail occasions.

M. de Perevoschtchikoff has endeavoured to support experimentally the objections made by Bellani against Volta's theory of Hail. He thinks that Volta lost sight of the principal cause of the cooling of clouds, and also of the concentric structure of Hail-stones. When the clouds, he remarks, consist of many thick strata, which gradually rise, they become an obstacle to the free distribution of the radiant heat from the Earth, which being reflected back again, produces that suffocating sensation which usually precedes a Hail storm. Above the clouds, however, the heavens are serene, and consequently radiation goes on freely from their upper surface. Hence the principal cause of the refrigeration, upon which depends the formation of the nucleus of the Hail-stone. The Specific Gravity of these nuclei being too great to allow of their remaining suspended in the cloud, they fall; and traversing different strata of clouds, they become covered at each by a fresh opaque coat of the Liquid congealed at their surface, the number of layers in the Hail-stone corresponding to the number of strata it has passed through. The Hail-stones, by concussion against each other, are supposed to have a rotatory motion given to them, tending to produce a spherical form.

It is proper to observe that this theory of the radiation of heat from the superior surfaces of clouds had already been proposed by Gay Lussac; but after all it must be reduced to that of Volta.

Hail in Europe generally by day.

appears to occur at particular periods. In the middle of France, Italy, Spain, &c., it commonly hails most abundantly during the warmest hours of the day, in Spring and Summer;* and in Europe generally, it falls principally during the day, though there are examples of great Hail storms which have taken place during the night. In August 1787, one ravaged the borders of the Lake Como, for an extent of 600 square miles, and began precisely at midnight; and another, no less disastrous, took place in August 1778 at the same hour; and a third in July 1806, just at the dawn of day. In our own country, generally, Hail is of rare occurrence in Winter,† if we except a sprinkling of small opaque grains, which in the former part of the night indicate the approach of a low temperature, and are found on the frozen ground, and on ponds in the morning, and sometimes by day after a descent of snow. In the Equatorial regions it seldom hails in places situated at a lower level than 350 fathoms; for although Hail is doubtless formed in the upper regions of the atmosphere, in that great division of the Globe, the warmth of the lower must prevent it from reaching the ground in that shape. Von Buch remarks, that it very rarely hails on mountains in the temperate climates of the Earth; and this he attributes to the low elevation of the clouds, from which Hail commonly descends.

Hail storms have definite limits.

Remarkable storm in France.

(628.) That Hail storms have definite limits, may be gathered from the tremendous storm which desolated so great a portion of France in July 1788.‡ It began in the South, and proceeded in two parallel bands from the South-West to the North-East; the extent of one of them being 175 leagues, and of the other 200; thus traversing nearly the whole length of that great Kingdom, and even a portion of the Low Countries. The mean breadth of the Eastern band was four leagues, and of the Western two, and what is very remarkable, the interval between the two bands, amounting to five leagues, was deluged with heavy rain.

Account of progress of this storm.

(629.) M. Tessier, who published an interesting account of this remarkable storm, informs us that its progress from South to North was at the rate of 16½ leagues an hour, and that the velocities of the two bands were precisely uniform. In the Western band it commenced hailing at Touraine near Loches at 6½ A. M.; near Chartres at 7½ A. M.; at Rambouillet at 8 A. M.; at Pontoise at 8½ A. M.; at Clermont in Beauvoisis at 9 A. M.; at Douai at 11 A. M.; at Courtray half an hour after noon; and at Flessingue at 1½ P. M. In the Eastern band, the storm reached Artenay, near Orléans, at 7½ A. M., corresponding precisely with the time of the Western band discharging itself near Chartres; at eight o'clock it arrived at Andonville in Beauce; the Faubourg St. Antoine in Paris at half-past eight; Crespy in Valois at half-past nine; Câteau Cambrésis at eleven, and at Utrecht at half-past two P. M. At each of these places, the continuance of the Hail was limited to seven or eight minutes.

Hail storm in Orkney, of confined extent.

(630.) Another example of the definite extent of a disastrous Hail storm is that which occurred in Orkney on the 24th of July, 1818, of which Mr. Neill has given an interesting account in the IXth volume of the *Transactions of the Royal Society of Edinburgh*. The thick layer of large Hail resulting from this storm, formed a tolerably well-defined belt across the Island, in a direction from South South-West to North North-East, and about a Scotch mile broad; the course of which we have endeavoured to illustrate, after Mr. Neill, in fig. 9. plate i., and beyond this line, on each side, the ground merely appeared "spotted with ice." In proof of the extremely local nature of the shower, persons who had been employed the whole day in digging turf, at a distance of little more than two miles Westward from what appeared to be the very centre of the storm, were wholly exempted from its effects. They had remarked a black cloud, and the lightning and thunder which resulted from it, but no Hail came near them; and the same thing was observed at a similar distance on the Eastern side. To the South also, the direction in which the storm came, its range was very confined. The peninsula of Deerness, belonging to the main land of Orkney, was directly in the line, and only seven or eight miles to the

---

* It is worthy of remark, that rain falls at all seasons of the year, snow in winter, and Hail principally in Summer.

† This is the opinion of Howard, but Mr. Giddy's Tables for Penzance offer a decided exception. The following are the results of his Hail showers for the aggregate of the several months; during a period of twenty-one years.

January	23	July	1
February	25	August........	0
March	25	September	5
April	27	October........	17
May	7	November......	22
June	5	December	43

The month of August is here absolutely zero, and December affords the maximum.

‡ We extract the following notice of the calamitous consequences of this storm from the *Annual Register* of that time.

This tremendous storm was ushered in by a dreadful and almost total darkness which suddenly overspread the whole country. In a single hour the whole face of Nature was so entirely changed, that no person who had slept during the tempest, could have believed himself in the same part of the world when he awoke. Instead of the smiling bloom of Summer, and the rich prospects of forward Autumn, which were just before spread over the face of that fertile and beautiful country, it now presented the dreary aspect of universal Winter, in the most sterile and gloomy of the Arctic regions. The soil was changed into a morass, the standing corn beaten into a quagmire, the vines were broken to pieces, and their branches bruised in the same manner; the fruit trees of every kind were demolished, and the Hail lay unmelted in heaps, like rocks of solid ice. Even the robust forest trees were incapable of withstanding the fury of the tempest; and a large wood of chestnut trees in particular, was so much damaged, that it presented, after the storm, little more than bare and naked trunks. The vines were so miserably hacked and battered, that four years were estimated as the shortest period in which they could become again in any degree productive. Of the sixty-six parishes included in the district of Pontoise, forty-three were entirely desolated; while of the remaining twenty-three, some lost two-thirds, and others above half their harvest.

The same Historian also adds, that this unforeseen and irresistible calamity coming on at a season, already so strongly and unhappily marked by the violence of faction, by public discontent, and by political dissension, when all men were looking to, or apprehending some great convulsion in the State, produced such an effect upon the people in general, that the nation seemed to have changed its character; and instead of that levity and gaiety for which it had ever been distinguished, and which was ill concealed even in the most serious affairs, a settled and melancholy gloom now seemed fixed in every countenance.

M. Arago has lately remarked, that the damage done to a thousand and thirty-nine parishes on this occasion, amounted to 24,962,000 francs.

Leslie computes that Hail-stones sometimes fall with a velocity of 70 feet per second, which is at the rate of about 50 miles an hour. "Striking the ground with such impetuous force, it is easy," he says, "to conceive the extensive injury which a Hail shower may occasion in the hotter climates. The destructive power of those missiles in stripping and tearing the fruits and foliage, increases besides in a faster ratio than the momentum, and may be estimated by the square of their velocity multiplied into the mass. This fatal energy is hence as the fourth power of the diameter of the Hail-stone."

South South-West, yet remained untouched. The duration of the violent wind and heavy Hail, of the storm last described, continued about eight minutes.*

Appearance of Hail clouds.

Of low elevation.

(631.) The appearance of Hail clouds seems to be distinguished from other stormy clouds by a very remarkable shadowing. Their edges present a multitude of indentations, and their surfaces disclose, here and there, immense irregular protuberances. As a proof of the occasional lowness of Hail clouds, Arago remarks, that he has more than once seen clouds,—from which Hail would in a few minutes later have escaped abundantly, cover as with a thick veil the whole extent of a valley, whilst the neighbouring hills enjoyed at the very same time a pure sky and an agreeable temperature.

Forms of Hail very varied.

Change of wind alters them.

Six-sided pyramids changed into convex lenses.

(632.) The forms of Hail are very varied, but all Hail-stones resulting from the same shower, generally present considerable uniformity, when they fall nearly on the same level. It has been remarked that Hail-stones of the same storm, are found to be much smaller on the tops of mountains than in the neighbouring plains. If, however, any alteration takes place, either in the temperature or the wind, the figures of the Hail-stones become immediately changed. On the 7th of July, 1769, M. Adanson observed six-sided pyramidal Hail-stones to descend at six P. M.; but on the wind changing to the North-East, the Hail-stones which then descended, were in the form of convex lenses, and so transparent, that they increased the dimensions of objects without at all distorting them. In the great storm which desolated France, some of the Hail-stones were globular, others elongated, and others armed with different points,—probably the result of altered temperature or wind.

Flakes of spongy snow at their centres.

Surrounded by concentric strata of ordinary ice.

Sometimes transparent, sometimes opaque.

(633.) Very frequently in the centres of Hail-stones, small flakes of spongy snow are to be found; and generally speaking, this is the only dark part in them, the concentric strata with which it is surrounded having all the transparency of ordinary ice. Hence it has been supposed by many, that the internal and external parts of these stones are not formed under the same conditions. Sometimes, indeed, large Hail-stones have been found which present this snowy texture at their centres; but around their central parts, concentric layers, alternately transparent and opaque, are disposed. Leslie imagines the spongy texture to result from an atom of water having been suddenly frozen, and particles, of perhaps rarefied air, suddenly driven from the surface towards the centre. In his curious experiments on the production of ice by evaporation, in a receiver containing air very much rarefied, he constantly remarked the ice to be more porous and less transparent than when formed under the ordinary pressure of the atmosphere.

Surface of Hail covered with dust like fine flour.

Other instances.

(634.) Sometimes a small kind of Hail occurs, which is scarcely solid, and whose surface appears as if covered with particles of dust like very fine flour; and from its general texture it seems to occupy a kind of intermediate rank between Hail in its ordinary state and snow. This sort never falls during Summer in Southerly Countries. Another small kind of Hail is also found, exhibiting no trace of a central snowy flake, but differing in transparency from the former.

Hail-stones observed b Humboldt in the Andes.

In Orkney polished like marbles.

(635.) Whilst ascending the volcano of Poracé in the Andes, Humboldt observed Hail-stones from five to seven lines in diameter, formed of layers of different degrees of transparency, and not only flattened at their poles, but so much increased in their Equatorial dimensions, as to permit rings of ice to be separated from them with a very slight blow. Twice before he observed the same phenomenon, in the mountains of Bareuth, and near Cracow. In the storm before adverted to, which fell in Orkney, some Hail-stones were found as finely polished as marbles. Their colour also was worthy notice, being generally of a greyish white, not unlike fragments of light-coloured marble.

Hail-stones at Bonn delineated.

Sections.

(636.) Some interesting examples of Hail-stones were observed at Bonn on the 7th of May, 1822, of which illustrative figures have been given. Their general size was about an inch and a half in diameter, and their weight 300 grains. When whole, which was not always the case, their general outline was elliptical, with a white and nearly opaque nucleus of a round or spheroidal figure in the centre, about which were arranged concentric layers, increasing progressively in transparency to the outside. Some of them exhibited a beautiful stellular and fibrous arrangement, the result of rows of air bubbles disposed in different radii. Fig. 70 denotes the external form of one, and fig. 71 is the section of another having the concentric lamellar structure and system of radiation; and fig. 72 represents a third, cut in the direction of its shorter axe.

Forms observed by M. Delcro

Composed of pyrami dal parts.

(637.) M. Delcros has also given some figures of Hail-stones, having a concentric lamellar structure, and with a stellular fibrous arrangement. Fig. 73 is a section of one, where the surface appears covered with pyramidal forms, but having their summits somewhat blunted by incipient melting. When masses of this peculiar structure are burst asunder from any cause, the fragments disclosed are pyramidal, as in figures 74 and 75, thus forming what has been termed pyramidal Hail. And this peculiar formation would seem to be very common, at least in France, since M. Delcros has been able to trace it during ten years' observation. The apex, he remarks, is sometimes found wanting, but when present, it is apparently part of a hard nucleus. These forms were observed by M. Delcros in great perfection in a storm which happened at La Bacconière, in the Department of Mayenne, on the 4th of July, 1819.

Observed also by Lindsay.

(638.) Examples of pyramidal Hail-stones were observed likewise by Mr. Lindsay, on the 29th of November, 1823, at Aberdeen. At five P. M. there fell a shower, composed at first of distinct drops of rain, but which afterwards became changed into violent Hail. The Hail-stones were hard, and in almost every case presented five surfaces—four perfectly plane, constituting the sides of an irregular pyramid, and the remaining one spherical, serving as a base. These are represented in figs. 76 and 77. The spherical surface, to the depth of $\frac{1}{20}$th or $\frac{1}{30}$th of an inch, appeared solid and transparent.

Hail-sto of irregu polyhed forms.

(639.) Some Hail-stones have been observed of irregular polyhedral forms, and composed of an assemblage of smaller Hail-stones, united previous to their reaching the Earth. In some cases, icy masses have been

---

* This storm, considering its limited extent, was productive of very disastrous consequences. Mr. Neill informs us, that of a large flock of tame geese feeding on a down, many were killed on the spot, and the others so much injured, that all of them pined away, and died in a short time. Great numbers of small birds, as skylarks, starlings, corn-buntings, and wheat-ears, were found dead, and afterwards collected into heaps by the boys belonging to the farm. On the shore were observed numbers of rock-pigeons, hooded-crows, guillemots, and ducks, which had been killed at sea by the Hail and left by the receding tide. A boy received a severe blow on the back of the neck, which stupified him, and produced a contusion, from which he had not recovered after the lapse of some months.

found,—the result of a storm, resembling fragments of a vast plate of ice, broken in its descent to the Earth.

Hail-stones with pyritic nuclei.

(640.) Some Hail-stones having pyritic nuclei have been noticed by Professor John of Berlin. They fell at Sterlitamak, and contained a stony and crystallized nucleus. Their colour was brown, like the auriferous pyrites of Beresowsky in Siberia, and their surface shrivelled and resplendent. The crystal formed a flattened octahedron, with salient edges. The diagonals of the base were respectively four and five lines, and the distances of the summits two lines. In some cases, the four angles of the base were truncated.

Hail of blood colour.

(641.) At Parama de Guanacas, Humboldt and Bonpland saw Hail fall of the colour of blood.

Elasticity of Hail-stones.

(642.) On some occasions, as in a storm in the Department du Gard, on the 21st of May, 1828, such was the hard and elastic character of the icy masses, that those which fell on the stones rebounded, often without breaking, to the height of several yards.

Hail-stones projected almost horizontally.

(643.) Howard records a case wherein Hail-stones were projected from a cloud almost horizontally; and their velocity was such, that in many instances a clear round hole was left in the glass they pierced; and one large pane had two such perforations distinctly formed in it. The advocates of the electrical origin of Hail explain these oblique discharges by two electrical clouds drawn vertically towards each other, the Hail issuing in the resultant of the parallelogram of which the component forces are Gravity, and the common direction of the clouds. A change in the density of the air, however, is sufficient to account for the approach of clouds to each other, and thus the phenomenon in question becomes reduced to the theory of Hutton.

Noise heard before descent of Hail.

(644.) Arago remarks, that sometimes before the descent of Hail, a noise is heard,—a particular kind of cracking, which it would be difficult to describe in any other way, than by comparing it to the emptying of a bag of walnuts. This is accounted for by some Meteorologists, by supposing the Hail-stones to be driven by the wind against each other, in the clouds which carry them. Others imagine the Hail-stones themselves to be strongly and differently electrified, and consider the cracking in question to result from electrical discharges a thousand times repeated.

Frequency of electrical changes during Hail.

(645.) As a proof of electrical action, it is sufficient to follow for a short time the movements of an atmospherical electrometer on the approach of Hail, when the electricity will be found frequently to change, not only in intensity, but also to pass from positive to negative, and *vice versâ*, ten or twelve times in a minute.

Table of remarkable Hail-stones.

(646.) In the succeeding Table we have recorded some authentic instances of Hail-stones of considerable dimensions and weight, with the dates and localities of their descent.

TABLE CXL.

Date.	Place.	Authority.	Weight or Dimension.	Remarks.
April 4, 1697.	Flintshire.	Halley.	5 ounces.	Many of this size appear to have fallen.
May 4, 1697.	Hitchin in Hertfordshire.	Robert Taylor.	A perimeter of 14 inches.	Hence it may be inferred that they had a diameter of more than four inches.
May 15, 1703.	Le Perche.	Parent.	As large as his fist.	
July 11, 1753.	Toul.	Montignot.	3 inches in diameter.	Of polyhedral forms, and made up of an assemblage of small Hail-stones, united before they reached the Earth. They fell at six P. M.
Aug. 19, 1787.	Como.	Volta.	9 ounces.	
July 13, 1788.	From the middle of France, to the Low Countries, and Holland.	Tessier, and adopted by Arago.	Half a pound.	The largest stones weighed half a pound. Their forms were various. Some round.
July 15, 1808.	In Gloucestershire.	Howard.	From 3 to 9 inches in circumference.	It was remarked, that these stones appeared like fragments of a vast plate of ice, which had been broken in its descent to the Earth.
June 4, 1814.	North America.	Dr. Crookshank.	13 to 15 inches in circumference.	These appeared to be aggregates of many.
July 24, 1818.	Orkney.	Mr. Neill.	From four ounces to nearly half a pound.	Of a greyish white colour, not unlike fragments of light coloured marble.

Difficulty in accounting for such large masses.

(647.) We conclude with the single remark, that there is certainly a considerable difficulty in satisfactorily accounting for the formation of such masses as the preceding Table records. The clouds from which Hail descends, are, as we have before remarked, commonly very low; and it has hence been inferred that a Hail-stone can hardly employ more than a minute in reaching the ground. But in so short a time, it can scarcely be supposed, as Arago properly observes, whatever may be the dampness of the air, that the primitive kernel can cover itself with so many envelopes, as ultimately to acquire the size of the egg of a hen. The theory of Volta has thus an air of probability about it, when he supposes that the Hail, being once formed in the atmosphere, may remain suspended even for hours in space, and thus continue to acquire new accessions of matter, until the Gravity of the stones overcomes at length the electrical attractions by whose power they are suspended. Let us hope, that the new inquiries to which the Prize question lately proposed by the Academy of Sciences will probably lead, may remove the difficulties which unquestionably still cling to the subject.

On Dew.

Dew depends on radiation of heat and condensation of vapour by cold.

Bodies become colder than air, before Dew forms on them.

Cold formerly thought to be an effect of the moisture deposited.

(648.) An investigation of the subject of Dew, involves a multitude of most interesting phenomena, which, in the hands of Dr. Wells, have been perfected into a very beautiful and instructive theory. Strictly speaking, this theory will be found to depend upon two single principles, in constant activity around us,—the radiation of heat, and condensation of invisible vapour by cold; and although the discovery of the now apparently evident principle by Dr. Wells, that bodies must become colder than the neighbouring air, *before* Dew can be formed on their surfaces, might, according to the ingenuous and modest opinion of that estimable man, have been made at any time since the invention of the thermometer,* yet when we consider, that prior to the publication of his *Essay on Dew*, the cold which accompanies Dew† was constantly regarded as an *effect* of the moisture deposited, instead of the *cause*, and that from the time of Aristotle, the prejudices of the vulgar, as well as the opinions of Philosophers, had concurred in giving every possible weight to the opinion, we cannot but admire the patience and sagacity, and the pure spirit of inductive research which enabled him, in the midst of sometimes apparently discordant phenomena, to trace a principle entirely the reverse; converting that which had ever been regarded as a *cause* into an *effect*, and proving by a single principle, that a body ALWAYS became colder than the air in contact with it, before Dew could be deposited on its surface, and finally raising from it a theory, which should satisfactorily account for all the varied and beautiful phenomena of Dew, and harmonizing in every way with the established laws of Heat.

The cold which is the cause of Dew is the effect of radiation.

(649.) The cold here referred to as the cause of Dew, is the result of radiation. The power of radiation is enjoyed by all bodies in different degrees, and is developed both by day and by night. In our ordinary experience, we are most familiar with its effects by day, but there are phenomena quite as remarkable disclosed by its agency by night. The Earth covered with a variety of soils, the herbage of all kinds which adorn and beautify its surface, the rocks, the metals, and other bodies which the industry of Man has converted to his use, all possess this power in some shape or other, and all contribute to that infinite diversity of phenomena which the subject of Dew so abundantly unfolds.

(650.) But how, it may be asked, can these varied effects be traced? Every clear and tranquil night discloses in an ample degree their power, the green mantle of nature soon becoming colder than the surrounding air. Each blade of grass throws out a portion of its heat into empty space, but receives from the interminable void around no heat in return. The lower parts of the grass may communicate some of the Earth's internal store of heat by conduction; but the radiating power, more active, at least in this case, will at length cool the grassy surface below the temperature of the surrounding air. These effects will be rendered manifest, by placing one thermometer on the grass, and another at some moderate distance above it.

Examples of bodies having high radiating powers,

and of the great depression of temperature they undergo.

(651.) But this same property may likewise be traced in other substances besides the green covering of the Earth. Polished metal and polished glass will exhibit it in very opposite degrees; and among the metals a considerable diversity will be found, not only in their polished state, but also, when, from any mechanical action, their surfaces have acquired different degrees of roughness. It will also be found, that not only the substance and surfaces of bodies exercise a powerful effect on the phenomena of radiation, but that their texture likewise exerts a very great influence. Those of a close and compact kind radiate feebly, but bodies of a looser texture will be found eminently favourable to radiation. The delicate shining thread of the gossamer which sometimes covers our hedges and fields, swansdown—a substance exceedingly well adapted for observing the phenomena of Dew,—fine raw silk, masses of unwrought cotton, flax, wool, hair, fresh unbroken straw, and shreds of white paper develope this radiating power in a very high degree. Substances of this nature are often found twelve or fifteen degrees colder than the ambient air; and Dr. Wells remarks, that in a Country like Russia, in the season of Winter, a difference of thirty degrees may sometimes appear on a calm and tranquil night, between a small thermometer placed with its naked bulb on the middle or leeward side of a stratum of a downy substance, and a similar thermometer enclosed in a case of gilt paper, and suspended in the air a few feet above.

What conditions of the atmosphere are most favourable to radiation.

(652.) It will be found, however, when pursuing the inquiry, that some conditions of the atmosphere are much more favourable to the developement of the radiating power than others; and that when the night is perfectly clear, and an unclouded sky prevails in every direction around, and no terrestrial object intervenes to diminish the extent of view, a body exposed horizontally will develope this energy in the highest possible degree. Hence it is, that bodies which radiate their heat most freely, and at the same time possess the feeblest conducting powers, will, under such circumstances, become the coldest.

Effects of clouds.

They diminish the Earth's radiation.

Alternate states of a clear an cloudy sk depress and raise the temperature.

(653.) If, however, the clearness of the atmosphere be in any degree impaired by the presence of clouds, some change in the radiating power at once takes place. Even a solitary cloud in the zenith, as in fig. 1, plate iv., will occasion this change, and the effect becomes manifest on a delicate thermometer in a very short time. If the sky becomes more overcast, the thermometer will still rise in temperature, indicating the radiating power to be still more impaired; and in an entirely cloudy night, it may be said to be suspended altogether. If the clouds suddenly disappear, the radiating power is at once restored; and a succession of clouds passing the zenith, with alternate intervals of clear sky, will be marked by corresponding changes in a thermometer,—the presence of a cloud, as before observed, increasing the temperature, and its absence at once diminishing it. Dr. Wells

---

* Mr. Six of Canterbury mentioned in a Paper communicated to the Royal Society, that on clear and dewy nights, he always found the mercury lower in a thermometer laid upon the ground, than it was in a similar thermometer suspended in the air, six feet above the former. But it is one thing to mark a difference of this kind, and another to trace its Philosophical relations, and make it the foundation of a refined theory.

† Dr. Wells remarks that Dew is often spoken of as being cold, by popular writers. Thus Cicero and Virgil apply to it the epithet of "*gelidus*," Milton that of "chill," and Collins that of "cold." Of the same import is a passage in Herodotus, in which it is said, that in Egypt the crocodile passes a great part of the day on dry land, but the whole of the night in the Nile, this being warmer than the atmosphere, and the *dew*. Among Philosophers, however, Dr. Wells thinks, Mr. Patrick Wilson of Glasgow was the first who ever suspected the existence of such a conjunction.

Example.

quotes a case wherein the temperature of a grass-plot at half-past nine was 32°, but twenty minutes later was raised to 39°, the sky in the mean time being covered with clouds. On the clouds disappearing, the temperature was again restored to 32°.

How clouds produce these effects.

(654.) The cause of these varied phenomena,—and they are most interesting when pursued through all their relations,—result from a general law which seems more or less active at all times,—the reciprocal radiation of bodies. It is in virtue of a law of this sort, that the clouds return to the Earth the whole or a great part of the heat which may have been radiated from it; although dense clouds may sometimes be formed so high, as to be colder than the Earth, and thus to radiate to it less heat than the ground imparts;—accounting, therefore, for the phenomenon sometimes observed on cloudy nights, of good radiating bodies being several degrees colder than the air.

Other bodies raised above the ground produce a similar effect.

(655.) But it is not only by the presence of clouds in the atmosphere, that the power of radiation can be checked. The interposition of any bodies whatever, between the radiating surface and the sky, will produce the same effect. The thinnest cambric handkerchief,* or even a piece of open wirework placed at a moderate elevation above the ground, as in figures 2 and 3, have the power of checking the force of radiation, and the fact may be readily verified in grass. Trees, houses, or whatever objects intercept the view of the sky, exercise a proportional effect; and so powerful in this respect are the influences of particular localities, that two bodies, in themselves precisely similar, and destined to illustrate the same experiment, may, nevertheless, from the influence of surrounding objects, present very opposite results. A metallic plate in one field, may remain free from moisture during an entire night, when a plate precisely similar, in another field, will be covered with innumerable particles of Dew. The existence of a gravelled walk near the scene of observation, is sufficient to modify an experiment; and Dr. Wells, in remarking that a portion of the garden in which he performed his experiments was employed in raising culinary vegetables, exhibited by no means too much nicety respecting the effect of local circumstances in influencing his results.* One general remark may therefore be made, and it is one of great importance,—whatever cause diminishes the aspect of the sky, whether it be a terrestrial object on the plane of observation, or a distant cloud floating in the air, will impair, in some degree or other, the force of radiation.

Necessity of attending therefore to localities.

Caution of Dr. Wells.

The radiation of a body must at length cause moisture to be condensed on it.

(656.) The result of this radiating power, in whatever degree it be developed, must, at some temperature or other,—dependent on the conditions of the body itself, and on favourable atmospheric circumstances around it,—occasion a condensation of humidity on its surface; and it may be observed as a confirmation of all that has been advanced on the necessity of an ample exposure to

---

* "I had often," says Dr. Wells, "in the pride of half knowledge, smiled at the means frequently employed by gardeners, to protect tender plants from cold, as it appeared to me impossible, that a thin mat, or any such flimsy substance, could prevent them from attaining the temperature of the atmosphere, by which alone I thought them liable to be injured. But, when I had learned, that bodies on the surface of the Earth become, during a still and serene night, colder than the atmosphere, by radiating their heat to the heavens, I perceived immediately a just reason for the practice, which I had before deemed useless. Being desirous, however, of acquiring some precise information on this subject, I fixed, perpendicularly, in the earth of a grass-plot, four small sticks, and over their upper extremities, which were six inches above the grass, and formed the corners of a square, the sides of which were two feet long, drew tightly a very thin cambric handkerchief. In this disposition of things, therefore, nothing existed to prevent the free passage of air from the exposed grass to that which was sheltered, except the cambric handkerchief. The temperature of the grass, which was thus shielded from the sky, was upon many nights afterwards examined by me, and was always found higher than that of neighbouring grass which was uncovered, if this was colder than the air."

The same effect also was noticed by him, when the sheltering substance was at a much greater distance. Thus he had "four slender posts driven perpendicularly into the soil of a grass field, and so disposed that their upper ends were six feet above the surface, forming the angular points of a square having sides eight feet in length. Over the tops of these posts was thrown an old ship flag of a very loose texture," and it appeared to Dr. Wells from different experiments, that the higher shelter had the same efficacy with the "lower, in preventing the occurrence of cold upon the ground, greater than that of the atmosphere in a clear night, provided the oblique aspect of the sky was equally excluded from the spots on which the thermometers were laid." When a thin handkerchief like this, is placed even vertically, it sensibly increases the warmth of the grass. To diminish radiation, contact should at all times be avoided. Dr. Wells found the warmth of grass, sheltered by a cambric handkerchief raised a few inches in the air, was three degrees greater than that of a neighbouring piece of grass, sheltered by a similar handkerchief in actual contact with it. On another occasion it was four degrees.

Mr. Daniell, in his able Essay on *Climate considered with regard to Horticulture*, remarks, "that the radiation is only transferred from the tree to the mat, and the cold of the latter will be conducted to the former in every point where it touches."

* The choice of a suitable locality for performing experiments on Dew, is of much greater importance than we should at first suppose. A wall, a house, or some distant trees will modify results, and in some cases prevent Dew from being deposited at all; and this will often be the case with regard to metals. It was from an inattention to circumstances of this kind, that Le Roi imagined that Dew was never deposited from the air of cities; whereas at the time his experiments were performed, either the conditions of humidity or temperature were not favourable to the formation of Dew; or what is more probable, the place of observation was so surrounded by lofty buildings, as to diminish, or prevent altogether, the radiation necessary for its formation. Experiments therefore performed in a garden situated in the heart of a great city, must often lead to results very different from that which would have been obtained in an open plain. And from a circumstance of the same kind, doubtless it was, that both Muschenbroek and Dufay inferred that metals were altogether destitute of the power of receiving Dew; although it is now known, that many most interesting phenomena of the kind are disclosed by them.

Dr. Wells, when he undertook his inquiries respecting Dew, described the exact locality. "I think it right," he observes, "to describe the place, where by far the greater part of my observations on Dew were made. This was a garden in Surrey, distant by the public road, about three miles from the bridge over the Thames at Blackfriars, but not more than a mile and a quarter from a densely built part of the suburbs on the South side of that river. The form of the garden was oblong, its extent nearly half an acre, and its surface level. At one end was a dwelling-house of moderate size, at the other a range of low buildings; on one side a row of high trees, on the other a low fence, dividing it from another garden. If this fence had been absent, the garden would have been on the latter side entirely open. Within it were some fruit trees, but, as it had not been long made, their size was small. Towards one end, there was a grass-plot, in length 62 feet, and nearly 16 broad, the herbage of which was kept short by frequent mowing. The rest of the garden was employed for the production of culinary vegetables. *All of these circumstances, however trifling they may appear, had an influence on my experiments, and most of them, as will hereafter be seen, must have rendered the results less remarkable than they would have been, if they had occurred on a wide open plain, considerably distant from a large city.*"

As an example of his great caution respecting the influence of surrounding objects, he remarks on one occasion, "It seems certain that the houses surrounding Lincoln's-inn-fields, had an influence upon my thermometers, during my experiments there at night, beyond what arose from their merely retaining a quantity of heat, equivalent to that which they received from the surface of the garden."

Popular belief that Dew falls destroyed by a simple experiment of Dr. Wells.

the sky, that the first and simplest experiment which can be performed in illustration of the actual deposition of Dew, at once proves its correctness, and destroys the popular belief in the *fall* of moisture from the sky in an invisible form. "I placed," observes Dr. Wells, "on several clear and still nights, 10 grains of wool upon the middle of a painted board, 4½ feet long, 2 feet wide, and 1 inch thick, elevated 4 feet above the grass-plot, by means of 4 slender wooden props of equal height; and at the same time, attached, loosely, 10 grains of wool to the middle of its underside. The two parcels were consequently only an inch asunder, and equally exposed to the action of the air. Upon one night, however, I found the upper parcel had gained 14 grains in weight, but the lower only 4. On a second night, the quantities of moisture acquired by like parcels of wool, in the same situations as in the first experiment, were 19 and 6 grains; on a third 11 and 2; on a fourth 20 and 4; the smaller quantity being always that which was gained by the wool attached to the *lower* side of the board."

Effect of limiting the view of the sky illustrated by experiment with a cylindrical vessel.

(657.) Again, as another experiment illustrating the effect of exposure to the sky, Dr. Wells placed upright on the grass-plot, a hollow cylinder of baked clay, the height of which was 2½ feet, and diameter 1 foot. On the grass, surrounded by the cylinder, were laid 10 grains of wool, which, in this situation, as there was not the least wind, would have received as much rain as a like portion of wool fully exposed to the sky. But the quantity of moisture obtained by the wool surrounded by the cylinder, was only a little more than 2 grains, while that acquired by a similar portion of wool, fully exposed, was 16 grains. In this case the amount of direct radiation to the sky A B, was limited to the diameter C D of the cylinder, see fig. 4, and the small increment of moisture gained by the wool within it, might have been anticipated. Harvey traced the effect of a diminished aspect of the sky,[*] by employing cylindrical and the frustrums of conical vessels, of a common diameter at the base, and of a common altitude. The greater the upper diameter of a vessel, all other things being the same, the greater was the amount of Dew on equal masses of wool placed at the bottom; and a sensible diminution in the quantity of Dew was perceived, whenever the upper end of a vessel had only a few narrow detached slips of wood placed above it, as in figures 5 and 6. In some shorter cylinders, he found that wire-work of various degrees of fineness, produced very sensible decrements of the kind.

Effects of even a few slips of wood.

Apparent exception to the principle explained.

(658.) An apparent exception to this general principle is mentioned in the XVIIth volume of the *Journal of Science*. On an evening when the deposition of Dew was expected to be considerable, a plate of polished tin was placed gently on long grass, and its weight compressing the herbage on which it rested, necessarily caused the polished surface to be surrounded on all sides by grass, reaching twelve inches above it. At eighteen inches above the ground, or two inches above the average height of the grass, a similar plate was placed on slender props, as in figure 7. Now the latter plate having its surface thus exposed to the entire canopy of the sky, and the former having its view confined to a comparatively small space, in the zenith of observation, it might be inferred from the principle above announced, that the former would have gained more moisture than the latter; whereas the plate surrounded by the long grass, had its superior surface completely covered with minute but distinct particles of moisture, and the plate elevated above the grass was perfectly dry. But the principle of Dr. Wells, as remarked by the author of the Paper in question, is evidently limited to the consideration, that the bodies are in other respects placed under like conditions. The cooling power of the grass surrounding one plate, must necessarily have extended its influence to the metal; and by lowering its temperature considerably, have occasioned the copious deposition observed. The upper plate not being in contact with the grass, permitted the air to pass freely on each side of it; and being itself a bad radiator, attained no condition during the night favourable to the deposition of Dew.

Influence of an oblique aspect of the sky.

(659.) The effect of an oblique aspect of the sky is also clearly shown by another experiment of Dr. Wells. Ten grains of wool placed at C, fig. 8, directly under the middle of the raised board, could only be influenced by the portions of the sky comprised between A D and B E; the interval between the points A and B producing no effect on C, in consequence of the interposed board F G. Accordingly Dr. Wells found, after repeating the experiment on three several occasions, that the mass of wool at C, gained only 7, 9, and 12 grains of moisture respectively, at times when similar parcels of wool, laid upon another part of the grass, entirely exposed to the heavens, gained 10, 16, and 20 grains severally.

Influence of trees i this way.

(660.) Similar effects also may frequently be traced in cases where wide spreading trees prevail. Around the trunk of a tree, and as far as its branches extend, less Dew will at all times be found, than in the open space beyond. In the case of fig. 9, the space between A B, determined by vertical lines C A and D B from the extremities of the branches of the tree, is prevented by the foliage of the tree from radiating its heat to the upper sky, and hence the space referred to enjoys only the oblique radiation below A C and B D. The temperature within A B must hence be greater than in the free open field, where no interruptions to radiation exist, and a less amount of Dew consequently be found.[*]

Horizont surfaces more de than per- pendicul

(661.) Gersten long ago remarked, without being able to account for it, that horizontal surfaces are more abundantly covered with Dew than those which are perpendicular, an effect, however, which is now clearly to be traced to the diminished radiation of the latter. Harvey placed a hollow cube of block tin in a meadow, two inches above the herbage, with its vertical faces equally exposed to the cloudless horizon. To these faces, and to the upper surface of the cube, equal parcels of wool were attached, with equal radiating surfaces. At five

Experiments.

---

[*] Connected as the formation of Dew is with temperature, we may trace the first indications of the effects of a diminished aspect of the sky, in the suggestion made by Dr. Black,—to whom Chemistry is under everlasting obligations, to Mr. Patrick Wilson, Professor of Astronomy at Glasgow. On the 24th of January, 1784, that celebrated man suggested an experiment of placing some gauze over a thermometer. Mr. Wilson accordingly fastened a piece of open gauze to a hoop of eight inches diameter, and an inch deep; when the sheltered thermometers were found commonly to rise nearly two degrees.—*Edin. Trans.* vol. i.

[*] Milton beautifully alludes to this when in his *Paradise Regained*, he says:

> Full forty days he pass'd, whether on hill
> Sometimes, anon on shady vale, each night
> Under the covert of some ancient oak,
> Or cedar, to defend him from the Dew.

the next morning, the upper mass of wool had gained fifteen grains of moisture, and the parcels attached to its vertical surfaces, equal increments of five grains; the equality resulting from the perfectly tranquil state of the air.

Effects of different obliquities illustrated.

(662.) On surfaces variously inclined, different amounts of Dew will be found, in virtue of the change that different obliquities produce on the radiating powers of bodies. Hence we may account for the diversities sometimes to be met with in the amounts of Dew obtained on the same substance in different localities. Thus, if fig. 10 be supposed to represent a vertical section of a country, where considerable inequalities of surface prevail, and we further suppose the soil and herbage which cover it to possess, independently of these inequalities, the same radiating power; then will the results of Dew obtained on the open and horizontal surface A B, exceed those deposited on the inclined ground B C. An observer situated also at C D, although enjoying a surface equally level with A B, will nevertheless obtain smaller amounts of Dew, on account of the place enjoying a less expanse of sky; and an experiment performed in the valley at E will again disclose other results. In like manner, a mass of wool placed at H on the plane F G, having a common level with A B, may nevertheless gain less dew, from the aspect of the sky being partially cut off by the walls or hedges at F and G. How different then must be the results of an observer who may carry on his observations in a woody and enclosed country like the foreground of fig. 11, where the radiating power is checked on every side, and another who may be situated on the open surface of the high ground above;* and how different both the results of these, from what an experimenter would find on the inclined ground visible in the same scene. The choice of a locality, as before remarked, must therefore be of great importance in all inquiries relating to Dew.

Experiment illustrating effects of radiation and deposition of Dew.

(663.) Another beautiful experiment illustrating the effects of a free aspect of the sky, may be performed by suspending a glass globe a little above the ground. On a perfectly tranquil night, and in a free open space, the first particles of moisture will be formed on the very zenith of the ball; and as the superior hemisphere of the ball continues to lose heat by radiation, these atoms of Dew will increase in size, and at the same time others will begin to be deposited around them, but of gradually decreasing dimensions, as they recede from the zenith, until at length they will be found to terminate in a slight film of moisture round the Equator of the ball. This beautiful effect is attempted to be illustrated in fig. 12. If, however, the radiating power be checked on any part of the ball, the uniformity will be destroyed. A similar effect may be produced by exposing a sheet of paper to the evening sky, having its surface disposed in round ridges as the section in fig. 13. After some time the summits of all the raised parts will be found with large particles on them; and from these, others diminishing in size may be traced; until at length, in the hollow parts of the paper, particles only of the smallest possible kind will be found. The gradation of these watery atoms will be found worthy of notice. So also if a dead beetle be exposed, a like gradation of the particles of Dew will be found, as in fig. 14. A similar effect may also be discovered upon the back of a sheep, which may have been reposing quietly on the ground. The woolly coating of the animal will be found covered with a great abundance of Dew on its upper part; but round its sides the moisture will be less abundant; and a limit may almost be traced to it in the greatest horizontal section of the animal, as A B C, fig. 15.

Glass best adapted for observing formation of Dew.

(664.) Plane pieces of glass horizontally disposed, are best adapted for observing the actual formation of Dew. The appearances on surfaces of this kind are altogether similar to those which occur on them when exposed to the action of steam a little warmer than itself. The exposed surface has first its lustre diminished by a slight damp uniformly spread over it, as in fig. 16; but as the moisture increases, it gathers into flat drops of very dissimilar forms. These drops are at first very small, but afterwards they enlarge, and run into each other, and by forming streamlets, cause a great portion of the moisture to escape from the body, as denoted in the figures 17, 18, 19, and 20.

Example of its progressive formation.

Wool well adapted both for obtaining and retaining Dew.

(665.) It is an important object, however, in a pursuit of this nature, to obtain a substance admitting of the ready formation of Dew, and at the same time with a power of retaining it for the purpose of examination. Such is wool. Many precautions, however, are necessary both in selecting and using it. Uniformity in the fibre is necessary, and great care should be taken that the masses selected for comparative observations, should in all cases expose equal surfaces to the sky. Equality of mass or weight by no means implies equality of radiating surface. The same mass of wool may be disposed in a variety of forms, and each form differ in the quantity of its radiating surface. Ten grains of wool made into the form of a ball, will obtain much less Dew than an equal quantity disposed into a flattened form. In the globular form, the upper half only can obtain Dew, and the particles will diminish in size to the Equator A B, fig. 21, as already remarked in the glass globe; whereas in the mass of equal weight disposed into a flattened form, as fig. 22, the whole of its upper surface must uniformly gain Dew, and in particles equal in size to those deposited on the zenith of the globular mass. The surface of this flattened form also may be obviously very much changed. Much precaution, therefore, is necessary in attending to the deposition of Dew on wool.

Uniformity of fibre necessary. Equal radiating surface necessary.

Comparison of different forms into which wool may be disposed.

Metals present a striking contrast to glass and wool in formation of Dew.

(666.) While glass and wool, therefore, are distinguished for the readiness and abundance with which Dew is deposited on their surfaces, the metals afford examples entirely the reverse. Such is the resistance indeed which polished metallic surfaces present to the formation of Dew, that some perseverance is necessary in pursuing the inquiry; and yet the slowness with which they receive moisture, discloses relations infinitely more varied than arise in the better radiators of heat.

(667.) On the same night that Dew is copiously deposited on glass, swansdown, wool, and the grassy

---

* There are exceptions, however, respecting some particular hills which merit attention, and require caution in the observer. Dr. Wells remarks, that "in hills which are insulated and of inconsiderable lateral extent, the air surrounding their summits, on nights favourable to the deposition of Dew, is warmer than that at their bases; and hence the superiority of the cold of a low plain from radiation, over that of a wide expanse of hilly ground, will, for obvious reasons, be less; but no superiority of this kind will probably exist in a low plain, when the high ground is not only extensive, but flat on the top, forming what is called table land; unless indeed, which seems to be actually the case, the air of such an elevated country should be commonly more agitated than that of lower places equally level."

Difficulty in obtaining Dew on them.

surface of a field, a polished metallic plate in contact with the grass, may retain its lustre undiminished during the whole time of observation. When indeed moisture is deposited upon metals, it commonly sullies only the lustre of their surfaces; and at times when it is sufficiently abundant to gather into drops, they are generally small and distinct.

Arises from their small radiating powers.

(668.) This slowness of metals to receive moisture from the air, is dependent in the first place on their feeble radiating powers; and, secondly, on their capability of receiving, by aid of their conducting powers, at least as much heat from the atmosphere as other bodies, and more than others from the warmer substances they may happen to touch. Before Dew, indeed, can be deposited on the surface of a metal, it is necessary, not only that its surface should be cooled, but that the whole of its mass should be so lowered in temperature, as to condense the watery vapour, affording thereby another remarkable contrast to the feeble conductors of heat, which gain moisture on their surfaces, even when their parts a very little below are warmer than the air.

Not only the surface of a metal, but the whole of its mass must be lowered in temperature before Dew is formed.

Metallic plate several feet above ground may have Dew on both sides.

(669.) From the same ready passage of heat from one part of a metal to another, arises the phenomenon that a metallic plate suspended in the air, several feet above the ground, is covered with moisture on its lower side, as well as on its upper, and this at a time when the under surfaces of bodies more capable of receiving Dew are without any deposition of the kind.

If in contact with ground, Dew often formed on lower side, while its upper remains dry.

(670.) When a metallic plate, however, is laid upon the bare earth, on a night favourable to the deposition of Dew, moisture will be deposited on its lower surface, at the time the upper remains dry. And the cause of the phenomenon is to be sought for in the under side of the metal partaking of the cold produced by the exposure of its upper side to the clear sky, and thereby condensing the moisture ascending from the warmer earth below.*

Deposition of Dew facilitated by changing position of metal.

(671.) The deposition of Dew on a metallic plate may be facilitated by applying it to different portions of cold grass in succession.

Size of a metal plate influences formation of Dew.

(672.) But the dimensions of metallic plates appear to influence the formation of moisture upon their surfaces. A large metallic plate lying on grass will resist Dew more powerfully than a small one similarly circumstanced. If, however, the two plates be suspended at the same height in the air, the small one will resist the formation of Dew more powerfully than the large. The lesser plate, in the first instance, gains Dew most rapidly, from its relative size permitting a more active exercise of its conducting power, thus enabling it to partake of the diminished temperature of the grass; whereas, in the latter example, the small plate receives, in proportion to its size, a larger share of heat from the atmosphere than the other.

A large metal plate on grass less readily dewed than if raised a few inches above it.

(673.) If a large metallic plate be placed on the grass, it will be less readily dewed than when raised a few inches above it. In the former position, such a plate freely obtains, by its great conducting power, heat from the earth; whereas, when it is suspended freely in the air, it reflects whatever heat may be radiated from the grass below. The grass also will have less heat than when the metal was in contact with it, partly from the small oblique view of the sky afforded to it, and partly from receiving air which has been cooled by passing over other grass fully exposed to the heavens.

Small increase of temperatu in metals sometime causes De to disappe on them.

(674.) As the temperature of metals is never much below that of the neighbouring air, a small diminution of their radiating powers, from any cause, will often occasion the Dew previously formed upon them to evaporate; though other substances, like wool, which had been more cooled by radiation, are still gaining moisture from the air. For a like reason, a metal which has been purposely wetted, will often become dry at night, while other substances are moistened by Dew.

Results o union of good and bad radia tors.

(675.) Having thus briefly treated of the formation of Dew on good and bad radiators, let us next inquire into some of the phenomena resulting from their union. In the first place, a good radiator, as wool, when placed upon a bad radiator, as tin, will, by gaining heat from it, acquire less dew than an equal portion of the same substance laid upon a good radiator like grass. But when the metallic body, having wool in contact with its upper surface, is raised above the ground, the wool will gain more Dew, on account of the metallic surface reflecting the heat which is radiated to it by the warmer grass; thus enabling it to preserve undiminished the cold it acquired by the radiation of the upper surface of the wool to the sky.

Good ra tor attac to bad o checks d position Dew on ter.

(676.) If a metal be closely attached to a substance of some thickness which receives Dew powerfully, the radiation of the metal, instead of being increased from this circumstance, will be diminished, provided the metal covers the whole of the upper surface of the body. And if to the non-metallic side of a piece of gilt paper several wooden letters be attached by means of gum, the portions of the metallic surface not in contact with the letters will be found covered, under favourable circumstances, with minute particles of Dew; while the parts in actual contact with the wood will remain perfectly dry. This experiment, when performed with the letters DR. WELLS, presented the appearance denoted in fig. 23.

Such is the regularity which guides these depositions, that whatever may be the forms of the wood actually in contact with the non-metallic side of the paper, the dry spaces will be rigorously confined to them. Hence we shall find in figs. 24 and 25, that a wooden cross being attached to the former, the dew will be confined to the triangular spaces not in contact with the wood; and in the latter, the triangular areas with wood attached to them, will remain free from moisture, the form of the cross being visible by the innumerable drops that cover it. The same observations apply to figs. 26, 27, 28, and 29. In fig. 30, where the form of the body in contact is more fanciful, the Dew is still confined to the other parts. Fig. 31 represents an interesting example of Dew just beginning to be deposited in small triangular forms, perfectly defined in the corners of the metallic paper; and in well-defined segments in the middle of the sides. Fig. 32 is an example in which these small depositions are more irregular.

Result arising from j tion of metal glass.

(677.) Some very interesting phenomena also result from the junction of a metal with glass. If two watch-glasses, with their concave sides uppermost, be placed on a plate of polished tin, and one of them be surrounded with a ferule of the same metal of the same diameter as the glass, and a depth equal to its versed sine, the following phenomena will be perceived. In the crystal without the ferule, of which a section is represented in

---

* Dr. Wells once observed on a cloudy night, a piece of glass laid over an earthen pan containing water, and placed upon the ground, to be wet on its lower side, while the upper was dry; the glass being in this situation sufficiently cold to condense the vapour of water heated by the earth, but not enough to condense the watery vapour of the air.

fig. 33. A zone of moisture will be found to surround the edge, the particles diminishing in size inwards, as denoted in fig. 34. At the bottom a perfectly dry circle will be found. In the other glass, of which a section is denoted by fig. 35, with the surrounding ferule A B, C D, a dry zone will be found to surround the outer edge of the glass, and a dry circular space at the bottom, but a dewy zone, E F G, H I K, will be found existing, as in fig. 36, having large particles in the middle, and others progressively diminishing in size towards both its edges. After these appearances have existed for a certain time, a secondary deposition of moisture, under favourable circumstances, will be found to take place. Within the dewy zone of fig. 34 another very narrow zone of moisture will be formed of exceedingly fine particles, as represented in fig. 37; and on each side of the moistened zone of fig. 36 similar zones may be seen, as in fig. 38. For the cause of these appearances, see vol. xvi. of the *Journal of the Royal Institution*.

Of wafers and glass.

(678.) An example of the regularity with which Dew is deposited round a series of wafers placed upon glass, is given in fig. 39.

Effects of covering glass with a smaller surface of metal.

(679.) Another very interesting experiment may be performed, by partly covering a surface of glass with a smaller surface of metal. On a favourable night, the uncovered portion of the glass will quickly become cold, and derive to itself a part of the heat of the metal. The surface of the metal will hence be more readily dewed, than if the whole exposed surface had been metallic. The actual deposition of moisture, on the two kinds of surfaces, will in such a case be very curious. Of the metallic part, moisture will be first and most abundantly deposited on the outer edge, from its being nearer to the colder glass; while the parts of the uncovered glass, contiguous to the warmer metal, will be the last and least abundantly dewed. Supposing A B C D, in fig. 40, to denote the glass, and E F G H the metal attached to it, an enlarged type of the Dew may be represented as in fig. 41; but a more perfect idea of the whole phenomenon may be gathered from fig. 42, in which the letters composing the celebrated name of LORD BACON are metallic, and applied on a large scale to a surface of glass, according to the conditions of the experiment.

Examples.

Example of conduction checking formation of Dew.

(680.) The following is an example of the effect of conduction in checking the formation of Dew. Fig. 43 represents a plate of iron fastened by screws to the top rail of a gate, of which fig. 44 is a section. The whole of the plate was covered with Dew; but the particles on the heads of the screws and the spaces around them, were the smallest, on account of the heat the screws derived from the internal mass of the wood.

Examples of progressive formations of Dew, and of effects of a gentle current.

(681.) An example of the progressive formation of Dew is given in the different appearances of the word DEW, represented in figs. 1, 2, 3, 4, 5, and 6, plate v; and also in the successive states of the word COLD, in figs. 7, 8, 9, 10, 11, and 12, the latter series exhibiting also the partial manner in which moisture sometimes continues to be deposited during a whole night, in consequence of the action of a gentle current.

Another example of effects of a current.

(682.) Another example of the influence of a gentle current is given in fig. 13, which represents a parallelogram of gilded glass, having its metallic side uppermost. The first deposition of moisture took place at A the leeward end, the Dew gradually advancing thence to the middle of the surface, distinct drops at the same time being deposited at D, B, E, C. As the particles increased in size round the three edges, other minute drops were successively deposited, more distant from them; accumulating, however, with the most rapidity on the leeward sides A and C. After many hours' exposure, an oval portion of the metallic surface was found entirely free from moisture. At the last observation the particles at A had increased to at least an eighth of an inch in diameter; those at C being rather less. The particles at the corners D and E preserved also their superiority in size above those at B.

Examples of deposition of Dew on insides of windows.

(683.) There are some interesting phenomena connected with the deposition of Dew on the insides of windows, which merit notice in this place. At times, and when the window is unscreened by a blind, it assumes forms of very great symmetry, as in figs. 14 and 15; but the effect of a blind is in general to destroy the uniformity which prevails in other cases, as in figs. 16 and 17; while in others, where the blind exerts a less decided influence, some small approach to uniformity may be traced, as in figs. 18 and 19. All these depositions result from the glass being cooled by the external air, and the internal air in contact with it depositing, in consequence, more or less of its moisture. The Dew will be found most copious, where the glass has been screened by a blind or a shutter. Dr. Wells proved, by applying the naked bulbs of two delicate thermometers to a covered and uncovered pane, that the former was three degrees colder than the latter; the air of the chamber being at the same time eleven degrees and a half warmer than that without. Here the closed shutter shielded the glass, which it covered, from the heat radiated to the windows by the walls and furniture of the room, and thus, as Wells remarks, kept it nearer to the temperature of the external air, than those parts could be, which, from being uncovered, received the heat emitted to them by the bodies just mentioned. In the case of an external shutter, the effect will be directly opposite to what has just been stated; since it must prevent the radiation, into the atmosphere, of the heat of the chamber through the glass.

Cause.

Effects of a blind or shutter.

Example of Dew on outside of a window.

(684.) It is not, however, on the insides of windows only that Dew is deposited, it being sometimes formed on their *outsides*. Fig. 20 represents an example of this kind, wherein the portion of the window above A B was covered on the outside with particles of Dew so very numerous, as to prevent objects from being seen distinctly through the glass; but below A B, where the *inside* of the window was covered with a muslin curtain, the particles on the *outside* were much less numerous. In some cases where a pane has been cracked but not broken, a perfectly dry margin on each side of the crack will be found, as in fig. 21, all the remaining parts of the glass being covered with innumerable particles of Dew.

Beautiful formation of Dew on threads of gossamer.

(685.) The formation of Dew on the delicate threads of the gossamer, is worthy of attentive consideration by the accurate observer of Nature. Very frequently detached lines will be found covered with innumerable particles like a string of beads, as in fig. 22; but often masses of web will be found the borders of which are covered with large globules of Dew, as in fig. 23, and their internal parts filled with innumerable threads intersecting each other in every possible direction, and covered with smaller globules, which become at last so small as to elude the eye. Mr. White of Selborne mentions, that he once found the whole face of the country covered with a coat of web drenched in Dew, and as thick as if two or three setting nets had been drawn one over the other.*

General circumstances which appear to influence formation of Dew. Clear weather.

(686.) Our limits will now only permit us to advert to some general circumstances which appear to influence the formation of Dew. In the first place, Dew is never abundant except in clear and serene weather. Some traces of it may, indeed, be met with in cloudy nights, if there be no wind; or notwithstanding the wind, if the weather be clear; but it is never observed to form under the united influences of the wind and a cloudy sky.

Dew may be formed during the whole night.

(687.) After Dew has begun to be deposited, it continues to form during the whole night, if the weather remains equally still and serene. Dr. Wells found, that by placing fresh parcels of wool upon grass every hour, during many suitable nights, and weighing each in succession, that Dew had been deposited upon all. The cause, moreover, is apparent when we consider, that after one volume of air has deposited its moisture, the gentle motion that at all times exists in the atmosphere, even when it is pronounced by ordinary observers to be perfectly calm, must cause some other volume to be translated, containing like moisture with the first; and supposing a motion of this kind to go on, the successive depressions of temperature that take place during the whole night, until the minimum temperature about sunrise is attained, will bring even the masses of air which had previously deposited the moisture permitted by their former temperatures, to discharge other portions, when they become again subjected to an increased cold of the radiating body.

Largest quantities formed between midnight and sunrise.

(688.) Whatever may be the quantity of moisture, however, deposited during an entire night, it does not appear that equal quantities are formed between sunset and midnight, or midnight and sunrise. According to Dr. Wells, more Dew is formed in the latter period than in the former. The conditions of the two are indeed very different. The absolute quantity of moisture existing in the air between midnight and sunrise, must necessarily be less than between sunset and midnight, in consequence of the previous precipitation of a part of it; but during the former interval, the temperature is diminished more than in the interval between sunset and midnight. We are not, however, to suppose that the periods of sunrise and sunset form absolute limits to the deposition of Dew, and accordingly moisture is frequently found on bodies capable of receiving it, both *before* sunset, and *after* sunrise.

Dew is more plentiful in Spring and Autumn than in Summer

(689.) Dew is more plentiful in Spring and Autumn than in Summer; and more abundant after rain than after dry weather. The greatest Dew occurred, during the long experience of Dr. Wells, when the barometer was sinking; and Deluc has observed that rain may be foretold, when Dew is very abundant in relation to the climate and season.* Howard mentions that he has sometimes found Dews so abundant in Autumn, as to be capable of daily measurement in the rain-gauge.

Very copious on nights followed by misty mornings.

(690.) Dew is always produced in great abundance on those clear and calm nights which are followed by misty mornings; and it is also found plentifully deposited on a clear morning succeeding to a cloudy night.

Increase of atmospheri temperatur during day promotes it formation.

(691.) Increase of atmospheric temperature during the day, supposing other circumstances favourable, promotes in a great degree the formation of Dew. The law by which the aerial columns gain moisture, increases more rapidly than that which regulates their temperature; and hence, a small decrease of heat in the air, during the night, must bring it, when the temperature is high, much nearer to a state of saturation, than when the temperature is low.

Gentle motion of air promote its formation.

(692.) A gentle motion in the lower strata of the atmosphere, by bringing fresh volumes of air into contact with the cold surface of the Earth, will produce a more abundant deposition of Dew, than if the atmosphere were entirely calm.

Unequal quantities of Dew may be formed in nights equally calm and clear.

(693.) In nights equally calm and clear, very unequal quantities of Dew may be precipitated. The great inequalities existing in the lengths of the nights in our latitudes, may be referred to as one cause of these differences; but another, and a more fertile cause, is found in the unequal degrees in which moisture exists in the air. At one time it was thought that the cold connected with the formation of Dew, ought always to be proportional to the quantity deposited; but Dr. Wells clearly proves, that the same degree of cold in the precipitating body, and which may take place in nights equally calm and clear, may be attended with much, little, or perhaps no Dew, according to the existing state of the atmosphere with regard to moisture.

Influence of particu lar winds.

(694.) Particular winds have a tendency to promote the formation of Dew in different Countries, from their transporting air highly charged with moisture. In Europe, Southerly and Westerly winds promote it, but Northerly and Easterly winds the contrary. On the Western shores of Africa, Southerly and Westerly winds are favourable to it; but in Egypt and the Barbary States, the North wind brings great accessions of moisture. Dew for these reasons must be more abundant in Norway also than in the Eastern Provinces of European Russia.

Attempts to find annual amount of Dew.

(695.) Various attempts have been made to determine the annual deposition of Dew, but without success. To measure the quantity deposited under the most favourable circumstances, is no easy task; and although Mr. Daniell observes, that the quantity of vapour existing in the atmosphere, in the different seasons, at the level of the sea, seems to follow the course of the mean temperature, such are the varied and uncertain conditions connected with the deposition

---

* A phenomenon sometimes mistaken for Dew is often seen on the fine and delicate web of the garden spider. "If you examine," says Kirby, "a newly formed net with a microscope, you will find that the threads composing the outline of the radii are simple, but those of the circles closely studded with minute Dew-like globules, which from the elasticity of the thread are easily separable from each other. That these are in fact globules of viscid gum, is proved by their adhering to the finger, and retaining dust thrown upon the net, while the unadhesive radii and exterior threads remain unsoiled. It is these gummed threads alone which retain the insects that fly into the net; and as they lose their viscid properties by the action of the air, it is necessary that they should be frequently renewed." The beautiful regularity with which these drops are disposed, and their gradual decrease in size as they approach the centre of the web, are worthy of attentive examination.

* *Rech. sur les Mod. de l'Atm.* sec. 725

Estimated annual amount for England.

of Dew, that no very accurate result for the average annual deposit can be obtained in the present state of our knowlege. It must indeed vary with every climate and every locality. In a general way it has been estimated for England at about five inches annually, which is computed to be about a seventh part of the average quantity of moisture received by the atmosphere in the same time. Instruments have been contrived to measure the quantity of Dew deposited at any time, but they are entirely fallacious.

Honey Dew.

(696.) There is a substance called Honey Dew to which we must briefly advert. It is well known to Naturalists that it is not deposited on vegetables by the atmosphere, as its name would seem to imply, but is excerned by insects of the genus *Aphis*, which inhabit the under sides of leaves, and deposit it on the surfaces of those below. This little creature seems to subsist by drawing the juices from the sap vessels, and by a peculiarity of constitution, rejects the richer saccharine part, which afterwards affords nourishment to many other insects. Ants are so fond of it, that a whole colony may be found travelling to the highest branches of a tree in search of it; and they have been seen to seize the clear drop, while yet attached to the body of the Aphis, which, although defenceless, was not molested further by the predaceous wanderers. Honey Dew is sometimes so abundant as to drop from trees.

Wells's Essay on Dew to be highly rated as an admirable specimen of the inductive logic.

(697.) We cannot close this division of our Essay, which we do with reluctance from its very great interest, without recommending most strongly to the reader's attention, Dr. Wells's valuable *Essay on Dew*. We know of no Work in our day which has been more universally admired than the Treatise of Dr. Wells; certainly none that practically exemplifies in a purer and better form the admirable inductive system which it was the object of Bacon to teach.

Hoar Frost.—Ice.

Hoar Frost.

(698.) There are conditions, however, of the atmosphere which sometimes cause dew to be frozen, on whatever bodies it may have been deposited, and such appearances are denominated Hoar Frost. Hoar Frost is formed in England much more frequently than is commonly supposed; and such is its occasional severity, that a single night, even when the warmth of the year would seem to secure us from its rigorous effects, will sometimes destroy all the hopes of the gardener.* For ten months in the year, says Mr. Daniell, vegetation is liable to be affected at night, from the influence of radiation, by a temperature below the freezing point of water;† and even in the months of July and August, which form the only exceptions, a thermometer covered with wool will sometimes fall to 35°. Howard, however, observes that a night on which Fahrenheit's thermometer remains for some hours below zero, hardly occurs in our climate more than five times in a century. In England, a continued Frost may be regarded as an exception to the rule of the climate, and occasionally some winters pass almost without Frost. As might be expected, Frosts generally disappear with a wind from the Atlantic. In Devonshire, three successive frosty mornings are regarded by the farmer as a sure harbinger of rain. The mean temperature of each of three similar periods of Frost, in the long winter of 1813—14, did not vary a degree from the freezing point, although preceded and followed by periods whose mean temperature was 44°; and Howard remarks. that the analogy might be carried even further. The most intense Frosts penetrate but a few inches into the Earth, but the depth must be variable from the diversity in the conducting powers of bodies.

Frequent.

Ten months in the year in England.

A continued Frost rare.

Frosts disappear with a wind from the Atlantic.

Dew must precede the formation of Frost.

(699.) As a deposition of moisture must in all cases precede the formation of Hoar Frost, whatever causes tend to modify in any way the deposition of humidity,—whether they arise from the substances of bodies themselves, the nature of their surfaces, or their textures; from the clearness of the sky, the varied influences of clouds, or from terrestrial objects modifying in some way or other the radiating power,—must in the same degree influence all the phenomena of Hoar Frost. If we take the case of grass, the fibrous texture of which is so favourable to the emission of heat, we shall find a copious radiation continuing, until a temperature at length is reached, equal or below the freezing point of water. The moment at which this happens, will of course vary with the circumstances of climate and of season. At some periods of the year, and in particular localities, it may reach the temperature of thirty-two, early in the evening, or even before sunset; whilst at others it may be protracted till the minimum temperature occurs about sunrise, or not sink to the freezing point at all. Any dew deposited, must hence, when the temperature is low enough, be frozen; and the Hoar Frost which whitens our fields in the morning, may thus have been of longer or shorter duration, according to the season of the year, and the continuance of the proper conditions of temperature during the night. Often, indeed, will the atoms of Dew that have been converted into Hoar Frost during the night, be dissolved again before the morning; and amidst the uncertain fluctuations of our atmosphere, both as regards temperature, aspect, and the variable circumstances of bodies themselves, it is possible to suppose conditions to arise, in which more than one transition of this kind may take place during the night. It should be borne in mind also, that Hoar Frost may be formed when the temperature of the air is above the freezing point of water, since a body may have a temperature at or below thirty-two, when the air around indicates a higher degree of heat. Its continuance, however, under such conditions cannot be very long.

Illustrated in case of grass.

Time of its formation variable.

Dew converted into Hoar Frost, and the Hoar Frost back again into Dew, several times during the night.

Modifications produced by radiation in Hoar Frost.

(700.) It may be useful briefly to advert to some of the modifications which different degrees of radiation produce in the formation of Hoar Frost. Where dew is amply deposited, that is, where radiation has been allowed to disclose its full power, Hoar Frost will be found most abundant. In wide and open plains,—or in those gently sloping grounds, which break only the undulations of the air, without limiting in any way the general aspect of the sky, every blade of grass, in favourable states of the atmosphere, will be found covered with delicate crystals of Hoar Frost. But beneath the branches of a noble oak, where radiation has been checked, this hoary appearance will be dimi-

Checked by trees.

---

* On the 6th of May, 1831, the temperature during the night sunk to 20°, at Edmonton. In the morning, the leaves of the vine, the walnut, and the oak appeared shrivelled and black. Their appearance was the same as if they had been burned, and when pressed they crumbled into dust. This temperature was 6° lower than it had fallen in that month, at that place, for forty years.

† In the month of June, a plant may be so circumstanced in this Country, as to undergo all the changes of heat from 154° to 30°.

Examples.

nished; or sometimes a moderate dew may be found in such a situation, while the grassy covering beyond the tree will be entirely frozen. In the fine park of the Earl of Morley at Saltram in Devonshire, we remember on one occasion seeing every tree surrounded as it were with an Oasis of green verdure, of sizes and forms regulated by the spreading branches of the trees, while the other parts of the ground were covered with Frost. A tall, slender poplar had but a small, circular spot surrounding it, whose limits were nearly fixed by the vertical lines A B and C D, fig. 1. plate vi., tangents to the greatest horizontal section of the branches of the tree; while a magnificent oak with its giant arms preserved a large and irregular surface, denoted also by a dotted line surrounding the trunk of the tree, and determined by similar vertical lines, E F and G H, fig. 2. Many interesting phenomena of this kind would be noticed in a woody and enclosed country like fig. 11. plate iv. In some parts, the Frosts would be found much more severe than in others; and where a wide expanse of sky is open in a low situation, there they would be found most intense. Daniell remarks, that the leaves of the vine, the walnut-tree, the succulent shoots of dahlias, and potatoes, are often destroyed by frost in sheltered valleys, while upon surrounding eminences they remain untouched. He has found a thermometer in a valley thirty degrees colder than on a hill. Such effects, however, according to Wells, are limited to hills that are insulated, and of inconsiderable lateral extent.

An enclosed country affords many examples.

Effects of position in influencing the formation of Hoar Frost.

(701.) As an example of the power of position in influencing the formation of Hoar Frost, we select the case of a printed paper, a portion of which, A B C D, fig. 3, was attached to the inclined surface of the coping of a wall, and the remaining part, C D E F, to the vertical surface of the same wall, so that the letters composing one of the words, and which we have here supposed to be METROPOLITANA, were partly on one of these surfaces and partly on the other. One morning, the sloping surface of the paper was found abundantly covered with Hoar Frost, but none was to be seen on the vertical part C D E F; and so well defined were the crystals, that the letters of the words THE ENCYCLOPEDIA, had all distinct groups upon them, separated from the crystals on the white paper, by visible boundaries. In like manner, the *upper* halves of the letters of the word METROPOLITANA were covered with crystals in the same manner as the letters of the word before mentioned; but none were to be seen on their *lower* halves, or on *any* part of the paper bounded by C D E F, the edge of the wall C D seeming to fix a definite limit to the crystalline power.

Example of radiation influencing the formation of Hoar Frost on the railing of a field.

(702.) Another striking instance of the effects of radiation in modifying the phenomena of Hoar Frost, is given in fig. 4, which represents the railing of a field composed of two horizontal rails, with vertical bars at moderate intervals. The upper edge of the rail A B, from being exposed freely to the sky, was found abundantly covered with Hoar Frost; whereas the corresponding edge of the lower rail disclosed rectangular portions only, C D, E F, G H, I K, &c. of Hoar Frost, leaving the alternate spaces D E, F G, H I, almost, if not altogether, free from it. Now, it will be remarked on referring to the figure, that the vertical bars were immediately opposite the last-mentioned spaces, and thus deprived them of the more abundant view of the sky which the others enjoyed. At the same time the whole upper surface of this rail was deprived of its direct radiation to the zenith, which is most effective in lowering the temperature of a body, thus accounting for the smaller sizes of the crystals covering the portions referred to.

Branches o trees and shrubs.

(703.) On some occasions the branches of trees and shrubs illustrate in a very beautiful way the power of radiation. Their upper parts exposed to the sky, discharge their heat rapidly; and hence become covered with an abundance of fine crystals. Where however one branch in any way intercepts the view of another, without being in immediate contact with it, as at A or B, fig. 5, the hoary crystals will be found much less numerous.

A Norway spar.

(704.) Another example bearing on the same inquiry, occurred in the case of a long Norway spar which had been deprived of its bark. It was lying on nearly horizontal ground, and during the night a portion of its surface, E F G H, fig. 6, had been covered with dew. In the morning, from the greater radiation of the upper part of the spar, a uniform portion, A B C D, of about two inches in width, was found covered with the minutest crystals of Hoar Frost; while the equally uniform spaces, A C F E, B D G H, about an inch in width on each side of it, retained their moistened character unchanged.

Check to radiation b coping of wall.

(705.) An interesting fact connected with the same important truth, is recorded in the VIth volume of the *Horticultural Transactions*. In fig. 7, A B C D represents a transverse section of a wall, covered with a coping A B. In the instance of a very severe Frost on the 29th of April, 1826, all the shoots of the vines projecting beyond the perpendicular line A C, that is beyond the salutary influence of the coping, were quite cut off by the frost; but the trees whose shoots did not project beyond that vertical line, were quite protected.

An interposing bod preventing the disappearance of Hoar Fros

(706.) The effect of an interposing body, in checking in some cases the formation of Hoar Frost, becomes of an opposite kind, when from any increase of temperature the Frost begins to disappear. Fig. 8 is an instance where Frost had formed very abundantly on the inside of the glassy surface A B C D. Early in the morning a piece of paper was carelessly placed so as to cover a portion, E F G D B, of the glass, but not in contact with it. In the course of the day, the icy particles covering the space A E F G C were the first to dissolve; and when the whole had become converted into dew, the frozen particles bounded by E F G D B remained, though not so beautifully defined as at first. On the same occasion, a druggist's window exhibited the appearance of fig. 9, the figures of the assemblages of frozen particles being nearly governed by the forms of the glass vessels on the inside.

Examples.

Remarkab phenomen connected with vegetables.

(707.) There are no objects which disclose more remarkable phenomena connected with radiation, than the different tribes of vegetables; and the effects of Hoar Frost upon them are eminently calculated to display its effects. We have before remarked, that every flower has a radiating power of its own, and so we may add has every leaf; differing in different plants, and varying in the same plant from exposure and position. The grasses disclose the same diversity, and while the Almighty seems in consummate wisdom to have adapted every plant, "from the cedar tree that is in Lebanon, even unto the hyssop that springeth out of the wall," to a locality in which the conditions of temperature and atmospheric humidity are best adapted to its general wants; it is worthy of

Tempera-ure and h midity adapted t their gene ral wants.

Radiation necessary for deposition of moisture on plants.

observation, how much an alteration of the circumstances in which Nature originally placed it, seems to affect its energies and growth. "To vegetables growing in the climates for which they were originally designed by Nature," says Daniell, "there can be no doubt that the action of radiation is particularly beneficial, from the deposition of moisture which it determines upon their foliage; but to tender plants, artificially trained to resist the rigours of an unnatural situation, this extra degree of cold may prove highly prejudicial."

Hoar Frost affects parts of the same flower differently.

(708.) The different degrees also in which Hoar Frost affects different parts of the same flower, are worthy of attentive observation. "Upon inspecting the young fruit of such trees as were at the time in blossom," observes Mr. Lindley in allusion to the great Frost recorded in the *Horticultural Transactions*, "it appeared as if no injury had been sustained by their flowers; but upon examining them more minutely, it was found that their ovaria were black with death, and it was subsequently seen that fruit so affected, all fell from the trees and perished." In the blossom of the strawberry, the ovaria were likewise destroyed, but the stamens were little injured, proving that a degree of Frost incapable of affecting the fleshy calyx, and the petals or stamina immediately enclosing it, entirely destroyed the ovarium through all those envelopes. But we can only hint at a subject of boundless interest and extent.

Trees frequently destitute of Hoar Frost when plants nearer the ground are covered with it.

Cause.

(709.) Trees are frequently destitute of Hoar Frost, when shrubs and plants nearer the ground are covered with its forms. Wells has remarked that "the leaves of trees often remain dry throughout the night, while those of grass are covered with dew; and the reason he assigns for the absence of moisture, will, by a simple alteration of the conditions of temperature, account for the absence of Frost. Shrubs and plants, says he, being in a stratum of air of a lower degree of temperature, but of greater humidity than that surrounding lofty trees, the lower stratum also being the most tranquil of the two,—there are causes in activity, more favourable to the formation of dew on plants and shrubs, than on the leaves of trees in the regions of the air above. The diminished temperature, therefore, which converts that dew into Hoar Frost on shrubs, may be insufficient to produce dew on trees; or should dew thus be formed, the greater warmth of the air above may cause it to preserve its watery form. Thus it is, that the diligent and sanguine gardener has often to lament the loss of valuable plants, while trees whose summits are only a few feet higher are entirely unhurt. Protecting plants,* therefore, whether by horizontal or vertical screens, or by an application of straw and mats, becomes an important object in the economy of gardening. Too often, however, the screen or mat is placed in *contact* with the object it is intended to protect; the gardener forgetting that the heat which the screen loses by radiation, is also lost by the tree, from its conducting power.

Appearances of Hoar Frost very beautiful.

(710.) It is remarkable, however, that the appearances of Hoar Frost, so beautiful and so varied, from the pendulous drops which adorn the sharp summits of grass, up to the infinite diversity of forms deposited on glass, should have met with so little attention from Philosophers, and that so few attempts should have been made to describe them. A sheet of common brown paper exposed to a clear and tranquil sky, will, under proper conditions of temperature, be soon covered with innumerable crystals of Hoar Frost, inviting the most delicate examination. A grain of sand will sparkle with innumerable points; while in more complicated formations, all attempts at analysis and description seem lost in the unbounded variety of Nature.

Reduced to three general classes.

(711.) There seems to be three ways in which this process of crystallization goes on. 1. A tendency to freeze the moisture that has been deposited in globules, without any alteration of figure, and denominated by Howard, granular forms. 2. The formation on the fibrous surfaces and edges of bodies, of minute and delicate icicles shooting into spicular forms; and 3dly, those infinitely varied figures, found on flat surfaces, as glass.

Granular forms.

On grass and coarser threads of the spider.

(712.) Granular forms are most generally found suspended from the edges of blades of grass, and sometimes they retain their transparency so completely, as still to resemble dew. In Autumn, the dew deposited on some of the coarser threads of the spider of that season, is found frozen, and arranged like a string of small beads, which may be taken up by the hand.

Spicular variety.

Examples on top of a rude post.

On branch of a tree.

On a tomb-stone.

(713.) The spicular variety is very common, and formed under many diversified circumstances, though the existence of an *edge* seems necessary for its complete formation. Fig. 10 is an example of a rude post in a field, the top of which had been chamfered by the carpenter. On all the edges produced by the chamfering, as A B, B D, D C, C A; E F, F H, H G, G E; A E, B F, D H and C G, delicate and uniform crystals were formed, none of which were confused or blended together. Fig. 11 represents a branch of a tree which had been stripped of its bark. On every fibre there was a line of crystals, and a great uniformity ran through the whole. Wherever the fibres were crooked, the crystals followed them. Fig. 12 is an instance derived from a tomb-stone of a country churchyard, with a long inscription on it, which we have restricted to the memory of PATRICK WILSON.* The whole surface of the stone, from the top to the line A B, was covered with crystals, diminishing in size downwards. The letters of the inscription, however, being cut angularly into the stone, were without any crystals, excepting on their edges, all of which were covered with larger crystals than those found on the surface of the stone; but their size diminished from the upper parts of the letters downwards. Thus in the letters of the word MEMORY, a perceptible difference was to be observed in the crystals at the tops of the letters, and those at the bottom; and so those round the edges of the name PATRICK WILSON, while they decreased in size from top to bottom, were very considerably less than those round the edges of the word MEMORY. A horizontal section of the stone through the latter word

---

* In the clear blue sky of the Valley of Chamouni, if the crops should not have ripened towards the end of the season, the peasants make fires of green wood, on the two sides of the enclosing mountain, the smoke of which, uniting in the middle, forms a kind of cloudy canopy, which not only prevents the escape of radiant heat, but increases its intensity, and prevents the formation of Frost.—*Quarterly Review*, vol. xxii.

* Dr. Wells has the following remark, "The last subject which I shall here touch upon, is that of Hoar Frost. This substance has, I believe, from the time of Aristotle, been uniformly, and according to my observations, justly, considered as frozen dew. I shall, therefore, frequently refer hereafter to the experiments of the late Mr. Patrick Wilson of Glasgow respecting it, as if they had been actually made upon that fluid. Indeed, several of my experiments upon dew were only imitations of some which had been previously made upon Hoar Frost, by that ingenious and most worthy man."

A star cut on a village tomb-stone.

Upper and under sides of autumnal leaves.

exhibiting the projecting crystals, is given in fig. 13. A star with which the piety of a villager had caused a humble stone to be adorned, had a most beautiful appearance, but feebly delineated in fig. 14. Here also the upper ray of the star had the largest crystals, and the lower the smallest; while the two horizontal rays had crystals of nearly a mean size. Figs. 15 and 16 are examples of the modes in which Hoar Frost is sometimes deposited on the upper and under sides of fallen autumnal leaves.

On iron railing.

(714.) Dr. M'Culloch has given a very interesting account of a formation of Hoar Frost on some iron railing, illustrated in fig. 17. The crystals were pyramidal, but formed of others so minute and entangled, as scarcely to admit of examination, even with a lens. Their length was about one-sixth of an inch, and their bases about one-thirtieth, which was also their distance from each other. All of them were attached to the edges of the bars, at right angles, according to their lengths, at the same time forming equal angles with the surfaces of the bars. The same arrangement was preserved in all the curvilinear parts of the bars; so that each group or pyramid was invariably placed at right angles to the tangent of the curve at that part, or in the direction of the radius of curvature. Hence it would appear that the effort of each pyramid was to recede as far as possible on each hand, not only from the planes, but from the edge; and thus to attach itself at right angles to the latter. The same effect took place also in the interior as well as in the exterior of the curved parts; and thus the whole, as the Doctor observes, "was ciliated like the leaves of some plants with a regular and beautiful fringed work."

Uniformity of crystals.

(715.) In the more intricate parts of the iron-work, and at the junctions of bars, Dr. M'Culloch found a most admirable uniformity. Where any two edges of a bar met at right angles, the crystals at the apex occupied the direction of the diagonal of the cube formed by the union of the bars; or maintained a distance equally removed from the edge of the joint on the one hand, and from the plane at right angles to it on the other; but the crystals on the two meeting edges nearest the apex, did not immediately assume a rectangular position towards these edges; but diverged gradually in succession from that on the angle, till they took the regular position which they held on the remainder of the edge.

(716.) In the re-entering angles of the joints, the crystal of the angle was in like manner prolonged according to the diagonal of the cube; and the crystals intermediate between that, and those which stood at right angles to the internal edges at a short distance, were so arranged, as to maintain equal distances at their bases, without touching at their summits. Thus, all the crystals *converged* for a short distance round the interior diagonal crystal, as they *diverged* from it on the exterior. Whatever were the magnitudes of the angles, the same law was observed; and in cases where very acute interior angles happened to exist, the crystals became so shortened, to avoid a contact with those on the neighbouring edges, that near the extreme point they vanished altogether. The cause of this repulsive power among all the crystals seems difficult to explain. It will be suggested," says M'Culloch, "that it depends on some electrical condition; but it seems hardly possible to explain how this mysterious agent acts in such a case." Fig. 18 is a section of a bar, the projecting lines at the angles denoting the true positions of the crystals. Fig. 19 is one of the crystals magnified.

Example o conduction checking formation Hoar Fro

(717.) As an example of the effects of conduction in preventing the formation of Hoar Frost, we select the following. Fig. 20 is a representation of some cast-iron railing, with massy stone pillars for a gateway, and buildings forming boundaries to the extreme ends of the railing. During a slight Frost with a fog, Mr. Patrick Wilson remarked, that the bars A, B, C, D, E, and F, were without Hoar Frost from top to bottom, in consequence of the heat gained by conduction from the pillars and walls, and the impediments those bodies afforded to the radiation of the bars. The bars G and H were observed to have only a little on them; but all the smaller bars, from I to K and L to M, had their edges beautifully fringed with Hoar Frost, and their flat surfaces also, to within twelve inches of their lower ends. The larger bars were less decidedly covered with Frost, and free from it, much higher above the parapet, as N O, P Q, than the smaller ones.

Probable cause of great dive sity in thi variety o glass.

Several example

Appear of print letters throug some st like pa ticles.

(718.) The great diversity of form in the third variety, of which the most beautiful examples are to be found on glass, results, according to a Memoir of Carena contained in the *Mémoires de Turin* for 1813 and 1814, from the interruptions which the natural force of crystallization undergoes, from the numerous and varied resistances which the surface of the glass presents, and from its imperfect and irregular conducting power, which impresses upon the condensed vapour, the instant before crystallization begins very diversified motions,—sometimes of a rectilinear and sometimes of a curvilinear kind. These diversities of form are most abundant, when the atmosphere is highly charged with moisture and the depression of temperature is very great; and it would seem in many cases as if they resulted from successive depositions,—an effect of alternate states of temperature. We have given a few sketches in figs. 1, 2, 3, 4, 5, 6, 7, 8, 9, and 10, some of which are distinguished for their beauty, particularly figs. 8, 9, and 10. Fig. 11, affords an example of the lower part of a pane covered with one uniform sheet of Frost, the upper edge being bounded by innumerable crystals of a fern-like appearance. Above these were others resembling leaves, of which enlarged representations are given in figs. 12, 13, and 14. Fig. 15 is a view of the diversified crystallizations on different panes of the same window. Fig. 16 is an instance where the deposition of separate star-like particles had been confined from some cause to a part only of a pane of glass, on the inside of which an advertisement had been previously placed, and which we shall here suppose to have contained the word **FROST**. The glass opposite the letter F and part of the letter R was entirely free from Hoar Frost; but the remaining portion of the R, and the other letters, exhibited the appearance in the diagram.

Hexah prisms glass.

(719.) M. Hesell once remarked a layer of ice on his window a quarter of an inch thick, which covered the lead as well as the glass. Instead of presenting the usual vegetative appearance, it was composed of a multitude of crystals more or less perfect; but many exhibited the forms of hexahedral prisms, having their axes perpendicular to the glass.

Air so times l with p cles of ing w

(720.) Howard remarks, that the air is sometimes loaded with particles of freezing water, such as in a higher region would produce Snow. These attach themselves to all objects, crystallizing in the most regular and beautiful manner. A blade of grass under circum-

Appearance of them on grass and shrubs.

stances of this kind, becomes converted into a pretty thick stalagmite. Shrubs covered with spreading tufts of crystal, look as if they were in blossom; while others, more firmly incrusted, appear like gigantic specimens of white coral. The leaves of evergreens are found with a transparent varnish of ice, and a delicate white fringe around. On such an occasion, the whole face of Nature seems dressed out in Frost work. Lofty trees covered with Frost, when viewed against the blue sky, in the sunshine, present a very magnificent appearance.

Freezing mists, called Rime.

(721.) Sometimes, during the existence of a mist, the temperature is so much diminished, as to cause a peculiar crystallization from the freezing mist, denominated Rime. It is most abundantly formed on surfaces opposed to the wind. Howard mentions a case, wherein the melted rime descended in showers from the trees; and there was enough on his rain gauge to produce 0.02 inches of water when melted. Freezing mists are common to the high lands of Tweedale and Lanarkshire. In August 1784 the whole barley crop was destroyed there by a creeping mist of this sort. Their influence is confined to the spot on which they rest. Hence one half of a field is often destroyed, while the other remains safe. From a knowledge of the locality of their effects, attempts have been made, though without success, to disturb these frozen mists, and to save the barley and oat crops, by dragging something over them before sunrise, to shake off the "Rime or Cranreuch." Sometimes the uppermost grains of the oats only are destroyed, the grains below ripening well. But even then the barley was totally destroyed.

Locality of their effects.

Surface of water itself loses heat by radiation and becomes frozen. Point of maximum density.

(722.) At the same time that Hoar Frost is formed in all the abundant varieties we have explained, by the cooling of the surfaces of bodies, and the actual deposition of moisture on them from the air, the surface of water itself, enjoying as it does so high a power of radiation, must have its temperature reduced, and when that depression is sufficient, it must become converted into Ice. The cooling of water has, moreover, a remarkable peculiarity, its density increasing until a maximum is reached at about 39°.5, below which the opposite law of dilatation begins.* As soon, therefore, as a copious radiation from the surface has lowered the temperature of the whole watery mass to the point of maximum density, the upper stratum, by further cooling, must become specifically lighter, and remaining on the surface, be at length converted into Ice.

Formation of Ice may be checked by diminishing radiation.

(723.) The formation of Ice, however, may be checked by any cause which diminishes radiation. Mr. Scott remarks, in the VIIIth volume of the *Edinburgh Journal of Science*, that a turban suspended across an Ice-pit, three feet above the pans, prevented the formation of Ice in those immediately below it; and in several which it only partially covered, Ice was formed on the half of the water, out of the perpendicular line, while that immediately under the turban remained fluid. Two strings, crossing each other at a less height above a pan, divided the Ice into four corresponding parts. These results must of course depend on circumstances of temperature; for if the degree of heat be rather lower than is necessary to freeze water, when no impediment to radiation exists, the whole may become frozen, although partially covered. On the other hand, should the temperature be just sufficient to freeze water under conditions the most favourable, the contents of a vessel, not fully exposed to the sky, may remain fluid throughout. It is to be observed also, that Ice is chiefly formed in Bengal,* when the temperature of the air is above

Formation of Ice in Bengal when temperature is above 32°.

---

* "Had water," says Dr. Ure, "resembled mercury, oils, and other liquids, in continuing to contract in volume by cooling, till its congelation commenced, the incumbent cold air would have robbed the mass of water in a lake of its caloric of fluidity, by unceasing precipitation of the cold particles to the bottom, till the whole sunk to 32°. Then the water at the bottom, as well as that above, would have begun to solidify, and in the course of a severe winter in these latitudes, a deep lake would have become throughout a body of Ice, never again to be liquefied. We can easily see, that such frozen masses would have acted as centres of baleful refrigeration to the surrounding Country, and that under such a disposition of things, Great Britain must have been another Lapland. Nothing illustrates more strikingly the beneficent economy of Providence, than this peculiarity in the constitution of water, or anomaly, as it has been rather preposterously termed. What seems void of law to short-sighted man, is often, as in the present case, the finest symmetry, and truest order."

* The formation of Ice in Bengal is so peculiarly interesting, and has led to so many mistaken views, that we are sorry we can only briefly allude to it in a note. According to Sir R. Barker, excavations thirty feet square and two feet deep are formed in a large open plain, their bottoms being covered with sugar-cane, or stems of Indian corn, dried, to the thickness of eight inches or one foot. On this layer are placed, in rows near to each other, small unglazed earthen pans, one-fourth of an inch thick, and one inch and a quarter deep filled with boiled soft water. The pans are sufficiently porous to allow their outer surface to appear moist, after water is poured into them.

In the process carried on by Mr. Williams, three hundred persons were employed. A piece of ground of about four acres, nearly level, was divided into portions of from four to five feet square, and these were surrounded by little mounds of earth, four inches high. In these inclosures, previously filled with dry straw, or sugar-cane haum, were placed as many broad, shallow, unglazed earthen pans, containing unboiled pump water, as they would hold. In the morning, between five and six, a thermometer with its bulb naked, placed on the straw, amidst the freezing vessels, was never found lower than 35°; and he has observed ice, when a thermometer so placed was 42°. Another thermometer, suspended five feet and a half above the ground, was commonly 4° higher than that among the pans; and hence it is possible, Mr. Williams may have seen Ice a little before sunrise, when the temperature of the air was 46°.

Mr. Scott, however, remarks, that porous pans are not necessary for the success of the experiment, and the natives use them only because they have no better; and so well are they aware that the porosity of the vessels is of no advantage, that they usually rub them with grease in order that they may more easily extract the Ice. Mr. Scott has also found by repeated experiments, that Ice may be produced, although a thin film of oil be spread over the surface of the water; the latter being contained in *glazed* plates, which indeed answer much better than the porous pans of the country, the Ice in them being invariably thicker, and the water, when it does not actually freeze, somewhat colder than the similar contents of porous pans placed in exactly the same situation.

Dr. Wells, in repeating the experiment in the way employed by Sir R. Barker, found at one o'clock in the morning of the 4th of May, Ice appear in watch-glasses placed on a grass-plot and on a raised board thinly covered with sand, the temperature of the air, as measured by a naked thermometer, being then, at four feet above the ground 39½°, and at seven feet, 40½°. At two A. M. Ice was observed in the pans in the pit, while a thermometer in the air, two and a half feet above the ground, was 36½°. Shortly afterwards, Ice began also to form in the pans upon the grass-plot. The temperature of grass, fully exposed to the sky, was at the same time 30°, while that of the Earth, an inch below the bottom of the grass, was 45°. During the time of these observations, Dr. Wells informs us, dew formed copiously.

In another experiment performed on the evening of the 22d of May, in the manner described by Mr. Williams, Dr. Wells found water in a watch-glass placed upon straw frozen, after an exposure of little more than an hour, the temperature of the air two feet above the straw being 37°. In half an hour more, Ice began to appear in some earthen pans. In another experiment, Wells placed upon the straw bed, a dry earthen pan, which in the course of the night became covered with moisture, and at length by a further depression of temperature converted into a film of Ice.

And as a beautiful experiment to prove that water may not only freeze at night, in air of a temperature higher than 32°, and at the

32°, on the clearest and calmest nights, which are precisely the conditions most favourable to the formation of dew; the interposition of clouds or the action of the wind preventing its formation altogether.

Experiments of Leslie.

Description of process of freezing.

(724.) Leslie, in his experiments on artificial congelation, has had abundant opportunities for tracing the process by which water becomes crystallized. "When the frigorific action," says he, "is most intense, the congelation sweeps at once over the whole surface of the water, obscuring it like a cloud. But in general the process advances more slowly; bundles of spicula, from different points, sometimes from the centre, though commonly from the sides of the cup, stretching out and spreading by degrees with a sort of feathered texture. By this combined operation, the surface of the water soon becomes a uniform sheet of Ice. Yet the effect is at times singularly varied; the spicular shoots, advancing in different directions, come to inclose, near the middle of the cup, a rectilinear space, which, by unequal though continued encroachment, is reduced to a triangle; and the mass below being partly frozen and expanded, the water is gradually squeezed up through the orifice, and forms by congelation a regular pyramid, rising by successive steps; or if the projecting force be greater, and the hole more contracted, it will dart off like a pillar. The radiating or feathered lines which at first mark the frozen surface, are only the edges of very thin plates of Ice, implanted at determinate angles, but each parcel composed of determinate planes. This internal formation appears very conspicuous in the congealed mass which has been removed from a metallic cup, before it is entirely consolidated.

(725.) "When very feeble powers of refrigeration are employed, a most singular and beautiful appearance is in course of time slowly produced. If a pan of porous earthenware, from four to six inches wide, be filled to the utmost with common water, till it rise above the lips, and then be planted above a dish of ten or twelve inches diameter, containing a body of sulphuric Acid, and having a round broad receiver passed over it; on reducing the included air to some limit between the one-twentieth and the one-fifth part of its usual density, according to the coldness of the apartment, the liquid mass will, in the space of an hour or two, become entwined with icy shoots, which gradually enlarge and acquire more solidity, but always leave the fabric loose and unbroken below. The icy crust which covers the rim, now receiving continual accessions from beneath, rises perpendicularly by insensible degrees. From each point on the rough surface of the vessel, filaments of Ice, like bundles of spun glass, are protruded, and forming in their aggregation a fine silvery surface, analogous to that of fibrous gypsum or satin spar. At the same time, another similar growth, though of less extent, takes place on the under side of the pan, so that continuous icy threads might appear vertically to transpierce the ware. The whole of the bottom becomes likewise covered with elegant icy foliations. Twenty or thirty hours may be required to produce these singular effects; but the upper body of Ice continues to rise for the space of several days, till it forms a circular wall of near three inches in height, leaving an interior grotto lined with fantastic groups of Icicles." Fig. 17 is borrowed from Leslie to illustrate the general appearance of these phenomena.

Examples crystals.

(726.) The small, triangular, needle-shaped crystals, frequently remarked at temperatures but little below the freezing point, are represented in figs. 18 and 19, the latter denoting a more advanced stage of their formation. Their uniformity is shown by the tendency they have to unite under angles of 60°, or its supplementary number 120°. Dr. Clarke observed water to crystallize in regular rhomboids, having angles amounting to the last-mentioned numbers. On a thaw taking place the crystals preserved the same constant inclination of their planes. In the subterranean glacier of Foudeurle, hexahedral prisms of Ice, secondary forms of the crystal, were found. When a thaw is going on, we sometimes find thin sheets of Ice reduced in vessels of still water to forms resembling branches of fern, as in figs. 20, 21, and 22.

Beautiful forms disclosed by Ice when thaw take place.

Effects of fissures a rents in I

(727.) On the American lakes, and even on narrow rivers, fissures and rents of enormous magnitude are often made in the Ice, and are always accompanied with loud reports, like those of cannon. On the return of warm weather, before the Ice melts, the fissures close, and sometimes the edges of them even overleap each other.

Ice at bot tom of rivers.

(728.) The phenomenon of Ice at the bottom of rivers is one of very great interest. Mr. Knight discovered some in the River Teme, in Herefordshire, which he has described in the *Philosophical Transactions* for 1816. On a morning succeeding an intensely cold night, the rocky bed of the river appeared covered with frozen matter, which reflected a kind of silvery whiteness, and which upon examination was found to consist of numerous frozen spiculæ, intersecting each other in every direction, but not assuming anywhere, excepting near the shore, the state of firm compact Ice.

Different opinions.

Radiation and eddie seem ade quate to count for

(729.) A variety of opinions have been advanced respecting the origin of Ice in a situation so different from its ordinary state, and so contrary to what might be anticipated from its known Specific Gravity. The ordinary laws of radiation, joined to the eddies and gyrations of the running streams to which it is peculiar, seem adequate, however, to account for its formation. On the occasion which afforded Mr. Knight the opportunity of examining this phenomenon, the temperature of the surface water was just at the freezing point, small pieces of Ice being every where formed upon its more stagnant parts near the shores; and upon a mill-pond just above the shallow streams, in the bottom of which the Ice had been formed, millions of small frozen spiculæ were floating. At the end of this pond, the water fell over a low weir, and entered a narrow channel, in which its course was obstructed by points of rocks and large stones. Here numerous eddies were formed, which drew the frozen spiculæ under water, as in a vortex. Mr. Knight found these frozen spiculæ to accumulate most abundantly upon such parts of the stones as stood opposed to the current, wherever it was not very rapid, below the little falls, or most rapid parts of the river. Upon some large stones near the shore, of which parts were out of the water, and upon pieces of native rock, under similar circumstances, the Ice beneath the water had acquired a firmer texture, but appeared, from its whiteness, to have been first formed of congregated spiculæ, and to have

---

same time gain an accession of weight, by humidity condensed from the air, Wells exposed water until it was cooled to 34°, of this he put twenty ounces into each of two China saucers, which had also been exposed to the air, and then placing the saucers upon the bed of straw. In the morning, a thin cake of Ice was found in both saucers, one of which had gained two and a half and the other three grains in weight. The deposition of dew was found to have been copious.

subsequently frozen into a firm mass, owing to the temperature of the stone or rock. Ice of this kind extended in a few places eighteen inches from the shore, and lay three or four inches below the level of the surface of the water, and did not dissolve nearly so rapidly as that deposited upon stones more distant from the shore.

Ice in Polar Regions results from freezing of fresh and salt water.

(730.) But the great seat of Ice is in the Polar Regions, and the immense depositaries there found, owe their origin to two very different sources,—the congelation of *fresh* and of *salt* water. So early as August, snow begins to fall, and the abundant formations of a Polar Winter, will again be partially melted by the transient vigour of the Summer Sun. The clear water resulting from the dissolution, by descending from all the higher parts of the land, will be collected along the shores, and in the deep bays which more or less fringe the inhospitable coasts. In those succeeding Winter, this water, governed by the ordinary laws of crystallization, becomes frozen; and as year after year, the same circle of changes goes on, the increment, however feeble, must, in the long lapse of Ages, produce masses of enormous magnitude and grandeur. It is remarkable, however, that the formation of these stupendous blocks, should take place in a locality, where powerful causes are in operation to prevent their unlimited increase. The action of the sea, whether silent and unobserved, or whether disturbed by the fury of the Polar winds, must gradually undermine the Icy mountains, until large avalanches descend into the abyss below.

Formation of Icebergs.

Freezing of salt water.

(731.) Sea water, on the contrary, is incapable of producing masses of this kind; nor does the crystallizing power begin, until the temperature has sunk five degrees below the freezing point of fresh water. Such a depression of temperature, however, soon takes place on the decline of Summer; and in a single night, a wide expanse of sea becomes frozen. As the Winter advances, the depth of this Ice is increased to several feet. On the return of the Solar rays, the icy floor gradually melts, and the swell of the Ocean breaks up the enormous fields into fragments, which rapidly disappear. This commonly takes place in June. The Ice from salt water differs in many very remarkable points from that produced by fresh water. While the latter is hard and pellucid, the former is whitish, porous, and almost opake. The difference in their Specific Gravities also is so great, that while the Saline Ice projects only one-fiftieth part above the surface, the Fresh-water Ice is raised one-tenth.

Different appearances of Ice of fresh and salt water.

Limits to indefinite increase of Ice in Polar Regions.

(732.) Nature appears to have set some bounds to the unlimited increase of Ice in the Polar seas. The formation of Icebergs is one powerful cause, and there are probably others in activity tending to the same end. The quantities formed in different years, may indeed be very unequal, but there seems something like a mean limit, between which the oscillations are performed. Meteorology is not sufficiently advanced to disclose this fact, but we may gather it from the memorials of Astronomy. "A continued accumulation of Ice," says Leslie, "would have occasioned a prolongation of the day;"* whereas we know that, from the time of Hipparchus, the duration of the Earth's rotation has not changed a single second in a year.

Mists and Fogs.

Causes.

(733.) Mists and Fogs owe their origin not only to the simple humidity of the air, and to the unequal temperature of its different masses, according to the theory of Hutton before explained, but also occasionally to the union of the vapours arising from the Earth and from marshy plains, the enormous combustion of coal and gas, and other causes of a like kind.

Application of the theory of Hutton.

(734.) In considering humidity alone as a cause of Mists, the examples best calculated to explain them are to be found in those peculiar to rivers.

(735.) The general surface of the Earth, as we have already seen, loses heat by radiation, as soon as the Sun disappears, but the land and water cool in very different degrees. The cooling of the land is limited to the surface, and transmitted but slowly to the interior; whereas in water of a temperature higher than 45°, the upper stratum, as soon as it is cooled, whether by radiation or evaporation, must sink in the mass of fluid, and its place be supplied by warmer water from below; and till the temperature of the whole mass is reduced to the point of maximum density, the surface cannot be the coolest part. Hence it follows, that wherever water exists in considerable masses, and has a temperature nearly the same as the land, or only a few degrees below it, and above 45° at sunset, its surface during the night, in clear and serene weather, will be warmer than that of the contiguous land; and the air above the land will become colder than that above the water; and when they both contain their due proportions of aqueous vapour, and the situation of the ground is such as to permit the cold air from the land to mix with the warmer air above the water, Mist or Fog will be the result. The density of such Mist or Fog will, moreover, be greater as the land surrounding the water is higher, and its depth and temperature greater. These views, first given by the late Sir H. Davy in the *Philosophical Transactions* for 1819, afford, by the experimental evidence on which they are grounded, another strong and convincing proof in favour of the theory of Dr. Hutton.

Views of Sir H. Davy.

Mists on the Danube.

(736.) On the 9th, 10th and 11th of June, the illustrious Chemist just adverted to, found, that the appearance of Mist above the Danube in the evening, uniformly coincided with the diminution of the temperature of the air from three to six degrees *below* that of the river; and the disappearance of Fog in the morning, as constantly resulted from the elevation of the temperature of the air *above* that of the river. Below Passau, where the Danube is joined by the Inn and the Ilz, the temperatures of the three rivers, at six A. M., were respectively 62°, 56°.5, and 56°, the temperature of the atmosphere on the banks, where the three streams mingled, being 54°. At that moment the whole surface of the Danube was covered with a thick Fog; the Inn had a slight Mist, and the Ilz a haziness, indicating the liberation of only a small quantity of moisture. About 100 yards below the place where the three rivers joined, the temperature of the central part of the Danube was 59°, and there the quantity of Mist was less than on the bed of the Danube before the junction; but half a mile lower, the warmer water had again found its place at the surface, and the Mist was as copious as before the union of the rivers.

(737.) Similar results were obtained by Davy in passing along the Rhine from Cologne to Coblentz, on

---

* *Edinburgh Cabinet Library. Polar Seas and Regions,*—an interesting and valuable Work.

Mists on the Rhine and other rivers.

Mists on the Tamar.

the Raab, near Kermond in Hungary, in July; on the Save, in Carniola, in August; on the Ironzo, in Friuli, in the middle of September; on the Po, near Ferrara, in the end of September; and repeatedly on the Tiber, and on the small lakes in the Campagna of Rome, in the beginning of October; and he remarks, that in no instance was Mist formed on a river or lake, when the temperature of the water was *lower* than that of the air, even when the atmosphere was saturated with vapour. An example tending to confirm these results, occurred on an excursion to the Morwell Rocks on the river Tamar. The river near that place is exceedingly circuitous, and it was remarked, that the Mist accommodated itself to all the turns and windings of the channel; thus affording an instance of the well-defined limits which proper circumstances of temperature impart. An attempt to represent this very interesting appearance has been made in fig. 1. plate viii. The following observations were made at the time.

Time.	Temperature of the River.	Temperature of the Air 6 feet above the River.	Mean Temperature of the Land on the borders of the River.	Temperature of the Air 6 feet above the Banks.
August 27th, 9 P. M.	56°	47½°	45°	49°

Limits of Mist confined to surface of the stream.

Mist exhibited appearance of pure wool.

(738.) These temperatures confirm in every way the views of Davy. The warmth of the water being greater than the air above it, was the cause why Mist was formed on the river; and the temperature of the banks being below that of the air which covered them, was also the reason why the limits of the Mist were confined to the actual surface of the stream. Fig. 2 is an example which confirmed the same fact; but the sketch is intended only to illustrate the upper boundary of the Mist above the trees, and which seemed as if formed of enormous packs of pure wool. The same beautiful whiteness was perceptible between the trunks of the trees, and formed a fine contrast to the Autumnal foliage.

Increase depends on continued action of first cause of radiation of heat from particles of water composing the Mist.

(739.) After Mists have been formed above rivers and lakes, their increase seems to depend not only upon the continued operation of the cause which originally produced them, but likewise upon the radiation of heat from the superficial particles of water composing the Mist. This cause must produce a descending current of cold air in the very body of the Mist, whilst the warmer water continues to send up vapour.

Cause of Mists rising above surrounding hills.

(740.) It is to the same circumstance also, that the phenomenon must be ascribed of Mists from a river, or lake, sometimes rising considerably above the surrounding hills. Sir H. Davy often witnessed this appearance during the month of October, after clear and serene nights, in the Campagna of Rome above the Tiber, and on Monte Albano, over the lakes existing in the ancient craters of that extinguished volcano. In one instance indeed, on the 17th of October before sunrise, the atmosphere being entirely calm, a dense, white cloud of a pyramidal form was seen on the site of the Alban Lake, rising far above the highest peak of the mountain. Its form gradually changed after sunrise, the summit first disappearing, and the whole body at last melting away in the sun beams.

Mists rarel form upon rivers springing from rock having mean tem perature c climate.

(741.) In cases where rivers springing from the interior of rocks, or strata, have the mean temperature of the climate in which they are found, Mists can rarely form upon them, excepting early in Spring, late in the Autumn, or during the Winter. In passing across the Apennines, the 1st, 2d, and 3d of October, Davy observed the beds of all the rivers in the valleys filled with Mist, morning and evening, excepting that of the Clitumnus near its source, which is a limestone bed; and when he examined it at 6½ A. M., on the day last mentioned, its temperature was found 7½° lower than the air.

Current of dry air passing across a riv prevents Mist.

(742.) Great dryness in the air, or a current of dry air passing across a river, will prevent the formation of Mist, even when the temperature of the water is much higher than the air. Thus on the 14th of June, near Mautern, though the Danube at five in the morning indicated 61°, and the atmosphere was 7° less, no Mist was perceived; but at the time of observation, a strong and very dry Easterly wind prevailed.

Mists foun in mornin when diffi ence of te perature o air and water amounts only to on degree.

(743.) It may be proper to add, that Mists are sometimes found in the morning, when the difference in the temperatures of the water and the air amounts only to a single degree, although to produce it, according to Sir H. Davy, the air must be cooled from three to six degrees *below* the temperature of the water.

Depositio of dew mu always pr cede Mist

(744.) The deposition of dew on land must always precede the formation of Mist on water. Suppose at some moment an equality of temperature to take place between the land, the water, and the air reposing over each. When the process of cooling commences, the former will *first* have its temperature reduced below that of the air; and although by this diminution the equality of temperature between the two volumes of air will be destroyed, and a condition favourable to the formation of Mist be created, still, as the cooling of the first volume and the mingling of the two are not contemporaneous, dew will be first deposited.

Rapid fo mation o dew favo able to qu formatio Mist.

(745.) In proportion, however, as the land radiates freely, with the same rapidity must the temperature of the superincumbent air be diminished, and the equilibrium between it and the atmosphere hovering over the water be disturbed. The rapid formation of dew is therefore accompanied by circumstances favourable to the quick formation of Mist; and it hence becomes probable, that, under such conditions, Mist will be formed at an earlier period of the night than when the land radiates less copiously, and dew,—the moisture in the air remaining the same, be deposited in less abundance.

Effect of clouds.

(746.) If in consequence of the interposition of clouds, the cooling of the land and water should be checked, and an equality of temperature be restored between the two masses of air, and the bodies on which they respectively repose, the deposition of dew will be suspended, and likewise all tendency to the further formation of Mist. The entire dissipation of the latter also may result from the change.

Dew an Mist ar formed former of nigh and bot disappe before mornin

(747.) It is sometimes the case that dew and Mist are both deposited in the former part of the night, and both disappear before morning; or, the former may be preserved, and the latter dispersed. The first of these phenomena may occur, when a portion of the night, favourable both to the formation of Mist and dew, is succeeded by a brisk wind; and the second, when by the interposition of dense clouds, the temperature of the land, and the atmosphere over it is raised, so as to render the latter equal or superior in temperature to that of the air over the water, thereby causing the Mist to disappear, from the increased capacity of the air for vapour. This latter circumstance will moreover account for the dispersion of Mists in the morning, before the disappearance of dew.

Mists in Ceylon of great density.

(748.) Dr. Davy, in his Work on Ceylon, remarks, that in the deep, moist valleys among the mountains of that island, Mists are very often formed of astonishing density, and resemble an expanse of water so much, that, to a spectator in the clear, cool air on a mountain above, were he ignorant of the features of the country, they would appear to be real lakes. Occasionally after sunrise, these Mists, formed in the higher mountain hollows, are displaced by the wind, and poured in immense volumes down into the warmer valleys, producing a sudden chill, and a disagreeable humidity of the air.

Arctic Regions peculiar abode of Mists.

(749.) But the Arctic Regions seem the peculiar abode of Mists and Fogs. Before the end of June, the shoals of ice covering those inhospitable regions, are commonly broken and scattered, the temperature of the Ocean being greater than that of the frozen masses. The cooling influence of these masses, in consequence of their elevation above the sea, will be diffused, not only by radiations from their upper surfaces to the sky above, but also by horizontal radiations to the air surrounding their sides; and so powerful are those radiations, that "navigators generally feel a cold stream of air from an iceberg long before it is seen."* A volume of the atmosphere, therefore, between two neighbouring masses of ice, must necessarily have its middle portion of a higher temperature than that of either of the portions of air between it and the icebergs;† and the consequence of such an unequal distribution of temperature must be, to cause the cold air to mingle with that of a higher temperature, and thus to produce Mist or Fog.

Horizontal radiation of icy masses.

Effects on intervening air.

Elevation of these Mists regulated by icebergs.

(750.) The elevation of these Mists above the surface of the sea will also be regulated by that of the icebergs near which they form; since the cooling influence of the frozen masses, by its rapid diminution above their summits, will as rapidly destroy all tendency in the atmosphere reposing on them to assume a condition favourable to Mist. A limit is thus prescribed to the elevation of Mists, governed by the height of the icebergs near which they are formed. Accordingly, Captain Ross remarks, "that the Fog was extremely thick on the surface of the sea, but at the mast head, and at the top of the iceberg, it was perfectly clear." Mr. Scoresby also, in his Paper on Fogs, read before the Wernerian Society, alludes to their definite elevation, and to the sky above being perfectly clear.

Fogs surround Terra del Fuego.

(751.) Fogs of great density prevail also in the sea which surrounds Terra del Fuego. Don Antonio de Ulloa says, in his Letter to Marian, that in sailing round Cape Horn, he found only a few moments when he could obtain a slight glance of the sky. It must not be inferred, however, from hence, that Fogs *constantly* prevail in those regions.

(752.) Van Mons, in his interesting Paper on Mists, (*Nouv. Mémoires de l'Acad. Roy. des Sciences et Belles Lettres de Bruxelles*, tom iv. p. 371,) divides them into dry, humid, and mixed. Dry Mists are either sweet scented, or have a fetid smell. The odour of dry, white Mists, however, is very different from that of coloured Mists. Dry Mists are either white, bluish, dusky-brown, or lilac. The deeper their colour, the stronger is their odour.

Mists in Belgium, dry, humid, and mixed.

Odour of Mists.

Colours.

Humid Mists of two kinds.

(753.) Humid Mists are either visible or invisible, and moisten all bodies. Visible humid Mists, without being odorous, are cold. Invisible humid Mists are not odorous.

Mixed Mists of various kinds.

(754.) Mixed Mists are of various kinds. Some arise from a mixture of two dry Mists, others from a humid Mist mingled with one of a dry kind. Van Mons thinks there is never a junction of an invisible humid Mist with one of a dry kind. Mixed Mists retire successively, one of the two disappearing after the other. They are moist and fetid at the same time.

(755.) A visible humid Mist mingled with a dry Mist of a white kind, produces one of a yellowish colour. This colour is most remarkable by night.

Dry and fetid Mists with Easterly winds.

Odorous Mists with a North wind.

(756.) These remarks apply to the phenomena of Mists in Belgium. Dry and fetid Mists occur there during Easterly winds, and Mists simply odorous during a North wind. Their appearance seems confined to particular localities, and masses may be observed at intervals from each other, in the direction of the wind. Fetid Mists are most frequent there in Spring and Autumn, and at the approach of the solstices, though they may be remarked at all seasons.

Their localities.

Fetid Mists disappear towards noon.

(757.) Fetid Mists, though often appearing in the morning and evening, generally disappear towards noon. When Mists occur in the elevated parts of the atmosphere, their colour becomes sensible before their odour. They are seen thus suspended for a day or two.

Indications of Mists.

(758.) In Belgium, a fetid Mist in Spring or in Summer indicates a dry and hot season. In Autumn it presages storms, and in Winter hard frost.

Dense Fogs common to large towns. Examples, London, Amsterdam, and Paris.

(759.) Dense Fogs seem common to large cities, and have been remarked in Winter, in perfectly calm weather. On the 16th of January, 1826, a Fog was so great in London, that no part of St. Paul's could be seen from the Western railing. The city presented a scene of desolation, and all the manufactories and shops employed their full complement of lights. Trade was universally interrupted. At the time this occurred, the environs of the city enjoyed a beautifully clear sky. In the great Fog which happened at Amsterdam on the last day of the year 1790, the people ran against each other, even though they had lights in their hands. Two hundred and thirty persons were drowned by falling into the canals. Their cries were heard, but people were afraid to advance to their relief. At Paris on the 12th of November, 1797, a great Fog commenced in the afternoon. The obscurity was so great, that persons lost their way completely in the streets, as if they had been blind. It was necessary to be near a very brilliant light, to perceive a faint trace of it. Fourcroy, who described this extraordinary Fog in the *Journal de la Société des Pharmaciens de Paris*, states that it showed itself in spiral groups like cork-screws, and that it had a remarkable taste.

Simultaneous appearance of Fog in different cities.

(760.) The appearance of Fogs in different cities is frequently simultaneous. At the time a great Fog prevailed in London, Dublin was enveloped in one of equal density. Fogs have been known also to precede a

---

* *Quarterly Review*, No. xxxvi. p. 448.

† If the water in the vicinity of the icebergs presents considerable inequalities of temperature, the air which reposes on it must be subject to like variations. Captain Franklin remarks, that "the temperature of the surface water was 35° when among the ice, 38° when just clear of it, and 41°.5 at two miles distant;" and there are differences of temperature here sufficient to form Mist abundantly.

strong Westerly wind at Manchester, London, and Paris, and by nearly the same short interval of time at each station.

Cause of these Fogs according to M. Defrance.

(761.) M. Defrance, in a Paper in the *Annales de Chimie*, tom xxxiii., has endeavoured to account for the origin of these Fogs. On some days of Winter, he says, the smoke of village chimneys instead of being elevated in the air, and dissipated in the usual manner, is thrown back again on the ground, and moves over its surface. When this takes place, a current of air has been observed to descend through chimneys which have no fire, producing in the apartments a strong odour of soot, proving the action of descending currents in the atmosphere.* If, therefore, we suppose one or two hundred thousand chimneys to discharge their smoke into the air, and to become mingled with the aqueous vapour, and by the action of currents forced again to descend, a dense Fog like those already described, ought necessarily to happen.

Quantity of moisture deposited by Fogs of this kind.

(762.) The quantity of moisture sometimes deposited by Fogs of this kind, is very remarkable, particularly as no motion is perceptible in them. Dr. Thomson recorded one in 1814, which continued a week, covering London and the country for miles around. It appeared *without visible motion*, and deposited moisture in the greatest abundance. The low temperature, 27°, occasioned, however, some crystalline depositions on the trees, and which were remarked by an ingenious observer, to be *four times thicker on one side than on the other*. Such an excess implied motion, and Thomson inferred from it that six atmospheres must have passed over a given surface in a single day, at the rate of a mile in four hours, and forty-two atmospheres during the whole continuance of the Mist. Copious Mists accompany the setting in of long frosts.

Mists accompany long frosts.

Colours of Mists in this Country.

(763.) Mists have also peculiar colours in this Country. Howard has seen some of a perfect rose colour in the Western horizon, in March and June. One in January also, chiefly of an indigo-blue, but passing below into opake-white, and above into a faint transparent red. Another in May of a transparent brownish-red colour, which gave a pink tinge to the twilight. Daniell mentions also the case of a Mist in London, in August, through which the Sun appeared of a pale blue colour, resembling the flame of Sulphur. The same was observed in Essex and Worcestershire, and Howard saw it in Sussex from nine till near noon, and describes it as of the colour of watch-spring steel.

Mists at Malta.

(764.) When Mists prevail in the neighbourhood of Malta, a particular tinge in the Mist is instantly recognised by the mariners of those seas, as an index of the Island.

Hansteen's idea of cause of Mists.

(765.) Professor Hansteen attributes the formation of Mists to the Polar Lights. The electrical meteors penetrate, he thinks, the vapour of the air, depriving it of its heat, and rendering it opake. When the streamers are flowing, he says, the sky has a tendency to become opake and misty.

Splendid Mist at Cape of Good Hope.

(766.) The great bank of the Lagullas near the Cape of Good Hope has been minutely described by the learned accuracy of Rennel; but Dr. John Davy was the first to trace its effect in promoting that curious condensation of Mist on the Table Mountain, called in the language of the Mariner, "The Table Cloth." On the borders of the bank, the current is strongest, the temperature of the water being at least ten degrees above the neighbouring sea. Such a difference, the Doctor remarks, must produce an effect on the superincumbent air. When a South-East wind blows, it mingles with the warmer air over the bank, the resulting vapour being carried forward to the land. Davy saw it once advancing rapidly over the sea, which it entirely concealed, while the air above was perfectly clear. As soon as it reached the land, it spread gradually along the coast, ascending the mountain and enveloping its summit. There undergoing a further condensation, by the cold contact of the mountain, it descends on the opposite side, and overhangs Cape Town. According to the observations of the Rev. William Hennah, from the Harbour of Rio Janeiro a dry silvery Mist may often be seen creeping down the valleys from the higher land. It begins to form at sunset, and the next morning the whole harbour is densely covered with it.

Mists at Rio Jane

Varied example Mist on hills for- ing Harbour of mouth.

(767.) Many beautiful condensations, but upon a less grander scale, are frequently to be met with on the sea-coast of England. The opposite hills which form the Harbour of Plymouth, and between which the Breakwater lies,—shown by the dark line in the figures of plate ix., afford frequent examples of the kind. Denoting the hill on the left hand by A, the projecting cape in the middle with the tower on it by B, and the wooded mount by C, we shall perceive in fig. 1 a considerable condensation on A, which took place July 22, at 5 P. M., but only a slight condensation on B. Half an hour later, fig. 2 exhibited the appearance of A the same, but on B the Mist had deepened, and encroached partly on C. In fig. 3, the observations being at 6 P. M., the Mist had enlarged on A, but completely enveloped B; on C it had shortened, but increased in altitude. In fig. 4, half an hour later, the appearance of A was the same, and B was enveloped, but with a less elevation of Mist. The portion of Mist on C, which appeared in contact with B in fig. 3, though not really so from the actual locality of the hills, was transferred considerably to the right, leaving the beautiful woody promontory quite clear. The next day at 3 P. M., a continued band of Mist appeared from one headland to the other, at a less altitude above the sea, as in fig. 5. The bottom at A, above the water, and at B were admirably defined, but at C it dropped into beautiful festoons. The Mist disappeared in all parts at once, diminishing from the bottom upwards. The well-defined line and the broken form of the festoon were preserved to the last. The wind was South. On the 2d of June, at 8½ A. M., the form of fig. 6 was exhibited, but the upper boundary of the Mist was not uniform like the last. At 4 P. M. the Mist on A had disappeared as in fig. 7, and a dense cloud apparently reposed on the hill, which seemed to join with the Mist over the water, but the whole of B and C were completely lost in Mist. At 6 P. M. the cloud remained over A, but the Mist at C had formed with a perfectly uniform line below, as in fig. 8. Figs. 9 and 10 contain two views only of C. The former exhibits a Mist reposing on the water, with a perfectly uniform boundary above, and concealing only the *lower* half of the mount; and the latter figure discloses that portion to view, leaving the *upper* enveloped in a Mist of the most perfect uniformity above, but dropping into the most beautiful forms below;—this moment falling in graceful festoons between cedars and oaks; and in the

* A smell as of something burning, arising from this cause, has doubtless been often remarked by the reader in his house. By night it may, perhaps, have cost him some anxiety.

next, rising suddenly above elms and pines, becoming lost at last in the azure above. For two hours and a half this appearance continued, changing its form every instant, and disclosing infinite varieties of light and shade. Now and then also, tinges of red and yellow, and grey, falling on the misty forms, increased in a high degree the beauty of the scene.

(768.) No description more accurate can be given of the calm Fog, than the following from the masterly pen of the late Mr. Crabbe.

> When all you see through densest Fog is seen,
> When you can hear the fishers near at hand
> Distinctly speak, yet see not where they stand;
> Or sometimes them and not their boat discern,
> Or half-conceal'd some figure at the stern;
> Boys who, on shore, to sea the pebble cast,
> Will hear it strike against the viewless mast;
> While the stern boatman growls his fierce disdain,
> At whom he knows not, whom he threats in vain.

ON CLOUDS.

Remarks on the sky.

(769.) The sky is an object of interest under whatever point of view it be contemplated. Spread out on all sides like a splendid canopy, it presents to the eye in every clime some peculiar characteristic, in England seeming of a lower elevation than in France, and in Italy disclosing a purer and more extended scene.

Small masses of air no colour.

Viewed on a great scale is blue.

This colour augments from horizon to upper sky, and from valley to mountain top.

(770.) Contemplated in small masses, air of a perfectly dry character appears destitute of colour, nor does the presence of moisture in a state of vapour, seem in any way to alter its appearance; but on the great scale in which Nature presents it to our view, it puts on the colour of a lively blue, and we become sensible of the existence of vapour, by the increased distinctness with which distant objects are seen, and the consequent enlargement of the boundaries of the whole visible sky. At the same time, also, the intensity of colour augments by almost insensible gradations from the horizon to the upper sky; and, as the testimony of all travellers confirms, a similar augmentation takes place from the valley to the mountain-top, until the whole hemisphere puts on a deepened indigo tone.

Transparent sky rare in a climate like our own.

Causes. Formation of Clouds.

(771.) A sky perfectly transparent, however, is a phenomenon of very rare occurrence in an insular situation like our own. A variety of causes,—unequal temperatures, diversified currents, and different stores of moisture, soon compel the humidity with which the atmosphere is charged, to put on an opaque form; and rolling masses of visible Cloud are seen, exhibiting every diversity of magnitude, shadow, and form, and sometimes lights and varieties of colour more beautiful than it is in the power of language or the pencil to describe. It is then that the Heavens address a language intelligible to Man;—and which is interpreted by the Philosopher, the Poet, the Painter, the Mariner, and the Peasant, with all the varied feelings which belong to their different occupations and desires, and which Superstition herself has not failed to appropriate to some of her dark and mysterious uses.

(772.) An inquiry into the origin and phenomena of Clouds, is, therefore, far from being an unprofitable branch of Meteorological investigation. Unable to examine the actual constitution of the immense masses of vapour which diversify the sky, we are left almost entirely to the dim light of conjecture respecting them. That they are composed of drops or vesicles of some kind, seems admitted on all hands; and while the optical phenomena they present, entirely exclude the idea of these drops being solid, there is every thing in favour of their vesicular structure; that is of their being made up of innumerable small globes filled with damp air, analogous in some way to soap bubbles. Saussure in one of his Alpine journeys saw drops float slowly before him, having greater diameters than peas, and whose coating seemed inconceivably thin; and Derham, by microscopic observation, obtained very strong proofs tending to the same end. But while the existence of vesicles seems to have a high probability in its favour, there are difficulties in the way respecting their density, which merit a more extended examination.

Composed of vesicles of some kind.

Optical phenomena opposed to their being solid drops.

Probability of their being vesicular.

Seen so by Saussure and Derham.

Formation of Clouds results from union of strata of different temperatures.

(773.) Of the cause of the formation of Clouds, there seems no theory more probable than that which refers them to the union of atmospheric strata of different temperatures, unequally charged with moisture, in the same manner as we have endeavoured already to account for rain. At the time, however, in which this union takes place, electricity is evolved, disposing the watery particles to assume a vesicular form. The vesicular atoms, charged with the same kind of electricity, cause a general repulsion among all the vesicles, imparting, probably, to Clouds their peculiar forms, and preventing them from descending in the shape of rain. In what way the Clouds become charged with electricity, it is indeed difficult to say; but as electricity is evolved in the process of evaporation, there seem grounds for supposing that they are at all times more or less charged with it. Pouillet,* indeed, has endeavoured lately to overturn the theory of Volta respecting the evolution of electricity by evaporation, by showing that nothing of the kind can be traced, unless some chemical combination takes place; but the experiments of the French Philosopher clearly prove that electricity is evolved during combustion; and that the carbonic acid emitted by vegetables is charged with negative electricity, and the oxygen with positive electricity, thereby amply accounting for the vast quantities of electricity so often accumulated in the Clouds.

Vesicular atoms charged with same kind of electricity causes repulsion among particles.

Experiments of Pouillet.

Suspension of Clouds.

Density of vesicles, equal, less, and greater than air.

(774.) If the density of a Cloud were at all times on an equality with the surrounding medium, or less than it, there would be no difficulty in accounting for its suspension. The case of a stationary mass of Cloud, a phenomenon of frequent occurrence, is one that can be completely reconciled to the laws of Hydrostatics; and if the aerial matter with which the vesicles are filled, were saturated with moisture, while the medium they float in is dry, a reason becomes evident why they should be lighter than the air. In such a case, Clouds should rapidly ascend and diminish in size, by their gradual conversion into vapour, and at length vanish entirely away, independently of every consideration of distance, all of which often occur. But if we refer to the condition of vesicles whose density is greater than the air, a phenomenon which in some circumstances of the atmosphere takes place, considerable difficulties present themselves upon the very threshold of the inquiry; and accordingly many ingenious hypotheses have been contrived to account for it. Gay Lussac has had recourse to the action of warm currents, which he considers to ascend incessantly from the Earth during

---

* *Annales de Chimie et de Phys.* vol. xxxv. p. 401.

Theory of Gay Lussac.

Theory of Fresnel.

the day.* If the thinnest soap-bubble, says he, be blown in a room, it will never rise, but descend by its own weight; but if formed in the open air, above a heated soil, the rising current pushes the bubble before it, until weakened by its dilatation, or by its mingling with cooler air, the force of its impulsion is found to be in equilibrium with the air; and hence the illustrious Chemist thinks, that the aqueous vesicles may remain suspended at a considerable height, variable according to the Seasons, and greater in Summer than in Winter. To account for the same phenomenon, Fresnel imagines Clouds to be formed of minute globules of water, or very fine crystals of snow, from the extreme division of which, a very multiplied contact with the air is produced. These watery atoms, he further supposes to gain an increase of temperature from the solar and terrestrial rays, and that the air within the Cloud, and in the neighbourhood of its surface, becomes more dilated than the surrounding atmosphere, and consequently lighter. From this hypothesis it results, that the particles composing a Cloud, may be so near each other, as to leave but small intervals between them, and that the particles themselves may be even smaller than those intervals. Hence it follows, that the whole weight of water in a Cloud, forms but a small fraction of the weight of air it contains; and so minute may be this fraction, that the difference between the density of the air in the Cloud, and the air which surrounds it, shall more than compensate it. When the weight of air and water in a Cloud is less than that of an equal bulk of the surrounding air, the Cloud will ascend until it reaches a region where these two weights are in equilibrium. This height will depend on the fineness of the particles of the Cloud, and the intervals which separate them. During the night, the Clouds are of course deprived of the solar rays, and their temperature should become less, but they must still receive warm rays from the Earth; and should their thickness be very great, their temperature will but slowly diminish. Hence a cause is in activity for maintaining the suspension of Clouds by night.

Clouds often in equilibrium with the air in which they are situated.

That masses of Cloud are often in perfect equilibrium with the stratum of air in which they are situated, may be gathered from the fact, that when the mercurial column rises, the Clouds also ascend, to reach a new region which may be in equilibrium with them. The masses of smoke encircling the crater of Mount Etna, ascend and descend with the quicksilver of the barometer; and the motion of the smoke even predicts to the Philosophic Observer, the kind of change going on in the mercurial column.

Great di versities among Clouds.

(775.) A very slight attention to the appearances of the sky will prove great diversities of character to exist among the Clouds which cover it; that there are some Clouds peculiar to one region and some to another; and that among them there are varieties of density and varieties of form; and that some system of classification was called for "to enable the Meteorologist," as Howard expresses it, "to apply the key of analysis to the experience of others, as well as to record his own with brevity and precision." This is what that distinguished Meteorologist accomplished in his admirable nomenclature of the various modifications of Cloud.

Howard' classifica tion of them.

Clouds were divided by Howard into seven modifications, three of which he regards as primary, two as intermediate, and two as compound. They are as follows:

Primary Modifications.

Cirrus.

1. CIRRUS. *Def. Nubes cirrata, tenuissima, quæ undique crescat.* Plate x. fig. *a.*
   Parallel, flexuous, or diverging fibres, extensible in any or in all directions.

Cumulus

2. CUMULUS. *Def. Nubes cumulata, densa, sursum crescens.* Plate x. fig. *b.*
   Convex or conical heaps, increasing upward from a horizontal base.

Stratus.

3. STRATUS. *Def. Nubes strata, aquæ modo expansa, deorsum crescens.*
   A widely extended, continuous, horizontal sheet, increasing from below. Plate x. fig. *c.*

Intermediate Modifications.

Cirro Cumulu

1. CIRRO CUMULUS. *Def. Nubeculæ densiores subrotundæ et quasi in agmine appositæ.*
   Small, well-defined, roundish masses, in close horizontal arrangement. Plate x. fig. *d.*

Cirro Stratus.

2. CIRRO STRATUS. *Def. Nubes extenuata subconcava vel undulata. Nubeculæ hujus modi appositæ.*
   Horizontal or slightly inclined masses, attenuated towards a part or the whole of their circumference, bent downward, or undulated, separate, or in groups, consisting of small Clouds having these characters. Plate x. fig. *e.*

Compound Modifications.

Cumulo Stratus.

1. CUMULO STRATUS. *Def. Nubes densa, basim planam undique supercrescens, vel cujus moles longinqua videtur partim plana partim cumulata.*
   The Cirro stratus blended with the Cumulus, and either appearing intermixed with the heaps of the latter, or superadding a wide spread structure to its base. Plate x. fig. *f.*

Nimbus.

2. CUMULO CIRRO STRATUS *vel* NIMBUS. *Def. Nubes vel nubium congeries pluviam effundens.*
   The Rain Cloud. A Cloud, or system of Clouds, from which rain is falling. It is a horizontal sheet, above which the Cirrus spreads, while the Cumulus enters it laterally and from beneath. Plate x. fig. *g.*

These are the original definitions and figures given by Howard in his celebrated Essay read before the Askesian Society in 1802-3, and are here introduced as standards of reference.

---

* A beautiful example of the action of the currents here referred to is to be found in the case of the spiders that produce gossamer. "Apparently actuated by the same impulse," observes Mr. Blackwall, in a most interesting Paper in the XVth volume of the *Linnæan Transactions*, "all the spiders were intent upon traversing the regions of the air. Accordingly, after gaining the summits of various objects, as blades of grass, stubble, rails, gates, &c. by the slow and laborious process of climbing, they raised themselves still higher by straightening their limbs, and elevating the abdomen, by bringing it from the usual horizontal position into one almost perpendicular, they emitted from their spinning apparatus a small quantity of the glutinous secretion with which they construct their webs. This viscous substance being drawn out by the ascending current of rarefied air into fine lines several feet in length, was *carried upward, until the spiders feeling themselves acted upon with sufficient force in that direction, quitted their hold of the objects on which they stood, and commenced their journey by mounting aloft.*"

In what manner Howard limits the term modification.

(776.) The term "Modification" is limited by Howard to the structure or manner of aggregation of a given mass of Cloud, and not its precise form or magnitude, which in most Clouds varies every instant. To the young Meteorologist, it may be at first difficult to distinguish one modification from another, or to trace the narrow limits which sometimes separate the different modifications; but a moderate acquaintance with the subject, will soon enable him to distinguish the varieties as readily, to adopt the language of Howard, "as a tree from a hill, or the latter from a lake; although Clouds in the same modification considered with respect to each other, have only the common resemblance which exists among trees, hills, or lakes, taken generally"

The Cirrus exhibits an unbounded variety.

(777.) The Clouds belonging to the first primary modification exhibit an unbounded variety, and in some conditions of the atmosphere may be observed to undergo perpetual changes. The Cirrus is always to be found in the loftiest regions of the sky, from the smallness of its density, and is the first to be met with in serene weather. Its earliest traces are indicated by fine whitish threads delicately pencilled on a clear blue sky, and as they are augmented in length, others are frequently added laterally. The first-formed threads often serve as stems to support numerous branches, which in their turn give rise to others, sometimes propagated either in one or more directions laterally, or obliquely upward or downward, the same direction often prevailing in a great number of Clouds visible at the same time. Transverse lines are often formed, which, intersecting those in an opposite direction, give to the sky the appearance of delicate network. When the weather is dry, the Cirrus exhibits a more fibrous texture than when it is damp; and whatever may be its figure, its extremities are always fine evanescent points. When the air is damp, it is seen in the intervals of rain, badly defined, and of a less fibrous structure. Cirri of this kind are generally of short duration, and have a great tendency to change into the other modifications. There is often a haziness in the atmosphere when they appear, and they are frequently soon followed by rain.

Earliest traces.

Different examples

Great elevation.

(778.) The great elevation of these Clouds, when formed in their ordinary state, has been ascertained both by trigonometrical observations, and by viewing them from the summits of the highest mountains, where they appear as when seen from the plain. Howard infers their great elevation by noting the time during which they continue to reflect the different coloured rays after sunset, and which they do much longer than any others.

Its continuance very uncertain.

(779.) The continuance of this modification is very uncertain, varying from a few minutes to many hours. The same configuration of Cirrus has been observed in the same quarter of the sky, even for two successive days, during which a smart breeze from the opposite quarter prevailed below. When in the vicinity of other Clouds, their duration is the shortest. Although in appearance almost stationary, they are intimately connected with the variable motions of the air. In fair weather, with light variable breezes, the sky is seldom quite clear of small groups of the oblique Cirrus. These frequently come on from the leeward, the direction of their increase being to windward. Continued wet weather is attended with horizontal sheets of this Cloud, which subside quickly, passing into the Cirro Stratus. Before storms they appear at lower elevations, with a denser character, and generally in the quarter opposite to that from which the storm arises. Steady high winds also are preceded and attended by streaks running quite across the sky in the direction they blow in. Howard observed a Cirrus consisting of many light tufts of a sort of horseshoe figure, rising one above the other. The Cirrus gives every appearance of being a conductor of the electric fluid. Its texture seems to indicate this office, the long parallel and elevated lines which distinguish it being probably employed in equalizing the electricity of remote masses of air. The buoyancy of the Cirrus seems most perfect during its first increase. Many diversified examples of Cirri may be seen in plates xi. and xii.

When in vicinity of other Clouds its duration shortest. Other remarks on the modification.

Dense structure of Cumulus.

(780.) Clouds of the second primary modification are commonly of a very dense structure, and hence are found in the lower regions of the sky, moving gently along with the current next the Earth. Their silent and gradual formation discloses many interesting phenomena. A small but irregular cloud first appears, which sometimes changes into a nearly hemispherical mass, and sometimes rises into mountains of stupendous magnitude and beauty, disclosing summits tipped with the brightest silver. During these transitions, the lower surface of the Cloud continues irregularly plane; and whether the cloudy masses are few or many, their bases always lie nearly in one horizontal plane. Their increase appears to bear at all times a relation to the extent of their bases, and has an evident reference to their mechanical stability. The growth of a Cumulus is a most interesting phenomenon. The shaded mass of Cloud in fig. 3, plate viii. represents a finely formed Cumulus as it appeared at ten A. M. on a calm and brilliant day in July; and the differently dotted outlines surrounding it, show the successive changes of figure it underwent, during six consecutive intervals of five minutes each.*

Characteristics of the Cloud.

Its formation during the day.

(781.) In fair weather, the Cumulus is generally first seen to form some hours after sunrise, to go on augmenting to the hottest part of the day, from which point it declines, and totally disperses about sunset. But while the ordinary variations of temperature in fine and tranquil weather, seem to impress on this modification of Cloud a system of analogous changes, the more variable conditions of the atmosphere impart all their own unsteady influence to them. In such cases they sometimes disappear almost as soon as formed, while in others, they are no sooner formed, than they pass into one of the modifications of a compound kind.

The Cumulus peculiar to fair weather.

(782.) The Cumulus peculiar to fair weather has a moderate elevation and extent, and a rounded surface of a well-defined kind. Before rain it augments with great rapidity, and sinks to a lower elevation, becoming fleecy and irregular in its appearance, and with its surface full of protuberances.

Cumuli during a strong wind.

(783.) The formation of large Cumuli to leeward during a strong wind, indicates the approach of a calm with rain. When they do not disappear about sunset, but continue to rise, thunder may be expected during the night. Forster remarks, that when a Cumulus,

---

* And now the mists from Earth are Clouds in Heaven;
Clouds slowly castellating in a calm
Sublimer than a storm; while brighter breathes
O'er the whole firmament the breadth of blue,
Because of that excessive purity
Of all those hanging snow-white palaces,
A gentle contrast, but with power divine.
WILSON.

moving with the wind, has from any cause altered to the Cumulo Stratus, the change has been uniformly attended with a retardation of the motion of the Cloud.

Cumulus performs an important part in the economy of Nature.

(784.) The Cumulus appears to perform an important part in the economy of Nature. While it screens the Earth from the direct rays of the Sun, it diffuses the solar light by its multiplied reflections, and conveys, moreover, immense stores of vapour from the place of its origin, to a region in which humidity may be wanted. Several examples of this Cloud are given in plates xi. and xii.

The Stratus properly the Cloud of night.

(785.) The Stratus, or third primary modification, has its inferior surface resting commonly on the Earth or water. It is properly the Cloud of night, and makes its first appearance about sunset. It comprehends all those creeping mists, which on tranquil evenings ascend in spreading sheets, like inundations of water, from the bottoms of valleys and the surfaces of lakes and rivers. It continues frequently through the night; but on the return of the Sun, its beautiful level surface puts on the appearance of a Cumulus, the whole mass rising at the same time from the ground. The continuity of the Cloud is at length broken, and it ascends and passes away with the appearance of the nascent Cumulus. The Stratus has long been regarded as the harbinger of fine weather. There are few days in the year more calm and serene than those whose morning breaks out through a Stratus. In the New World the most magnificent examples of the Stratus occur. Humboldt mentions one which filled the Valley of Caraccas. It appeared to be full of water, and seemed to be an arm of the sea, of which the adjacent mountains formed the steep shore.

An example of a Stratus is given in plate xi. with a nascent Cumulus above it.

Formation of the Cirro Cumulus. Its beautiful changes.

(786.) In passing to the consideration of the intermediate modifications, the formation of the Cirro Cumulus will be found to disclose the most beautiful system of changes. The Cirrus having remained for some time stationary in its proper region of the upper sky, increases at length in size, which is followed by its descent into a lower region of the air, where it puts on a new character, from the collapsing of its fibres, and its passage into small roundish masses, in which its original texture can no longer be traced. This change of condition takes place, either throughout its whole mass at once, or progressively from one extremity of the cloudy mass to the other; and the same effects may be traced with great uniformity in a number of adjacent Cirri at the same time, and in the same order. In some instances these changes seem to be accelerated by the approach of other Clouds.

Beautiful appearances also when disposed in beds.

(787.) The sky presents a very interesting appearance when several beds of these small connected Clouds are seen floating at different altitudes. These diminish as the eye follows them into the blue expanse. The Cirro Cumulus is frequent in Summer, and is attendant on warm and dry weather. On a fine Summer's evening, the nubeculæ which compose this Cloud are often large, well defined, and detached from each other. The whole sky is sometimes covered with them. This Cloud is also occasionally, but more rarely, seen in the intervals of showers, and in Winter. It either disappears in the region in which it is formed, or by ascending in the atmosphere, reassumes its original condition of a Cirrus; or conversely, by sinking lower in the sky, puts on the form of the Cirro Stratus. In stormy weather, previous to thunder, a Cirro Cumulus often appears, composed of very dense and compact round bodies in very close arrangement. When accompanied by the Cumulo Stratus, it is a sure indication of a coming storm. Examples of the Cirro Cumulus are given in plates xi. and xii.

The Cirr Stratus.

(788.) The Cirro Stratus appears to result from the subsidence of the fibres of the Cirrus to a horizontal position, at the same time that they make a lateral approach to each other. Its figure is very variable, sometimes consisting of dense longitudinal streaks; and at other times, when seen in the distance, it puts on the appearance of shoals of fish. Sometimes the whole sky is so mottled with this kind of Cloud, as to obtain for it the name of the Mackerel-back Sky, from its great resemblance to the back of that fish. It sometimes assumes an arrangement like discs piled obliquely on each other. Frequently it appears like parallel bars, and at other times with interwoven streaks like the grain of polished wood, the structure of the Cloud inviting attention rather than the form. In other cases this Cloud is spread out into plane horizontal sheets, more or less dense. It is always thickest in the middle, or at one extremity, but diminishes towards the edge. There is a variety of the Cloud which presents the appearance of the Cyma in Architecture.

Variable figure.

Mackerel back sky

Cirro Stratus p cedes wi and rain

(789.) The Cirro Stratus precedes wind and rain, and the approach of foul weather may sometimes be inferred from its greater or less abundance, and the permanent character it puts on. This Cloud is almost constantly to be seen in the intervals of storms. The waved Cirro Stratus indicates heat and thunder. Sometimes the Cirro Stratus and the Cirro Cumulus appear together in the sky; and they are even seen to alternate with each other in the same Cloud. During these transitions, a multitude of beautiful phenomena are presented to the observer, and some opinion of the weather likely to ensue may be formed, from the modification which at last prevails.

Alternat with Ci Cumulu

Cirro S tus exhi optical p nomena

(790.) The Cirro Stratus is the Cloud which commonly exhibits the beautiful phenomena of the solar and lunar halo; and by inferences drawn from a few observations, the parhelion and paraselene also. Hence the reason of the prognostic for rain and tempestuous weather commonly drawn from the halo.

Examples of Cirro Stratus are given in the plates last referred to.

Cumulo Stratus,

(791.) The Cumulo Stratus, the first of the compound modifications, occupies a sort of middle state between the Cumulus and rain, and hence in a variable climate like our own, it is by far the most common Cloud both in changeable and very fine weather. The Cumulus seldom preserves its original character long, when the vapour surrounding it is in any excess. In such a case, it either expands spontaneously as it rises, into a spreading crown, with occasional irregular protuberances which overhang its base in uneven or rugged folds, or it unites with the superior modifications already formed by their descending on it. Sometimes this class of Cloud gains additions by lateral increase, from Cirro Strati floating in the same region, or by the union of loose portions of its own kind; and compounds are formed of different kinds, all of which are comprised in this modification. Banks and ranges of Cloud, therefore, of every description, presenting a flattish surface and bounded by vertical or overhanging cliffs, are to be referred to the Cumulo Stratus. Wherever, amidst the light and shade which diversify the magnificent scenery

a Cloud very co monly

Gains a tions b Cirro S

Magnificent aerial scenery presented by it.

of the sky, there is what the artist terms a recess tint, it may be presumed to result from some combinations peculiar to this modification. Trees and towers, magnificent ruins and glaciers, natural bridges and other diversified scenes, which are sometimes fancied in the Clouds, are in general parts of the same arrangement.[*] Before thunderstorms it seems frequently reddish.

Cumulo Stratus seen in profile.

Beautiful form.

(792.) A Cumulo Stratus, well formed and seen singly in profile, is quite as beautiful an object as the Cumulus. Its form, in general, may be compared to a *Boletus*, or to a fungus having a very thick stem and protuberant gills. Howard has occasionally seen specimens constructed almost as finely as a Corinthian capital, the summit throwing a well-defined shadow upon the parts beneath. The Cumulo Stratus is sometimes of vast vertical dimensions. The finest examples of it occur between the first appearance of the fleecy Cumulus, and the commencement of rain, while the lower atmosphere is comparatively dry, and during the approach of thunderstorms. The appearance of the Cumulo Stratus among ranges of hills presents some interesting phenomena. It appears like a curtain dropping among them and enveloping their summits, the hills reminding us of the massy Egyptian columns which support the flat-roofed Temples of Thebes or Tentyra. The more indistinct appearances of it are chiefly confined to the longer or shorter intervals of showers of rain, snow, or hail. Examples illustrating this variety of Cloud may be seen in the plates last referred to.

It has sometimes vast vertical dimensions.

So long as preceding modifications preserve a separate existence, no rain results.

(793.) Any of the Clouds belonging to the preceding modifications, whether existing in a separate class at some uniform elevation, or in two or more classes of different altitudes, may so increase in magnitude, as completely to obscure the sky; or at times, such an appearance of density may be put on, as to lead the inexperienced observer to apprehend a speedy descent of rain. An attentive observation, however, of their phenomena, has induced Howard to infer, that so long as they preserve a separate existence in one of these states, no rain at any time falls from them.

Atmospheric phenomena before rain takes place. Rain from upper regions of sky.

(794.) Before rain takes place, the external characters of the Clouds undergo a change, and their altered conditions have been found sufficiently remarkable to constitute the intermediate modification of Cumulo Cirro Stratus, *vel* Nimbus. When rain comes from the upper regions of the sky, it is indeed difficult to trace the phenomena that occur. All that we can do before the arrival of denser and lower Clouds, is to observe, that, at a great altitude, a thin light veil, or a hazy turbidness exists. When this has considerably increased, the lower Clouds become diffused, and, uniting at length in all points, form a uniform sheet. Rain then commences, and other Clouds from windward passing under this sheet, become successively lost in it. When the latter cease to arrive, or the higher sheet becomes broken, an abatement or cessation of the rain is the result. There often, however, follows an immediate and great addition to the mass of Cloud; but the actual obscurity is lessened, on account of the readier passage the new arrangement affords to the rays of light. On the cessation of rain, the unbroken Clouds below rise into Cumuli, the superior sheets put on the varied forms of the Cirro Stratus, which sometimes pass into the Cirro Cumulus. If the interval be long before the next shower, some form or other of the Cumulo Stratus appears, and sometimes very soon after the first cessation of the rain.

Formation of Nimbus best observed in stormy weather.

(795.) Forster remarks, that the formation of the Nimbus may be best observed in stormy weather. Cumuli may then be seen rising into mountains and afterwards changing into Cumulo Strati, while long ranges of the Cirro Stratus permeate their summits. After existing for some time in this form, they increase in irregularity and size, and at length become of a dark and dense form, with a Cirrose crown extending from the top, and ragged Cumuli entering from below. In the end the whole resolves itself into rain.

Distant shower in profile discloses the formation of the Nimbus best.

(796.) A distant shower in profile discloses the formation of the Nimbus very distinctly. Should the Cumulus be the only Cloud present at such a time, its upper parts may be observed to become tufted with nascent Cirri. Adjacent Clouds also approach and unite laterally by subsidence, the Cirri increasing, and extending themselves upwards and by the sides. These interesting changes are succeeded by the shower. At other times the Cirro Stratus is first formed above the Cumulus, and their sudden union is followed by the production of Cirri and of rain. In either case the formation of Cirri seems to be proportional to the quantity of rain, giving an external character to the Cloud by which it is readily known at great distances, and which induced Mr. Howard to apply to this intermediate modification the name of *Nimbus*.[*] When one of these is transported rapidly by the wind, very little rain is produced, but frequently some hail or driven snow. In heavy showers, the central sheet being once formed, is, as it were, warped to windward, the Cirri being propagated above and against the lower current, while the Cumuli arriving with the latter, cause it to be augmented. Humboldt saw large drops of rain fall at Cumana, when the sky was quite blue, and without the slightest trace of Cloud.

Uses of the Cumulus and Cumulo Stratus as carriers of moisture.

(797.) Since rain may be produced, and continue to fall from the slightest obscuration of the sky by the Nimbus, while a Cumulus, or Cumulo Stratus, of a very dark and threatening aspect, passes on without discharging any, until some change of state takes place, it would seem as if Nature had destined the latter as reservoirs, in which water is collected from extensive regions of the air, for occasional and local irrigation in dry seasons, and by means of which it is arrested at times in its descent, in wet ones.

Nimbus adorned by the rainbow.

(798.) The Nimbus, although one of the least beautiful of Clouds, is, nevertheless, now and then adorned by the splendid colouring of the rainbow, which can only be seen in perfection, when the dark surface of this modification forms for it an extended back-ground. Examples of Nimbi are given in plate xii.

(799.) Masses of Cloud, however, frequently appear, which seem incapable of being referred to any of the

---

[*] It must have been this compound modification which suggested to Shakspeare the following splendid and well-known lines.

> Sometimes, we see a Cloud that's dragonish;
> A vapour, sometimes, like a bear or lion,
> A towered citadel, a pendent rock,
> A forked mountain, a blue promontory
> With trees upon 't that nod unto the world,
> And mock our eyes with air.—
> That which is now a horse, even with a thought
> The rack dislimns, and makes it indistinct
> As water is in water.

[*] *Qualis ubi ad terras abrupto sydere* nimbus
It mare per medium, miseris heu prescia longe
Horrescunt corda agricolis.

Clouds which seem to belong to no modification.

modifications; but these, if they continue long enough visible, generally assume some definite form at last; and hence the difficulty which the young Meteorologist sometimes feels, of fixing the modification to which a Cloud belongs. There are Clouds, indeed, intermediate between the Cirrus and Cirro Stratus, or between the Cirrus and Cirro Cumulus, which seem not to partake of the character of either, and which, therefore, it is not easy to name. Loose, shapeless portions of Cloud moving swiftly in the lower current of the atmosphere are called *Scud*. Sometimes a great mass of Cloud will break up into several distinct modifications. One was seen by Howard which became resolved into Cirro Cumulus, into Cirri spreading out into continuous sheets approaching the Cirro Stratus, while flocks of Cumuli floated along in the wind below. To become acquainted with all these diversities, as well as with the more perfect examples of the distinct modifications, requires much diligent observation. The subject has higher claims on our attention than is commonly admitted, and is, perhaps, destined to attain a high rank in Meteorology. Nor should its cultivation be confined to one locality; it should be extended to many diversities of climate, to mountainous and level Countries, so that a body of facts may be collected to enable us to draw more general conclusions than we are yet able to do.

Uniformity of the Clouds.

Circumstances which contribute to it.

Clouds in upper sky roundish, in middle sky oval, and in lower sky linear.

Clouds on opposite sides of sky. Clouds seem to converge.

Clouds appear to cross each other and to converge. Dark segments. Effects of wind.

(800.) However irregularly the masses of Cloud may seem to be distributed in the air, the observer may nevertheless trace, in some way or other, an approach to uniformity. The general aspect of the sky, the tone and lights and shadows of the Clouds, and the laws of the aerial perspective which govern the whole concave of Heaven, each in their degree tends to uniformity, even when the masses of Cloud seem to be dispersed in the utmost confusion. It may be remarked in the first place, that the Clouds which occupy the upper sky, have forms comparatively round, whilst in the middle regions, they appear of an oval figure, and nearer the horizon approach to a linear form, as attempted to be illustrated in fig. 1, plate xiii. On other occasions, detached masses may be seen similarly disposed on opposite sides of the sky, exhibiting dimensions more contracted as they are nearer the horizon, and becoming more extended as their elevation is augmented. At other times, Clouds of an arch-like form are seen to converge with beautiful uniformity towards opposite points of the horizon, as in figs. 2, 3, and 4; while in other conditions of the atmosphere, the bands are confined to one region only of the sky, as in fig. 5; or sometimes they may be seen more numerous, or better defined in dimensions, density, character, or colour, on one side of the sky than on the other. Sometimes the points of convergence are to be seen above the horizon, and sometimes they are invisible below. At other times one only is to be found above, and the other below; or the two points may not be disposed opposite each other, as in fig. 6. Separate arrangements of Clouds may cross each other, each of the series exhibiting a convergency, as in fig. 7. Sometimes a dark segment occupies a portion of the sky, and Clouds proceed from it as in fig. 8, or at other times as in fig. 9. These arrangements are sometimes rapidly dispersed by the wind, and at others are transported in mass quite across the celestial vault. The same band at A, fig. 10, may occupy a position in the zenith, and at length be found on the opposite side of the sky. Sometimes the whole region of the upper sky is covered with dense Cloud, and a perfectly clear band surrounds the horizon; but often instead of this beautiful parallel space, a clear segment only is seen. These and other interesting arrangements of the kind may be seen in *Nouvel Aperçu sur la Météorologie, par* J. A. Clos, Paris, 1828.

Examples given by Howard,

(801.) Such arrangements are far from being uncommon even in our uncertain and variable sky, but they are most frequent in regions where more uniform currents prevail. Howard has recorded many among the notes to his Tables, of which the following are instances. "The haze," says he, "which had long occupied the higher atmosphere, became arranged in long parallel bars of Cirri, extending North-East and South-West beyond the horizon. Cirro Cumulus passing to Cirro Stratus in bars from North to South nearly crossed the visible hemisphere. Bars of Cirri, pointing North and South, appeared to converge in the horizon. Cirro Stratus, and after it Cirri in elevated bars, stretched North and South. Cirro Strati appeared converging to the rising Moon." Parry frequently witnessed the arch-like and continuous forms of the Clouds in the Polar regions, and Humboldt alludes to the same in his *Personal Narrative.*

by Dr. Cl

(802.) An account of an actual example of the progressive formation and appearances of Clouds exhibiting this uniform arrangement may not be uninteresting. On the 19th of June, 1809, at three A. M., Dr. Clos saw the sky very fine, but soon a light-striped Cloud was formed in the West North-West quarter, a little elevated above the horizon. As the Cloud enlarged, it soon presented the figure of a well-defined arch extending from West to East, through the Northern region of the sky, as in fig. 11. The ascending Sun at length was concealed by the arch, and insensibly the sky became flaky in the West, as in fig. 12, the band becoming longer and deeper, and a gentle West North-West wind continuing to blow. These flaky Clouds progressively gained the Eastern region, until at length the rudiments of another arch was seen passing to the South, enclosing the flaky masses between the two bands as in fig. 13. The flaky Clouds in the West at length dispersed, leaving a small portion only in the East, as in fig. 14, the last formed band becoming at the same time more dense, the wind preserving its direction, but increasing in power. The flaky masses in the East at last dispersed, and there remained at half-past six the two bands only, that on the North being diminished, whilst the other was enlarged, as in fig. 15. About seven, the Northern band disappeared, the Southern forming a whitish and slightly dappled segment as in fig. 16. At half-past eight, the latter vanished, the West North-West and North-West wind blowing with increased force, and the sky continuing clear till noon.

Result from illu sions of t atmosph

The asp of the sl calculat to decei

Laws of perspect applicab to it.

(803.) All these phenomena are to be classed, however, among the illusions which the atmosphere so constantly presents. The face of the sky, the aerial landscape which delights us with its lovely forms, its snowy palaces, and its torrents of light, is indeed at best but a deceptive picture, and should be contemplated somewhat in the cautious spirit of Geometry. The first visible impressions of the sky are calculated to deceive, and from our earliest childhood we derive from it lessons, which in our riper manhood we are desirous to unlearn. The celestial vault is too often contemplated as a magnificent *superficies*, spread out in beauty before us, without considering that it possesses in every way all the attributes of space, and that the laws of a rigid perspective are disclosed in all its parts. The Clouds which

Motions of Clouds contribute to the deception.

pass in rapid succession before us, contribute in a remarkable degree to increase the deception. Their apparent movements are essentially different from those which are real, and the figures they present, afford no grounds for discovering their proper dimensions and forms. Masses of vesicular vapour that seem to be traversing the great concave of Heaven in a curve of some order, may be really advancing in a uniform right line. The same Cloud which to one spectator may be glowing with light, to another may be enveloped in shadow. That which appears to be its summit may be only a portion of its anterior edge; while that which seems to be its lower bed, may really be a portion of its posterior border. The young observer must indeed apply, with perseverance and caution, to the masses of Cloud that float in the aerial regions above him, some of the laws by which he has learned to discipline his judgment in contemplating the objects that more immediately surround him.

Apparent changes of a Cloud in its transit across the sky.

(804.) Let us endeavour briefly to trace some of the apparent changes a mass of Cloud undergoes during its transit across the sky. In whatever region we are, though a level country will display the phenomenon most strikingly, if a Cloud appear in the distant horizon, and be brought towards us by the influence of a steady wind, its first appearance, whatever be the absolute dimensions of the Cloud, must be very small. By little and little, however, it will rise in the air; and if we suppose, in order to simplify the subject, that its real dimensions remain constant during the whole time of observation, we shall find, that as its elevation increases, its magnitude will augment, and that this alteration will be accompanied by some modification of form. The progress of the Cloud, also, which at first was very slow, will during these changes be accelerated, seeming to advance through the air in a curve. Arrived, however at a certain point, its magnitude will appear to have attained a maximum; but having passed that point, its dimensions will seem to become progressively less and less, its motion proceeding by slower steps and the Cloud diminishing successively in elevation; until reduced apparently at length to a very small mass, it hides itself in the opposite part of the sky from which it emerged. In this way we may trace the phenomena of many Clouds, some moving through the upper sky, and others at a lower elevation on the right hand and left, their magnitudes, forms, and velocities varying in some way every instant, with their ever-changing distance and altitude.

Analysis of the phenomena.

(805.) If we attempt, however, to analyze these interesting phenomena, we shall find that the mass of Cloud did not proceed from the horizon itself; or in other words, was not in contact with the visible boundary around us. Neither was the actual magnitude of the vesicular mass when near the horizon, less than when over our heads, supposing the absolute dimensions of the Cloud to have remained constant during the time of observation; neither were its movements slower, nor did it really describe a curve of any kind in its progress through the air. To illustrate these phenomena, let H Z O, fig. 17, be a vertical section of the celestial vault, passing through the station of the observer S; and for the sake of simplifying the inquiry, let A G be the actual path of the Cloud passing through the same plane H Z O, the projection of which, A Z G, on the concavity of the sky, will be the apparent path of the Cloud. Suppose now A G to be divided into the equal parts A B, B C, C D, D E, E F, and F G, to denote the equal spaces uniformly passed over in equal times by the Cloud. In the actual translation of the Cloud from A to B, it will seem to pass from A to *b* in the vault of the sky, in some time *t*; and in another equal interval, while moving actually through B C, it will appear to describe *b c*, but with a velocity apparently increased. In like manner, when actually moving from C to D, the Cloud's apparent course will be from *c* to Z, with a velocity still more increased. Having passed however D, or its apparent place in the zenith Z, the converse of all these phenomena will take place, both as regards elevation and velocity, until the Cloud finally reaches G.

When actual path of Cloud is in same vertical plane with observer.

When not in same vertical plane.

(806.) Should the Cloud not move in the same vertical plane with the observer, let A G, fig. 18, be its actual path, parallel to a diameter, H S O, of the horizon. If this Cloud be now supposed to move from A to G, we shall find it augment as before from A to I, and diminish from I to G, but its apparent path, by a well-known property of the sphere, will be a curve; and although the actual motion of the Cloud is constantly parallel to the horizon, it will, nevertheless, be seen more elevated in its middle part, and lower at its extremes, the apparent place of B, D, F being at *b*, I, *f*.

Phenomena of a bank of Cloud.

(807.) A bank of Cloud A B C, fig. 19, in the horizon, by ascending gradually to the upper sky, will become elongated like G H I, and at the zenith be extended to K L M. Having passed, however, that limit, it will apparently become shortened, as N O P; and, supposing all other things to remain the same, become reduced at length to its original dimensions D E F, in the opposite horizon.

Phenomena when resolved into three small Clouds.

(808.) If we next suppose this bank of Cloud to be resolved into three small Clouds A, B, C, fig. 20, just emerging from the distant sky, and impelled by the same uniform breeze, the centre mass will pass over the head of the spectator and be enlarged and elevated during its transit to that point; but after passing the zenith, it will diminish in size and elevation as before described, until it disappears finally at E, opposite the point from which it arose. The other Clouds, A and C, as they mount in the sky, will both be enlarged, and have their apparent places, G and H, removed to a greater apparent distance than before from the central mass; but sinking at length at D and F, will regain their original apparent interval in the horizon.

Visible horizon not boundary of Clouds presented to our view.

Phenomena of two neighbouring horizons.

(809.) We are not to suppose that the visible horizon which surrounds us forms the actual boundary of the cloudy masses presented to our view. A bank of Cloud that may seem absolutely lost in the furthest verge of the sky, may indeed be a part only of an enormous mass, extending very far beyond it; and hence, though masses of Cloud may seem almost to converge to a single point, we are not thence to infer that they absolutely terminate there. To illustrate this, let A B, B A′, fig. 21, represent two neighbouring horizons, each being surrounded with its own canopy of the sky. Let *a a′* denote also a continuous band of Cloud, parallel or not paralled to the two horizons. Each of the observers at O and O′ will hence perceive his own band, *a b* or *b′ a′*, bending to the limits, A B or B A′, of his visible horizon, and seeming to have a common point of union at B, the intermediate portion *b b′* being seen by neither. To an observer between the stations O and O′, the mass *b b′* will however be visible. Hence a solitary Cloud driven in the direction *a a′*, though first seen at A, and reaching its maximum of apparent magnitude in the zenith, and disappearing on the other side of the horizon at B, will, nevertheless, though lost to the spectator at O, again emerge out of the same point B, to the observer at O′, as soon as it has arrived at b′ in its actual course. Here undergoing the same system of apparent changes as it did to the first spectator, it will finally vanish at A′. It is just in this way that a Cloud sometimes appears to furnish other Clouds continually, whereas the supply really comes from another sky.

Another illustration.

(810.) But it may be advantageous to the young Meteorologist to put the subject in another point of view. For this purpose let G Z P Y, fig. 22, be the boundary of the visible horizon, and at some height above it, let there be several parallel rows of Cloud, situated in a plane parallel to that plane. If we limit the inquiry in the first place to the three bands D E F, G O P, H I K, the second being found in the same vertical plane with the observer, will pass through the zenith of observation; and by the same laws of perspective as govern a plane higher than the eye, this middle band will have the appearance of descending, and of being lower at the parts most remote from the eye; and supposing its breadth to be uniform, will, as it recedes from the zenith, diminish more and more in breadth, as it successively recedes through the sky. The bands D E F and H I K, however, being out of the vertical plane of the observer, must assume concave forms, as *d e f*, *h i k*, diminishing likewise in breadth towards G and P, where they will seem to unite with the other band. In like manner by supposing other bands, A B C and L M N, to exist, they will be found to put on the appearances of *a b c* and *l m n;* and hence the whole system of parallel bands, however numerous they may be, will all appear to converge and meet in opposite points of the horizon at G and P. That arrangements of this sort, exhibiting the most perfect uniformity, are sometimes visible in this Country, may be seen by referring to the *Edinburgh Journal of Science*, vol. x. p. 33.

(811.) Let us next imagine another observer to be situated at *p*, and of course with another visible horizon surrounding him. Of the parallel bands of Clouds before adverted to, the portions actually existing over his horizon will be B C, E F, O P, I K, and M N; but the apparent positions of these will be b′ c′, e′ f′, e′ p, i′ k′ and m′ n′, all springing as it were from a common point O, and all widening as they seem to ascend in the sky. How different, therefore, the appearance of the *same* portions of these bands to the two observers! To the spectator at O, they will seem to spring up from *p*, diverging in one direction; while to the other observer at P, they will arise as it were from O, and diverge directly opposite. The phenomenon at P will account for those singular forms of Clouds which seem to spring up from the horizon, resembling a human hand. If the parallel bands be of less extent than the visible horizon, they will still exhibit the same tendency to convergency, but may not meet.

Further illustration of great banks of Cloud.

(812.) To illustrate further the phenomena of the great banks of Cloud before adverted to, let A R B, fig. 23, denote the horizon, and A B a large bank of Cloud extending beyond its limits. Should this bed have one uniform thickness, the laws of perspective will necessarily cause its extremities to appear depressed; so that supposing H O, fig. 24, to be the horizon, and H A B O a portion of the real mass of Cloud whose altitude or thickness is H A or O B, its appearance must be that of the segment H C O, the highest part being at C, and the points A and B appearing to unite in the horizon with H and O.

Upper sk covered with Clou and a clea horizon.

(813.) Sometimes the whole of the upper sky is shrouded with very dense Clouds, the lower sky through the whole range of the horizon, being perfectly clear. This arises from the base of the cloudy mass being of a less extent than the visible horizon. Thus if A B, fig. 25, be the extent of the Cloud, and H O that of the horizon, unless the elevation of the Cloud be very small, the points A and B, though apparently depressed, will not seem to meet the horizon; and intervals, H A and B O, of clear sky will exist all around. Should the horizontal extent of the Cloud be equal or greater than the horizon, its extremities will seem to coincide with it; and the whole celestial concave be covered with Cloud as in fig. 26.

Case of whole sky covered.

One side horizon with Clou the other clear.

(814.) Sometimes one extremity of a Cloud may appear to touch one side of the horizon, while the other side remains clear, fig. 27. In this case the Cloud may appear to coincide at H, fig. 28, but its horizontal extent being insufficient to extend to O, the effect of perspective will cause B to be depressed, but not sufficiently to make it apparently coincide with O, and hence a clear space from B to O will remain.

Variety of last.

(815.) At other times a large bank of Cloud will seem to begin at one verge of the horizon, and continue to some distant point opposite, as A B, fig. 29, when other detached Clouds, C and D, may be seen filling up the remaining interval of sky, the last of which appears to coincide with the opposite point of the horizon, the apparent phenomena being as fig. 30. Clear intervals will be seen between B C and C D.

Phenome of successive beds Cloud.

(816.) In some conditions of the sky, we see masses of Cloud disposed in continuous and nearly uniform beds, retiring successively behind each other, the shaded and lower parts of one bed hiding successively the lighter and upper parts of a more distant, but apparently lower bed. These beautiful appearances may be explained as follows: Let C, C, C, C, fig. 31, be four masses of Cloud at equal or unequal intervals, the lower beds, A B, of each being in shadow, while their upper parts are illuminated by the Sun at S. Now although these different masses of Cloud may be disposed at the same elevation, their apparent places will be by no means the same, each mass appearing successively at a lower elevation, in proportion as it is more distant, as C′, C′, C′, C′. Hence the lower bed of the first may conceal the upper bed of the second, the lower bed of the second, the upper bed of the third, and so on; the whole arrangement putting on the appearance of steps, and producing the most beautiful varieties of light and shade.

(817.) It is in the calmest states of the atmosphere, or when no actual current prevails, that the least regularity exists, the effects of a moderate wind being always to bring the masses of wind that may be floating in the air, into something like order. However great indeed may be the regularity of a cloudy sky, it is difficult not to find some traces of uniformity in it.

Mean alt tude of Clouds n known.

(818.) We are unable in the present condition of our knowledge to offer an accurate estimate of the mean altitude of the Clouds, taken either in their separate modifications, or as one great mass of vesicular vapour surrounding the Globe. Contemplated in the latter point of view, it would seem probable that the mean altitude of the whole vesicular mass, bears some relation to the mean conditions of vapour in the air, both as regards its increase from the Equator to the Poles, and from the surface of the Earth, through the higher regions of the atmosphere; but Clouds exist through a wide range of elevation, from the ground, which many of them actually graze, up to the lofty regions where the long lines of Cirri exist; nor are we sure that the highest we see, are the highest that really exist.

Altitudes of Clouds very deceptive.

(819.) Nothing can be more deceptive than our notions respecting the altitudes of Clouds. Their angular elevations can in no way assist us, since the different modifications sometimes appear inverted in the sky. "I have seen," says Forster, "the Cirrus in tufts moving along rapidly in the wind below Cirro Cumulus, and even Cumulus in a higher region," and we know too little of Meteorology to determine whether the phenomena be apparent or real; although the probability is that it is apparent, as the following illustration will prove. Let A, B, C, fig. 32, plate xiii., denote respectively the absolute positions of the Cirrus, the Cirro Cumulus, and the Cumulus, the Cirrus having really the highest elevation, and the other two Clouds occupying their proper positions below. To the spectator at S, the Cirro Cumulus and Cumulus will appear projected on the sky at B′ and C′; whereas the apparent place of the Cirrus will be at A′, below *apparently* the other two Clouds. Again, "I remarked," continues the same active observer, "a long Cirrus moving rapidly along in a North wind, not lengthways, but abreast. At one end of it, fibres pointed backward to the North, while at the other they pointed to the East. Higher up, light Cumuli passed over from the South; and higher still were flimsy, ill-defined masses of Cirro Cumulative Cirro Stratus in an air comparatively calm; but they were found to be passing over gently from North to West." Anomalies like these frequently occur in the pursuit of Meteorology.

Apparent inversions of modifications.

Inhabitants of plains less able to judge of altitudes of Clouds than those of mountainous regions.

(820.) The inhabitants of level plains are less able to judge of the altitudes of Clouds than those of mountainous regions. In Swisserland, for example, the mountains are often intersected in calm weather by horizontal bands of Clouds, whose inferior borders are so uniformly terminated, as to render the smallest change of altitude immediately perceptible. So constant, indeed, are these conditions of elevation, at times, that they remain for days suspended at nearly the same height. In ascending the sides of mountains, the traveller frequently passes through zones of Clouds,* and rising at length above them, beholds the vapours of which they are composed spread out in gentle undulations below him. Mountains therefore, or points on their surfaces, form a sort of scale, by which at least the elevations of the denser sort of Clouds may be measured; but we know of no example of its application, excepting the limited observations of Mr. Crosthwaite on Skiddaw; the comparatively low elevation of that mountain allowing by far the greater proportion of Clouds to pass above it. These observations, continued for five years, are contained in the following Table:

Use of mountains in determining their altitudes.

TABLE CXLI.

Altitudes of Clouds.	Number of Clouds.	Altitudes of Clouds.	Number of Clouds.
From 0 to 100 yards	10	From 600 to 700 yards	416
100 to 200	42	700 to 800	367
200 to 300	62	800 to 900	410
300 to 400	179	900 to 1000	518
400 to 500	374	1000 to 1050	419
500 to 600	486	Above 1050 yards.	2098

Hence it appears, that the *number* of Clouds *above* 1050 yards, were to the number *below* that elevation, as 2098 to 3283, or as 10 to 16 nearly. The theory of Howard not being known at the time these observations were made, the modifications could not be recorded.

Actual measurements of Riccioli.

(821.) Riccioli in his frequent determinations of the elevations of the Clouds by actual Trigonometry, never found them to reach above 4440 fathoms. Bouguer places among the most elevated Clouds, those which he has seen to pass 300 or 400 fathoms above Chimborazo. The Clouds, however, which sometimes mingle with the smoke of volcanoes in that region, rise, he thinks, 750 or 850 fathoms higher. Humboldt remarks, that the large Clouds which the inhabitants of the plains of South America see above them in the air, are contained in an atmospheric stratum of between 1000 or 2000 metres' elevation. Gay Lussac supposes the principal mass of Clouds to be sustained at a height between 1500 and 2000 metres. Dalton has found Cirri from three to five miles above the Earth; and even from the loftiest of the Andes, there are always to be seen delicately formed Clouds of this modification pencilled on the sky. The Clouds of the mackerel-back sky appeared to Dalton almost as distant from the top of a high mountain, as from the valley beneath. Aeronauts have ascended so high that the large Cumuli formed in the lower sky have appeared like "small silvery specks," but no one has ever approached the lofty regions where the lighter modifications abound. Gay Lussac and Biot found at the height of 4000 feet a horizontal stratum of Clouds, whose upper surface was formed into gentle swells. But all these measures are too vague and undefined to satisfy the present wants of Meteorology. The progress of this department of knowledge may eventually disclose to us, not only the mean altitude of the Clouds, but help us to inquire, whether the different modifications do not vary in elevation with the climate and the season, and have not different elevations over different soils, and whether the sea does not modify in some way the altitudes of the Clouds that pass above it. Leslie has made an ingenious theoretical attempt to determine the mean altitude of the Clouds, by means of a formula founded on certain considerations of the density and hygrometric conditions of the air.

Remarks of Bouguer.

Gay Lussac and Dalton on altitudes of Clouds.

Aeronauts.

Vague and uncertain measures.

Leslie's theoretical attempt.

Distances of Clouds cannot be determined.

(822.) While these difficulties exist respecting the proper altitudes of the Clouds, our judgments become in

---

* The following extract from Evelyn's *Memoirs* will be read with pleasure, although, as another able writer remarks, it should remind the reader of a sublimer picture in Burnet's *Sacred Theory of the Earth*. "Next morning we rod by *Monte Pientio*, or, as vulgarly called, *Monte Mantumiato*, which is of an excessive height, ever and anon peeping above any Clowds with its snowy head, till we had climbed to the inn at *Radicofany*, built by *Ferd$^{d.}$ the greate Duke* for the necessary refreshment of travellers in so inhospitable a place. As we ascended we entered a very thick, solid, and dark body of Clowds, w^{ch} looked like rocks at a little distance, which lasted neare a mile in going up; they were dry misty vapours, hanging undissolved for a vast thicknesse, and obscuring both the sun and earth, so that we seemed to be in the sea rather than in the Cloudes, till, having pierced through it, we came into a most serene heaven, as if we had been above all human conversation, the mountain appearing more like a greate island than joyn'd to any other hills, for we could perceive nothing but a sea of thick Clouds rowling under our feete like huge waves, ever now and then suffering thee top of some other mountains to peepe through, which we could discover many miles off; and betweene some breaches of the Cloudes we could see landskips and villages of the subjacent Country. This was one of the most pleasant, newe, and altogether surprising objects that I had ever behold."

a greater degree perplexed with regard to their distances. The union, indeed, is so intimate between distance and magnitude, that it is necessary one of these elements should be known, before the other can be determined. If a Cloud be presented, and an imaginary right line be drawn from the station of the observer to the surface of the Cloud, no estimate can thence be formed respecting its distance. Clouds are seldom so stationary as to permit the ordinary Trigonometrical methods, by two observers taking angles of elevation at the extremities of a known base, to be applied to them with any thing like success. The apparent position of a Cloud in the celestial concave can in no way assist us in determining its distance from us. To the observer at O, fig. 4, plate viii., the Clouds C and C′ have both the same apparent place P, and consequently no estimate can be formed of the distance of either, if indeed other circumstances permit us to distinguish one Cloud from the other.

Deception as to distance during a shower.

(823.) An example of a deception with regard to distance frequently takes place during a shower,—the rain falling nearer to us than we expected. For suppose the real place of the Cloud to be at *i*, fig. 20, plate xiii., while its apparent place is at I, the observer imagines the shower will descend from I, whereas the real place where it falls will be *i*. It may indeed be inferred generally, that Clouds are almost always much nearer to us than they appear.

Magnitudes of Clouds cannot be determined.

Their absolute dimensions cannot be deduced from their apparent.

(824.) The magnitudes of Clouds are open likewise to equal uncertainty. A single mass of Cloud may consist of only a few atoms of vesicular vapour, or it may extend far beyond the limits of the visible horizon, portions of the same Cloud affording an object of contemplation to the inhabitants of very distant places. There seems no method of deducing in practice the absolute dimensions of Clouds from their apparent dimensions; nor are we able at any time to contemplate more than two of these dimensions, the third being either concealed entirely from our view, or so altered from position, as to prevent us from arriving at any definite conclusions respecting it.

Causes of apparent magnitudes of Clouds varying. Illustration.

(825.) The apparent magnitude of a Cloud may vary either from alteration of distance, a change of its absolute dimensions, or from difference of elevation. Suppose F G, fig. 17, plate xiii., to be a Cloud of some determinate form, whose actual path in the air is G A. To the spectator at S, this Cloud will appear projected on the sky in G*f*; and if we suppose the real magnitude of the Cloud to remain unchanged, during the whole time of observation, at the moment the Cloud occupies the position E F, its place on the celestial vault will be *ef*; and when it arrives at D E, its apparent length on the sky will be Z *e*. While the Cloud therefore has preserved a constant length during its absolute translation from G to D, it will have seemed every instant to have increased in length, in its passage from G to Z, and during the time it occupies the zenith, it will seem greater still. As the Cloud, however, gradually retires from that point, its apparent magnitude will go on diminishing, until it is reduced to its orginal dimensions at A. An apparent change of volume, therefore, is no evidence that any alteration of the absolute dimensions of a Cloud has taken place. The apparent magnitude of a Cloud may, however, sometimes be less in the upper sky, than in a lower region thereof; and the point in the sky where a given Cloud may have the greatest apparent magnitude, will depend on the particular figure of the Cloud.

An apparent change of volume no evidence that an absolute change of dimensions place.

Position Cloud i the sky fluences apparen dimensi

(826.) We are, in like manner, incapable of judging of the real forms of Clouds. There must, indeed, be a great difference between the real and apparent forms of the same Cloud, nor can we by any means deduce one from the other. The forms of Clouds must necessarily be subject to considerable changes from a variety of causes, some of which are absolute and others only apparent. The absolute changes are those which result from a real alteration in the whole mass of Cloud, and the apparent those which arise from altered circumstances of position. The same Cloud, it is manifest, must put on different appearances in different positions; and to different observers at the same instant, it must present diversities of form. Nor do these changes relate to figure only but to colour and all the varieties of light and shade.

Effects alteratio position Cloud, i elevatio

(827.) Supposing no absolute change of form to take place, an alteration of position in a Cloud must at once communicate some diversity of appearance. The same Cloud at 20° of elevation cannot present the same form and the same disposition of light and shade, as when it has attained an elevation of 30°. At the first elevation A, fig. 5, plate viii., may appear to be its loftiest summit; but at the second, B, in a much lower region of the Cloud, may seem to be so. The whole surface visible from A to C in the lower Cloud, becomes changed from B to D in the higher. The entire aspect of the Cloud may from this single circumstance be changed.

Of a cu transpo ing it fr one regi of the s to the o

A current, moreover, by transporting the whole mass of a Cloud from one region of the sky to another, without any absolute change of elevation, must produce some changes in its appearance; and an alteration of wind may bring new surfaces into view.

Change form fr new ac sions of matter, dissolut Alterati of dens Centre gravity stability altered.

(828.) But the absolute form of a Cloud may change every instant, either by new accessions of vapour, or by parts of the Cloud being dissolved. The density will thus be varied, and the position of the centre of gravity become sensibly changed, and its buoyancy altogether altered. Its stability also,—an inquiry which has been hitherto singularly neglected, must during these interesting transitions be every moment altered. Sudden condensations may so far alter the circumstances of a Cloud, as materially to change the conditions of its equilibrium; and cases may occur wherein a stable equilibrium may be converted into one that is unstable, or *vice versâ*, and thus prepare the way for new variations.

A curr may c munica rotary motion. The sa Cloud present ferent a pearan person differen localiti

(829.) The action of a current may also communicate to a Cloud a rotary motion about a vertical axis, and thus by another mode disclose new surfaces to view. To persons situated in different localities, the same Cloud must present very different appearances, not only with regard to its entire form, but also in the arrangement of its parts. Thus, in fig. 6, plate viii., a Cloud may be placed between the observers A and B. To one of them, A, the surface presented may appear illuminated by the Sun, while the other surface, to B, may be entirely in shadow. The general forms of the two surfaces may also be very different; and as the Cloud moves towards one spectator or the other, new phenomena must be continually disclosed.

Decept relativ edges limits Cloud

(830.) Very often, what appears to be the superior limit of a Cloud, is no other than the border which is nearest to the eye; whilst that which we regard as the inferior bed, is really the edge most removed from the observer. Thus in fig. 7, though S be really the summit of the Cloud, to the observer at E, the point A will appear the most elevated; and B, which is only the posterior border of the Cloud, will seem to put on the appearance of its base. The same system of Clouds may hence appear to one observer under very different circumstances from what they do to another.

Greatest horizontal axis of a Cloud in direction of wind.

(831.) A Cloud when transported by a current, will always exert an effort to get its greatest horizontal axis into the direction of the wind; and hence the course of the wind ought to determine the direction of the greatest horizontal dimension of a Cloud. A current may so act as to cause a Cloud to advance or recede in a right line from the eye of the observer, and thus give to it the appearance of being stationary. Thus while seeming to be at rest as a mass, its apparent figure and magnitude may undergo considerable changes merely from alteration of distance.

A Cloud may appear stationary when really in motion.

Apparent permanency of a Cloud often an optical deception.

(832.) The apparent permanency and stationary aspect of a Cloud, is often an optical deception, arising from the solution of moisture on one side of a Cloud, just as rapidly as it is precipitated on the other. This is a phenomenon continually taking place among mountains, or upon hills by the sea-side, the Clouds upon their summits appearing immovable, while a strong wind has been acting upon them all the time. The vapour transported by the wind, is precipitated by the cold contact of the mountain; and when carried beyond the cause of condensation, it again exhales and disappears. Similar causes, Mr. Daniell remarks, may operate on either side of the planes of precipitation, at different altitudes in the atmosphere, the vapour being continually condensed, and as continually redissolved in the act of precipitation, the Cloud remaining all the time stationary and unchanged.

Clouds rolling onward without appearing to pass a particular point.

Example.

(833.) Another effect of an analogous kind is that wherein a long succession of Clouds continues to roll onward from the distant horizon, without appearing to be able to pass beyond a particular point. In the Xth volume of the *Edinburgh Journal of Science*, reference is made to a case of this sort, at Mount Edgecumbe in Devonshire, an illustration of which is given in fig. 12, plate ix. "About noon, on the 11th of May, a Cirro Cumulus, of a very dense and definite character, was perceived to come from the verge of the Western horizon with a moderate velocity, and after passing at a small elevation above the woody summit of the mount, vanished in the pure and cloudless air over the tower on the distant promontory. The moving mass formed a continuous Cloud, accommodating itself to all the changes and inequalities of the land.* Over the sea, however, not a Cloud was to be seen; but on the Eastern side, nearly over the flag-staff, the Cloud was perceived to form again, and with a steady and uniform velocity to roll its volumes at nearly the same elevation above the land, until it was again lost in the furthest verge of the Eastern sky. From the West, therefore, there continued incessantly to come forth large and visible volumes of Cloud, which became dissolved in the air just where the sea began to exercise its influence upon them; and where the water lost its power, just above the flag-staff, the vapour became again condensed; so that over the sea, between the extremities of the Clouds, a pure and cloudless sky prevailed; whilst over the land, on both sides, the moving masses continued their courses for upwards of two hours. It was most interesting to watch the gradual progress of the Cloud on the Western side; how steadily it advanced with the gentle South-West wind; how it maintained its character and form up to a particular point; and how soon it became lost in the brilliant expanse of sky, when the temperature of the sea began to exercise its power. Now and then a denser portion of the moving column would detach itself just before it reached the tower, and, passing on with the breeze, seemed to maintain an ineffectual struggle with the influence of the water below; but gradually losing its dimensions and form, would at last vanish." Fig. 11 is a case of a similar kind, but the Clouds were formed in detached masses on the right-hand hill. In fig. 13, the Clouds appeared, on the contrary, in detached masses over the left-hand hill, and a separate bank was formed on each of the peninsulas on the other side. In fig. 14, the Clouds were of a very dense kind over both hills, and their connection was maintained by a narrow, continuous band of Cloud of a less dense kind over the sea; whilst in fig. 15, the whole cloudy mass exhibited the form of a parallel bed, having a smaller density in the middle than at its extremes. All these observations were made during the day. Fig. 16, however, illustrates an observation made on a beautifully serene evening, at nine on the 25th of July, the Clouds being formed over the sea, whilst the air over the land remained perfectly clear. In some of the former figures of the same plate, Clouds were formed on one side, and mists only on the other, the two seeming perfectly united. A beautiful example of condensation is given in fig. 8, plate viii.*

Other examples.

Mountains sometimes cause the Clouds to disperse.

(834.) While mountains, however, commonly occasion condensation, there are examples in which they seem to cause the Clouds to disperse. Mr. Bakewell records an instance of Clouds driving towards Mont Blanc, which seemed to hide it entirely from view. On his arrival nearer the mountain, the cloudy masses disappeared as rapidly at a given point, as they advanced; and although volumes of Cloud continued to move towards the mountain, it remain brilliantly illuminated the whole day It seemed as though the North wind, striking against the mountain, repelled the Clouds; although a current of warm air from the South might have met that which proceeded from the North, dissipating the Cloudy masses before they could reach the Southern range of mountains in the Vale of Chamouni.

Clouds sometimes formed instantaneously.

(835.) Clouds are sometimes formed instantaneously. Saussure remarked an instance of the sort in one of his Alpine journeys. From the side of a lofty mountain, he observed the atmosphere below to be perfectly clear; but in an instant Clouds became formed of two or three fathoms length. So long as the weather remained fine, these Clouds ascended, diminishing as they rose, and at length dissolving entirely in the air. When rain was indicated, the cloudy volumes were augmented, sometimes in the place of their original formation, and at other times during their ascent in the air; and sometimes whilst the vesicular masses descended over the side of the mountain.

Different distribution of Clouds to spectators at different elevations.

(836.) A spectator in an elevated region, as A, fig. 9, may behold masses of Cloud distributed in the atmosphere with very great diversity at different elevations, and presenting all the characteristics of a beautiful sky.

---

* A small portion only of the land is shown in the figure.

* Humboldt remarked in the Cordilleras of the Andes, that the conical mountains, such as Cotopaxi and Tunguralma, are oftener seen more free from Clouds, than those mountains, the tops of which are broken into bristly points, like Antisana and Pichincha; but the Peak of Teneriffe, notwithstanding its pyramidal form, is a great part of the year enveloped in vapour, and is sometimes invisible for several weeks from the road of Santa Cruz.

One Cloud in a valley may conceal many in upper sky, or leave a clear sky above.

To another observer, however, at a lower elevation, as at B, the whole canopy of Heaven may appear entirely shrouded with Cloud, exhibiting no diversity whatever. A single Cloud in the valley may conceal the upper sky from the obsevrer beneath, while the spectator on the mountain may contemplate the mass of Cloud below, with all its gentle undulations, yet dense and compact forms, concealing the valley, but permitting, perhaps, an entirely unclouded azure above. Sir H. Davy records an instance, in one of his interesting Letters, of a Cirro Cumulus appearing in this way, and disclosing silver, grey, and blue tints of the most exquisite beauty, the sky above being entirely clear.

When a lower stratum of Cloud is broken up, another layer becomes visible.

(837.) Sometimes when a lower stratum of Cloud is broken up, another layer becomes visible above it. Thus in fig. 10, the spectator at S may perceive through the opening of the Clouds at A, another mass of Cloud floating above, and of whose existence he had no idea before. Sometimes these openings are very numerous, and the higher Clouds which are disclosed, give to the sky an indistinct character. This takes place not only in the upper sky, but at every elevation. In the lower regions, a fine Cumulus at A, fig. 11, may be concealed from the observer by an indistinct mass of Cloud, B. This latter Cloud may break up entirely and disclose the whole Cumulus to view; or it may be partially revealed by its breaking up into detached masses, and presenting an uncertain character, somewhat like fig. 12.

One Cloud may conceal another in lower regions of sky.

Motions of Clouds make known existence of very different currents.

(838.) The motions of Clouds make known the existence of differently directed currents, at different altitudes in the atmosphere. A stream of air may bring a Cloud from the North, and in its course it may meet with a new current, which will transport it to the East. In some other region it may be impelled in a new direction different from the preceding. Sometimes different Clouds may be seen travelling in very different paths through the air, and giving a very interesting aspect to the sky, as in fig. 13, the arrows denoting the directions in which the Clouds proceed. The ascent and descent of Clouds in the air, prove also the existence of vertically ascending and vertically descending currents. Clouds move horizontally also, far beyond the limits of the visible horizon; and likewise in directions having various degrees of obliquity. An inclined current may bring a Cloud into contact with the ground, while another may transport it into a loftier region of the air. Deluc saw a very elevated Cloud descend with rapidity to the Earth and discharge a violent shower of rain; after which, with equal velocity, it remounted to its original elevation. The cause may, however, have been Electricity. In ascending or descending in consequence of altered circumstances of density, different currents may give to a Cloud very different bearings in the sky.

Rapid descent of a Cloud.

Columns of smoke disclose currents.

(839.) Columns of smoke confirm also the same interesting fact; and fig. 14 is an example, observed by Mr. Lauder Dick in July 1817, of the smoke of ignited furze on an eminence several miles distant, which after curling gently upwards, was caught by an under stream of wind and carried seaward in an Eastern and Western direction. After proceeding in this course for several miles, and gradually increasing in elevation, it came at length within the influence of a counter current blowing from West to East, which drove it back at an angle so acute, as to give to the Cloud the appearance of an arrow, and defining very precisely the line *a b* which separated the two currents from each other. The Cloud moving on to *d*, was acted on by a less violent current from the South-East, which transported it to the opposite quarter of the Heavens, where it was eventually lost. A Cloud, it is obvious, might have been acted on in the same way. Small balloons have been employed for making known the existence of currents.

Small b loons al

Inoscul tion of Clouds

(840.) Masses of Cloud of very different characters are often brought into absolute or apparent contact with each other, by the action of currents, or altered circumstances of density in the air. These combinations are sometimes distinguished for their variety and beauty. If we suppose M and N, fig. 1, plate xiv., to be two masses of Cloud, acted on by curents in the directions A and B, a junction at some point or other may probably take place, and a new mass of Cloud be formed at O. The two masses united may then move on in obedience to the stronger current, or an intermediate course be pursued by the necessary composition of forces. A union may result also from masses existing at different elevations, but moving with unequal velocities in parallel directions, A and B, fig. 2, the swifter overtaking the slower, and a junction of the two Clouds taking place at O, exhibiting quite a new appearance to the eye.

produce currents

by alte tions of density

(841.) Altered circumstances of density may likewise produce very beautiful examples of inosculation. A Cumulus with a Cirro Stratus may be situated as in fig. 3, and a change of density may either cause the Cumulus to ascend in a mass and join the Cloud above it; or the Cirro Stratus may descend to a lower level and meet the Cumulus, producing in either case an appearance resembling fig. 4. A Cumulus, Cirro Cumulus, and Cirro Stratus may also exist as in fig. 5, and a mass be formed from the same cause, as in fig. 6. Frequently light and delicate Cirri descend upon the summits of Cumuli as in fig. 7, disclosing the most beautiful union of opposite densities and forms. On the other hand, a Stratus may inosculate with the base of a Cumulus and conceal it as in fig. 8. At other times a Cumulus may be seen with its summit cut off as it were by a perfectly horizontal stratum of Clouds, so as to give to it the form of a table mountain, as in fig. 9. Sometimes a Cirro Stratus intermingles with the base of a Cumulus, but this is of rare occurrence, and but imperfectly represented in fig. 10. The inosculations resulting from changes of density are very slowly produced.

Many exampl

Inoscu tions c be app rent a real.

(842.) But these inosculations may be apparent and not absolute. The former may only alter the appearance of the sky; but the latter not only changes the appearance, but some phenomena result, such as rain, hail, or thunder. Apparent inosculations take place when Clouds are brought into nearly a right line with the eye of the observer, but are still separated by some interval from each other. Thus to the spectator at S, fig. 11, the two Clouds M and N may appear in contact with each other, though there is really a great distance between them; but to the spectator at P, no inosculation takes place. Forster mentions that a Cirro Cumulus may sometimes be seen under a spreading sheet of Cirrus of a milky appearance, like a bas-relief, as in fig. 12. This was no doubt an apparent inosculation. A series of Cumuli appeared in like manner on a dark and dense bank of Cloud, somewhat like fig. 13. Fig. 1, plate xv. is an example of two Clouds brought into absolute contact with each other, and in front of them a long band of thin Cloud, seemingly uniting them together, but which was probably an

Exam

One appea on an like a relief.

apparent inosculation only. Fig. 2 is an example also of apparent inosculation, where Cirri and a thin transparent coat of vapour were decidedly in front of a mackerel-back sky. Fig. 3 is an instance somewhat of the same kind. Figs. 4 and 5 are examples of banks of Cloud in apparent inosculation with other Clouds behind them.

(843.) Clouds sometimes inosculate with smoke. Howard mentions several cases in his Journals. "The smoke of London," he observes, "when passing away in a body swelled up into distinct heaps, each of which inosculated at its summit with a small Cloud. Groups of the Cumulo Stratus, the Cumulus, and Cirro Stratus occupied the South part of the sky attracting the smoke."

(844.) Showers resulting from inosculation are often mentioned by Howard. "A Cumulus," he says, "inosculated with a Cirro Stratus and showers prevailed. A large Cumulus inosculated both with a Cirro Cumulus and a Cirro Stratus, and a Nimbus appeared."

(845.) It is from the inequalities of light and shade which the Clouds display, that we derive all our notions respecting their apparent dimensions in space, and also of their great irregularities of form. Composed probably of vesicles capable of intercepting in some degree the passage of light, the manner in which they are disposed, as different circumstances of temperature and humidity prevail, must necessarily produce masses of very great diversity of form; and as the causes themselves are for ever varying, their figures must be perpetually changing; and hence it is that the most expert artist, when endeavouring to delineate a beautiful Cloud, finds its figure and very character altered in a single instant of time; and while he is seeking only to catch the general attributes of a Cloud, the shadows and brilliant points it displayed are totally changed; what was light is become darkened; and parts that were shrouded in shadow, are now adorned by the rays of a glowing Sun.

(846.) But the shadows which are disclosed amidst this great system of changes, are nevertheless subject to the laws that govern shadows in general. Wherever the Sun and a Cloud may be situated, some portion or other of the vesicular mass must present a shadow. It may be that the whole surface which it turns to the eye is in shade, or a portion of it only, sometimes its upper part and sometimes its lower; but however the shadows may be disposed, there is something to invite attention, something especially which it may be well for the young Meteorologist to dwell on.

(847.) Let us take as a first example, the case of a Cloud whose section, passing through the Sun at S, fig. 6, plate xv., is A B C D. To a spectator at M, the portion of the Cloud A D will be luminous, the points A, B appearing strongly tipped with the solar light. The hollow portion, however, of the Cloud from A to B will appear dark, particularly on the side next A, and so also will the portion from B to C. The light striking on different parts of a cloudy mass, must therefore disclose brilliantly illuminated parts, and parts having different degrees of shadow. Sometimes a Cloud may present one entire mass of shadow, as in fig. 7; and at other times the upper edge may appear illuminated, as in fig. 8. On other occasions the lower edge may be brilliant, as in fig. 9; and sometimes the middle parts of the Cloud may seem only to be in shadow, a margin round their edges being partially luminous, as at fig. 10,* this last phenomenon resulting from the superior density of the middle parts of the Cloud. These phenomena must depend on the comparative elevations of the Sun and Cloud, and on the peculiar figure of the vesicular mass itself.

parts may be in shadow. Sometimes its middle part only.

Progressive changes of shadows in Clouds.

(848.) The progressive changes of shadows in Clouds, in tranquil conditions of the atmosphere, merely from the altered position of the Sun, are most interesting to trace. Early on a fine Summer's morning, we have seen masses of Cloud, as A, A, A, A, A, ... fig. 11, whose lower parts have been gilded by the solar rays B B, B, B, B, B, ... As the Sun has advanced in elevation, these lower parts have become shaded, and other parallel rays C, C, C, C, C, C, ... have illuminated other portions of the Clouds; and when the Sun has reached a higher region of the sky, a third system of parallel rays D, D, D, D, D, D, ... will render new portions of the Cloud brilliant, and produce other alterations of shadow; and thus every moment new arrangements of light and shade are disclosed.

Shadow on the surface of a Cloud.

(849.) Among a boundless variety of examples, we present fig. 12, as affording an interesting case of well-defined shadows on the surface of a Cloud. At A and B, it may be remarked, are dark and well-defined shadows, projected apparently on an even and snow-white surface, by the elevated portions of the Cloud denoted by C and D. At E a remarkably deep indentation of the Cloud was rendered visible by means of a very intense shadow.

Form of a shadow as variable as Cloud itself. Shadows very different to different observers.

(850.) But the form of a shadow is as variable as the figure of a Cloud itself. If we suppose A B C, fig. 13, to be a vertical section of a Cumulus passing through the Sun at S, the shadows of its projecting masses will be instantly changed, if by new aggregations its section should be changed into D B E; or if by the partial dissolution of the Cloud, the first formed section should sink to B F G. The same Cloud also must disclose very different shadows to observers in different localities.

Shadows differ according to different positions of the Sun.

(851.) The shadings of Clouds must differ also according to the different positions of the Sun. The same Cloud in the morning must exhibit very different shadows from what it does in the evening; and both must differ from the phenomena it presents at noon. If a mass of Cloud be in the Northern region of the sky, in this part of the Globe, it will exhibit different appearances from what it would do were it in the South, and presented a similar face towards us. If we suppose a Cumulus, A B, fig. 14, in the North, and another of precisely the same form in the South, the lower parts of both will be in shadow; but to the spectator at S, the phenomena will be very different. In the Northern mass, A B, the illuminated surface will be turned towards the spectator, and a small part only, perhaps, of the darkened part; but of the Southern mass, A′ B′, its shaded side will be presented to the observer, and, perhaps, a small portion only of its enlightened part. Hence it is, that in the middle of the day in a European sky, Cumuli in its Northern regions are so much more brilliantly illuminated than those in the Southern. The former display the most magnificent forms, glowing with light; whilst the latter seem sunk in vapour, and appear dull and dark.

Different appearances of Cumuli in Northern and Southern sky

(852.) The shadows of Clouds in the different zones

---

* There are instances where the edges appear with all the brightness and lustre of silver.

Effects of different elevations of Sun in different zones.

must present many diversities arising from the different elevations of the Sun. If S, fig. 15, be its meridian altitude in the warmer climates of the Earth, and S′ that in the Polar Regions; then will the shadow of the projecting mass A reach to C in the latter case, but will descend so low as D in the former. In like manner, the shadow of B for the inferior position of the Sun, will be at E, but for the superior it will be at F. In the Polar Regions, the lower sides of Clouds must be more frequently illuminated than their upper. There the edges of Clouds near the Sun often present "a fiery or burnished appearance;" and as that luminary never rises more than a few degrees above the horizon, they display these brilliant characters for some time. The lights and shadows of tropical Clouds must be necessarily very different from these.

Comparison of Polar and Tropical Clouds.

The whole body of a Cloud projects a shadow into space,

(853.) But it is not only with the shadows of the parts of Clouds which are thrown on the Clouds themselves that we have to do; the whole of a cloudy mass must project a shadow into space, passing with freedom through the air, until it is interrupted in its course by some other Cloud, or is intercepted at last by the ground. In the case of the shadow of one Cloud falling on another, let S be the Sun, fig. 1, plate xvi., and A and B Clouds so situated, that the shadow of one may darken the whole of the upper part of the other, the Cloud at B thus presenting to the spectator the appearance of fig. 2. Or the positions of the Clouds may be such, that the shadow may be thrown on the lower part of B, fig. 3, its upper part being luminous, the whole Cloud appearing as in fig. 4. The shadows of several Clouds may sometimes be thrown on some single Cloud, producing, apparently, many anomalous phenomena. Thus, in fig. 5, the shadows of the Clouds A, B, C may fall on the Cloud L M; and to the spectator at N, who may contemplate the greater Cloud, without any reference to the small ones, sees in it the dark spaces D E, F G, H I, which he cannot account for. The moment, however, he endeavours to connect the positions of these shaded parts with the situations of the lesser Clouds and the Sun, he perceives at once the cause of the anomaly; and thus may many analogous and perplexing appearances be explained.

which may fall on another Cloud.

The shadows of several Clouds may fall on a single Cloud.

Examples.

(854.) Examples are not wanting to illustrate these beautiful phenomena. Howard mentions the case of a Cumulo Stratus with a bright Sun. An obscurity like the Crown of a Nimbus came down upon the Cumulo Stratus, which could be attributed to no other cause than a shadow. He alludes also to the shadows of Cumuli being projected on the haze above them at sunset. Thus let S, fig. 6, be the Sun in the horizon, A the Cumulus, and B the haze. Such a combination, it is manifest, must exhibit a shadow on the haze.

Shadows of Cumuli projected on haze above them at sunset.

Shadows of Clouds in the air.

(855.) But the shadows of Clouds in the air, disclose the most interesting phenomena. A solitary Cloud may sometimes be seen with its shadow distinctly marked in the atmosphere; but often the shadow is not visible, until it becomes considerably foreshortened a greater depth of particles discloses it to view. The cloudy mass M, fig. 7, may throw out a shadow into space. Above the spectator at E, this shadow may present only the depth of A B; but in a more distant part, this apparent depth will be augmented to D C. These shadows, moreover, may be observed to change their positions with the Clouds themselves.

Shadows of several Clouds.

(856.) But the phenomena become much more interesting, when several Clouds are presented to our view. At sunset, says Howard, a group of dense Cirri cast their shadows into the air. When a Cumulus and Cumulo Stratus were changing into Nimbi, the Sun passed behind a group of dense Clouds in the North-West, and darted broad diverging beams of light, separated by distinctly formed shadows, both downwards to the horizon, and upwards in the air. This effect is feebly shown in fig. 8. In fig. 9 we have an instance of diverging shadows proceeding upwards from behind a Cloud, and above which were several delicately formed Cirri. Some of these Cirri were found in the diverging bands of shadow, and some in the enlightened intervals between; the former, it was remarked, being somewhat darker than the latter. Fig. 10 is an example wherein a wide band of shadows was but barely perceptible to the eye. The Cirri, however, which it covered, were sensibly darker than those which extended beyond it; and it was this difference of tone which first gave evidence of the existence of the shadow.

Other exampl shadow

Effects interst in Clo

(857.) At times, diverging bars of light and shade, resulting from the solar rays passing through the interstices of Clouds, present phenomena of a very interesting kind, and an example of which may be seen in fig. 11. The beauty and magnificence of aerial scenery is much increased when fine shadows of any of these kinds are delicately disclosed. An example is given in fig. 12.

Shadov converg to a po Twiligl streake shadow produc percept Clouds

(858.) Howard saw a considerable haze slightly reddened by the solar rays. In the midst of the haze appeared several broad bars of shadow, converging into a point of the horizon, and projected apparently by lofty dense Clouds. The twilight, also, according to the same respectable authority, is at times streaked with converging shadows, the origin of which cannot be traced to any visible Clouds intercepting the light.

Diverg shadow West.

(859.) At sunset, broad diverging shadows are frequently observed among the Clouds in the West, and sometimes their effect is exceedingly fine, particularly when they fall on a coloured twilight. After sunset, Howard remarked some beautiful diverging shadows on a pure, diluted, carmine sky. Such shadows, were they long enough to pass the zenith of observation, ought, by principles already explained, to converge again towards some point of the Eastern sky, opposite the Sun's place, the converse phenomena taking place at sunrise.[*] Dr. Smith, in his Optics, mentions an example of the convergence of long whitish beams towards a point diametrically opposite to the Sun, the converging beams not being so bright as those which usually diverge from him, and the sky beyond them appeared very black. Dr. Brewster saw also an example of diverging beams thrown out in great beauty through the interstices of broken masses of Cloud floating in the West. In the East was a dark black Cloud, which seemed necessary as a ground for the converging rays which appeared on it. The converging beams were very much fainter than the diverging, and the point to which they converged was, as near as could be estimated, as far below the horizon as the Sun was above it. About ten minutes after the phenomenon was first seen, the convergent lines *were black* or very dark. This arose from

These dows o someti to conv toward the Ea and su *versâ*. Examp diverg rays ii East a sunset.

---

[*] Saussure, in his ascent of Mont Blanc, saw at sunrise from the station he had selected as his observatory, six rays of a fine purple, which parted from the horizon to the West, precisely opposite the Sun. These rays had their centre a little below the horizon, and extended 10° or 12° from it. He seemed to have had no idea of their being shadows of Clouds in the Eastern sky.

the real beams having become very broad, and of irregular intensity, so that the eye took up, as it were, the spaces between the beams more readily than the beams themselves. Mr. Foggo mentions a case which displayed very delicate but distinct rays in the East, and vanished the moment the Cumulus, which veiled the Sun during their appearance, had somewhat altered its position. When the Cloud, however, had nearly reached the zenith, a broad, conical ray darted horizontally from between the eminences of the Cloud, extending to a great distance. Mr. Faraday, likewise, observed a remarkably beautiful example at sunset, on the 19th of August, in the Isle of Wight. Ten or twelve enormous rays of light and shade, says he, were observed towards the North-East, South, and South-East, all radiating apparently in straight lines from a spot, rather South and East, and just upon the horizon. The atmosphere contained a slight haze, which allowed the Sun's beams to pass forward with but little interruption, but yet in sufficient quantity to reflect a considerable portion of light to the eye. Clouds very far to the West, opposed the progress of the light, and immense parallel shadows were consequently cast in nearly horizontal directions along the sky, over the head of the observer. The difference between these shadows and the intervening illuminated parts, could be observed only after they had considerably passed the zenith of the observer, and had become foreshortened in the Eastern sky, where from the greater depth of mass they became visible. An increased haze in the Eastern part might also have rendered the phenomenon more visible, and hence, from what has been before said respecting parallel bands of Clouds, this system of shadows ought necessarily to meet in some spot opposite the Sun. The phenomenon here referred to is illustrated in fig. 13. The obscure cloudy mass from which the rays seemed to spring, must have been a bank of Cloud, which, from what we have before explained, ought to put on the form of a segment. Howard mentions that he found the diverging bars of light and shade sometimes to result from the great quantities of dust constantly floating in the air. He also alludes to an orange-coloured twilight delicately varied with dusky horizontal striæ.

Objects on the Earth may throw shadows into the air. Shadow of twilight visible in Moonlight, and vice versa. Shadows of persons falling on a Cloud.

(860.) Objects on the Earth may occasion shadows in the air. Thus, (fig. 14,) let A be the observer, S the rising or setting Sun, and M a hill. Such a mass in such a situation with regard to the solar orb, must necessarily project a shadow into the air. Howard records an example of the shadow of the twilight being distinctly perceptible in the moonlight at nine P. M.; but twenty minutes later, the Moon cast an equally strong shadow into the twilight.

(861.) Howard and some friends saw their own shadows, and the shadow of the cliff on which they stood, projected on a cloudy mass below. About half-past six P. M., he says, we perceived a body of mist appearing like a mixture of Cumulus and Cirro Stratus come under the sandy cliff on which we stood, and covering the sea below. The Sun shone clearly in the West, which projected our own shadows, and that of the cliff's edge, upon the Cloud beneath. This is illustrated in fig. 15, where A, B, C are the persons on the cliff, whose shadows were projected to D, E, F, the Sun being at S, the shadow of the cliff itself being G H.

Shadows of Clouds on the ground.

(862.) With the shadows of Clouds on the ground, which sometimes add so much to the beauty of the landscape, we are all familiar. One of their practical uses, is that of finding the altitudes of the Clouds which project them.

Coloured shadows.

(863.) Shadows are said to be sometimes coloured. Leslie remarks that near sunsetting, the shadow of a pencil along a blank card appears a bright azure on a lilac ground. Brougham alludes to some that are purple, blue, and red. Rumford, however, regarded them as mere fallacies.

Effects of shadows on the sky.

(864.) Shadows sometimes impart a high degree of repose to the Clouds, while others produce effects entirely the reverse. The lights and shadows of a serene Summer's evening, are very different from those which prevail when the sunbeams are dispersed in every possible direction by innumerable small flickering Clouds. There are days when the whole sky seems full of jarring lights, and there are others when it is softened into mellowness.

Colouring of the Clouds.

Optical phenomena of the sky.

(865.) The subject of Physical Optics was bequeathed to us by the immortal Newton; and in our own days we have seen the most splendid additions made to the rich inheritance. Meteorology, in the modern acceptation of the term, requires that at least some brief allusion should be made to phenomena, which in every region of the Globe impart so much grandeur and beauty to the sky. The difficulty, however, in beginning such an inquiry, is to know where to stop; and the limits of a brief paper will soon teach us, how very much our best efforts must fall short of the conditions which the present state of the Sciences require.

Colouring of the Clouds.

(866.) The harmonious colouring of the Clouds cannot but awaken a lively curiosity. Their most ordinary appearances must arrest the attention of the beholder; and from the deepened and sublime tone of the thunder Cloud, to the soft and tender colouring of the evening sky, how striking and wonderful is the transition! Who can behold the extraordinary magnificence of the Clouds, and the rapid transitions of colour which they sometimes undergo, without wishing to comprehend the cause of so much variety and splendour?

Passage of light through the atmosphere.

(867.) In the passage of light through the atmosphere, it is known to undergo many important changes. A portion of it is absorbed by the air, even in its purest state; and of the horizontal sunbeams transmitted through two hundred miles of that medium, scarcely a two-thousandth part reaches us. A densely formed Cloud must, therefore, of necessity detain a much larger share; and those dark and sombre forms, which sometimes impart so gloomy an aspect to the sky, can only result from the feeble transmission of the solar light. The brilliant whiteness too, which their edges occasionally disclose, must result from a more copious emission of luminous rays; and Leslie, therefore, has properly remarked, that the depths of shade which a Cloud exhibits, may be regarded as comparative measures of the varied thickness of its mass.

Clouds absorb light.

Their brilliant edges.

Leslie's remark on their shades.

Varied appearances of the Sun and Moon.

(868.) But this absorption of the solar light, brings another and a most interesting class of phenomena into view. While the Clouds have a property of sometimes absorbing equally all the solar rays, as is manifest by the Sun and the Moon appearing through them perfectly white, there are other occasions when they appear in a very different way. In the whole of Italy and the South of France, for example, the Sun lately appeared a pale blue, and instances have not been wanting in our own Country of the same kind. On the evening in which this page was written, its upper limb displayed a deepened orange, and its lower a brilliant red; and every one who has watched the changes of the morning and evening sky, cannot but have noticed the most remarkable varieties of colour. It is to the air, therefore, and to the Clouds suspended in it, that we must look for the cause.

Effects of Clouds.

Their powers of absorption and reflection.

(869.) The different modifications of Clouds, partaking as they do of all imaginable degrees of density and position, and presenting so many different dimensions to act on the Sun's light, cannot but occasion the greatest diversity of absorption, as well as of reflection. While some absorb the blue rays, and transmit a rich vermilion, there are others which exhibit successive transitions of yellow, orange, crimson, and purple, even to a dullish grey; and in the unbounded variety which the sky presents, the calm deductions of the Philosopher are apt sometimes to be lost in feelings of admiration, wonder, and delight.*

Example of a section of a Cloud.

Probable developement of colour.

(870.) Let us suppose, in order to render the subject in some degree intelligible to the young Meteorologist, fig. 16 to represent a vertical section of a Cloud of uniform density, divided into successive strata by a system of parallel rays. The first ray, A B, may pass through so small a number of vesicles, as to cause but a feeble absorption of the solar light, and thus permit that portion of the Cloud to appear nearly white. The second and third rays C D, E F, by passing each through a greater mass of vesicles, must render the absorbing process more active, and thus cause colours of some kind to be emitted from D and F; while the lower ray G H may disclose to the spectator another, or the same colour modified in intensity, at I and H. This last ray, from the form we have given to the Cloud, must, it is obvious, be very differently circumstanced from either of the upper rays, A B, C D, or E F, since the portion of it K I between the two projecting masses, will be acted on only by the air, and not by the vesicular atoms composing the Cloud. The supposition need not be limited to uniform circumstances of density even in the same Cloud.

Different Clouds may disclose diversities of colour by alternate absorptions of same ray.

(871.) Not only, however, may colours be developed by the absorption of light in the successive strata of the same Cloud, but different Clouds may disclose diversities of colour, by alternate absorptions of the same ray. Suppose the common ray A F, fig. 17, to pass through three successive Clouds in the same horizontal stratum of the atmosphere. The portion A B during its passage through the first mass of Cloud, will undergo absorption, and disclose some colour at B. From B to C, the ray will be further modified by the air, and at D it will have undergone another change, either by disclosing a new colour, or the former in some degree modified. For a similar reason, a new alteration will take place at F; and thus three different colours, or three varieties of the same colour, will be presented to the spectator at S. These Clouds may be even so situated as to appear like one mass, fig. 18, thus beautifully blending the colours together; an effect which will be readily understood from what has been already said on the apparent positions of the Clouds.

Position Clouds must infl ence the velopem of colour

(872.) The positions of Clouds must, indeed, considerably influence the developement of colour.* In the immediate vicinity of the Sun, the most brilliant colours may be disclosed, and their vividness and intensity diminish, and at last disappear at some distance from it. Parry records a beautiful instance of some white fleecy Clouds, which, at the distance of 15° or 20° from the Sun, reflected from their edges the most soft and tender tints of yellow, bluish green and lake; and as the Clouds advanced, the colours increased gradually in vigour, until they reached a sort of limit, 2° below the solar orb. As the current continued to transport them, the vividness of colour became weakened by almost insensible degrees, until the whole assemblage of tints vanished at an azimuth 10° from the Sun. Mr. Foggo observed, also, an extensive black Cloud which veiled the whole face of the heavens, to within 10° of the Southern horizon. So dense was the cloudy mass, that the Sun's place was completely concealed from his view. A small portion, however, A B, fig. 19, of the Southern edge of the Cloud, was of a dazzling yellow; and as a chain of scud crossed in rapid succession the illuminated part, each became adorned with the prismatic tints, and each in its turn returned to its first sombre hue.

Vertical rangeme of Cloud or altered elevation the Sun must infl ence the phenome of colour.

(873.) The vertical arrangement of Clouds, or altered elevations of the Sun, must also greatly affect the phenomena of colour. If we imagine A, B, C, fig. 20, to be a vertical section of Clouds, having different elevations, but the same azimuth, and rays S *a*, S *b*, S *c*, be transmitted from the Sun at S, through them, some variety of colour will be disclosed by each successive Cloud; but when by the descent of the Sun to S, or a change in the elevation of the Clouds, other rays are made to pass through them, new varieties of colour may be revealed. Scattered masses, like fig. 21,† must produce a very great diversity, according as the rays proceed in the directions *a a*, *a a*, &c., *b b*, *b b*, &c., or any other.

Absorbe power of Clouds shown in those whi pass befo solar disc sunset.

(874.) The great effects of the absorbent power of Clouds, is admirably shown in those vesicular masses which pass before the solar disc, near the time of sunset. A dense, stationary bank of Cloud, fig. 22, of a deep leaden colour was in contact with the horizon, and above it the solar orb suffused with a beautiful blush of red, diminishing in intensity upward. As soon as the Sun came into contact with the upper edge of the Cloud, a small, but exceedingly dark mass was pro-

---

* The phenomena of the absorption of light has, however, been too little studied to permit us to speak with entire confidence of the application of its laws to remote masses like the Clouds. We know, indeed, that many coloured, transparent bodies, both solid and fluid, do not absorb the solar rays proportionally; and that it is in consequence of their unequal absorptions, that they appear coloured by transmitted light at all. We also know that in coloured media, some attack the spectrum at one extremity, some at the other, and some at both; and that though the orange and green rays cannot be decomposed by prismatic reflection, they can be so by absorption. When we consider, therefore, how diversified are the general conditions of the Clouds, what variable circumstances govern their densities, how unequal are their magnitudes, and what different positions they occupy in the great hemisphere of the sky, we may look to the theory of absorption, as having at least very high probabilities in its favour.

Brewster remarks, that the light of the Clouds is partly polarized.

* So great is the effect of position, and so remarkable the differences it produces, that it seems difficult sometimes to believe, that the Clouds which in the evening we see drenched with crimson and gold, are the same as we beheld absolutely colourless in the middle of the day.

† An insular situation like our own, with a climate subject to perpetual vicissitudes, must be best adapted for studying the physiognomy of the sky. Here Clouds are no novelty, and it is their absence from the celestial vault which creates surprise. There are regions, however, where the contrary is the case, and where the appearance of a Cloud at some seasons, engages the whole attention of the inhabitants.

Clouds projected on solar disc sometimes rendered darker.

jected on its disc, as fig. 23, no other part of the cloudy bank seeming to alter its appearance in any way. As the Sun descended, other equally dark Clouds came into view; and when its upper limb arrived at length on a level with the superior edge of the Cloud, it was covered with the very dark forms shown in fig. 24, the other parts of the solar face remaining nearly as clear and as freshly coloured as before.* Now these very dark masses were clearly distinct portions of the great bank of Cloud, and existed while the Sun was above it, although blended apparently in a dense mass, when the light passed obliquely through them, as shown in the section, fig. 25; but when the Sun came into the position of fig. 26, some of the rays passed uninterruptedly between them; and the Clouds themselves being of great horizontal extent, absorbed in a very high degree the light that fell on them. In a case of this sort, as well as in the twilight generally, the hard and well-defined outlines of the Clouds are worthy of observation. Twilight, it has often been remarked, while it takes off the edginess of objects *below* the horizon, more sensibly marks the outlines of those *above* it, when they are opposed to the sky; and the principle is remarkably confirmed in the forms of Clouds.†

Hard outlines of Clouds in the twilight.

Clouds projected on solar disc not always rendered darker.

(875.) While the Clouds in the preceding case were, however, rendered so much darker by being projected on the solar disc, cases occur when the contrary is the case. Fig. 27 is an instance where the Sun's face was coloured nearly as before, and during its descent three masses of extended Cloud were brought into apparent contact with it. The parts of these Clouds projected on the disc, became luminous and coloured, but the parts beyond it preserved their original grey appearance.‡

Richest colours presented by the Cirro Stratus.

(876.) Among the different modifications, the most rich and copious colourings are presented by the Cirro Stratus. Shades of purple, crimson, lake, and scarlet are very common; and cases occur wherein they are tinged with violet. Howard saw two bars of this Cloud of a rich crimson, on a ground of almost a golden hue, extending from South-West to North-East, at the altitude of 20°. Cirri and Cirro Cumuli disclose also very different colours at different times, though their situations with regard to the Sun may be very nearly the same. Howard mentions a case of pink-coloured Cirri at sunset; and also others which displayed tints of orange passing through lake and purple, their edges glowing like bright flame. The burnished appearance of the edges of Clouds in the Polar Regions, we have already adverted to. Masses of Cirro Cumuli disposed in beds, on the decline of day, are sometimes very deeply tinged with crimson or vermilion. Howard mentions a case of a Cloud of this sort, coloured with lake passing into violet. A Cumulo Stratus dissipating beneath a veil of Cirrus at the moment of sunset was seen by him of a light silver grey. During the twilight, this same Cloud became successively yellow, orange, red, purple, dull grey, and finally somewhat red. He saw, also, that the sky seen behind a large Cumulo Stratus under the setting Sun, was of a deep brownish lake colour. When the sky above the setting Sun was of a rich yellow colour, a large bed of the same modification exhibited very beautiful deep red tints. Howard, likewise, saw the whole hemisphere overspread with Cirri passing to Cirro Stratus and Cirro Cumulus, and having an arched lowering appearance, the whole being dipt in a great variety of tints. A splendid exhibition was also made by dense Cirro Strati to the South-East and East, which assumed first a deep blood red, passing through crimson and a gradation of lighter reds to orange, and finally to flame colour. The afternoon and night of the next day proved very wet. There seems, indeed, to be some relation between the colours of the Clouds and rain. He speaks, also, of Clouds beautifully coloured, both at sunrise and sunset, with a double gradation of tints, and in which the successive effects of the direct and refracted rays were very distinctly marked. At Mexico, in extremely fine weather, Humboldt has seen large bands of Cloud having all the colours of the rainbow, spread along the vault of the sky, and converging towards the lunar disc. He saw, also, the thick veil of the Clouds rent asunder in shreds near the horizon, and the Sun on a firmament of indigo blue. The broken Clouds became gilded, and fasciculi of divergent rays, reflecting the most brilliant colours, extended even to the midst of the heavens.* Mr. Foggo mentions a chasm in a Cumulo Stratus driven rapidly by the wind, and through which was seen an extensive Cirro Stratus, entirely at rest in a higher region of the sky, beautifully striped with the prismatic colours.

Cirri and Cirro Cumuli disclose very different colours at different times.

Phenomena of Cumulo Stratus.

Phenomena of chasms in Clouds.

---

* How different are these Clouds from those adverted to by Humboldt of a brilliant whiteness, and through which he has distinguished the spots of the Moon so perfectly, as to give the idea of its disc being placed before them.

† The same fact may be noticed when terrestrial objects are thus presented to the sky. Price, in his Work on the Picturesque, remarks, "that many varied groups and elegant masses of trees, which were scarcely noticed in the more general diffusion of light, in the twilight distinctly appear. Then too, the stubborn clump, which before was too plainly seen, makes a still fouler blot on the horizon; while there is a glimmering of light he maintains his post, nor yields till even his blackness is at last confounded in the general blackness of night."

‡ The projection of Clouds on the solar disc, often discloses many interesting phenomena respecting their formation and texture. In the case last referred to, the cloudy bands appeared of uniform density, before they came into apparent contact with the Sun; but as soon as that took place, the parts on the solar disc immediately disclosed a fibrous structure. A remarkable instance of the kind occurred among some very irregular bands of dark Cloud, the intervals of which seemed to be filled up with Cloud of a less dense, but *uniform* texture, the whole seeming to be *stationary*. As soon, however, as the Sun's disc came into contact with the lighter part of the Cloud, it was immediately covered with an irregular and rapidly moving network, as fig. 28, although no perceptible motion was visible in the great mass of the Cloud, proving at once the fibrous texture of the Cloud, and the rapid motion existing among its parts. When it came into contact with the denser bands, this motion was not perceived.

It may, also, be worth while to advert in a Note to the following interesting phenomenon. When the lower limit of the Sun comes into apparent contact with the upper edge of a bank of Cloud, a curved indentation appears in it, the breadth of which is governed by the apparent size of the part of the solar disc on the edge of the Cloud. When the Sun first appears in contact, the indentation is very small, as in fig. 29, but it gradually increases until the horizontal diameter of the Sun reaches the Cloud, as in fig. 30, after which it diminishes as in fig. 31, and when the Sun finally disappears, the edge of the Cloud becomes instantly restored to its former state, as in fig. 32, the separated parts visibly approaching each other, and appearing to meet in the centre of the indentation. This final restoration of the edge of the Cloud, is often an interesting phenomenon. Sometimes colour is perceptible round the indentation, but there is always a more or less brillant emission of rays. In the morning, the lower edge of a Cloud ought to be thus affected. The phenomenon is probably owing to the diffraction of light. A distant hill at sunset may often be observed to be indented in this way.

* This occurred when a shock of an earthquake was felt about nine P. M. The disc of the Sun was enormously enlarged, distorted, and undulated towards the edges. There is some mysterious relation between the aspect and colour of the sky and volcanic action.

Rapid transitions of colour which the Clouds undergo.

(877.) The rapid transitions of colour which the Clouds undergo is worthy of more attention than it has hitherto received. It would seem to depend on something more than change of position, either in the Cloud or the Sun. Forster mentions an instance of some detached Cirro Cumuli being of a fine golden yellow, but in a single minute becoming deep red.* On another occasion he saw the exact counterpart in a Cirro Stratus, by its instantly changing from a beautiful red to a bright golden yellow. What, indeed, can be more interesting, than when by the breaking out of the Sun in gleams, a Cloud which a moment before seemed only an unshapened mass, devoid of all interest and beauty, is suddenly pierced by cataracts of light, and imbued with the most splendid colours, varying every instant in intensity. Numerous examples occur of this beautiful play of colour, which cannot but remind us of the phenomena displayed by the pigeon's neck and the peacock's tail, by opal and pearl.

Clouds assume their brightest colours a few minutes after sunset.

Most perfect examples of harmony occur in finest weather.

Colour of Alps at sunset.

(878.) After the Sun is set, the mild glow of his rays is still diffused over every part, and it has been remarked that the Clouds assume their brightest and most splendid colours a few minutes after it is below the horizon.† It is in the finest weather that the colouring of the sky presents the most perfect examples of harmony, in tempestuous weather it being almost always inharmonious. At the time of a warm sunsetting, the whole hemisphere is influenced by the prevailing colour of the light. The snowy summits of the Alps appear about sunset of a most beautiful violet colour, approaching to light crimson or pink.‡ It is remarkable, also, as an example of that general harmony which prevails in the material World, that the most glowing and magnificent skies occur, when terrestrial objects put on their deepest and most splendid hues.§ It has, also, been observed, that it is not the change of vegetation only which gives to the decaying charms of Autumn their finest and most golden hues, but also the atmosphere and the peculiar lights and shadows which then prevail; and there can be no doubt, on the other hand, that our perception of beauty in the sky is very much influenced by the surrounding scenery. In Autumn all is matured; and the rich hues of the ripened fruits and the changing foliage, are rendered still more lovely by the warm haze which a fine day at that season presents. So, also, the earlier trees of Spring have a transparency and a thousand quivering lights, which in their turn harmonize with the light and flitting Clouds and uncertain shadows which then prevail.

Peculiar lights and shadows of Autumn and Spring.

Splendid displays of colour when no Clouds appear.

(879.) But there are magnificent displays of colour, both in the morning and evening, when no Clouds can be seen. This may, probably, be accounted for on two suppositions, and both in unison with the theory of absorption. The air, uninterrupted by Cloud in its whole horizontal extent, may so absorb particular rays, as to disclose the glowing colours referred to; or there may be actual Clouds existing far beyond the limits of our visible sky, which absorb the light, and produce the same splendid effect. This last supposition will not be objected to, when we refer to the dark lines seen by Fraunhofer in the solar spectrum. Do not these dark lines, it has been asked, occupy the place of rays of particular refrangibilities, which have been absorbed in their passage from the Sun, before they reached our atmosphere? a condition seeming to be necessary from the absence of these lines in the spectra of the fixed stars. Have they not, it has been asked by Herschel, been absorbed in the solar atmosphere? We may apply to this subject, as well as to other parts of Meteorology, the remark of Bacon, "I would not have it given over, but waited upon a little."

Effects of Clouds far beyond the limits of o visible sky Elucidated by dark lines of solar spectrum.

Different examples beautifull coloured skies.

(880.) The following are incidental but valuable examples gleaned from Howard and other respectable authorities. At sunset Howard saw in the West a clear lemon-coloured space, close to the horizon. Above were crimson lights, with shadows of grey and purple in a variety of figures, streaked, waved, and clustered. In the *East* were Clouds, some rose-red, and others of a tender green. He speaks, also, of a ruby-coloured twilight; of orange surmounted by rose-colour; of a sunset with a pure dilute carmine tint; also of a sky on the decline of day reflecting a bronze hue from some Eastern Clouds. About the time of sunset also, or sometimes a little after, the lower part of the sky, to some distance on each side of the place of his setting, may be seen to incline to a faint sea-green. At greater distances this gradually changes into a reddish brown, the colour of the horizontal sky on the opposite side inclining sensibly to purple. In the different voyages to the Polar seas also, are some brief and scattered notices worth collecting. Ross frequently saw a yellow sky. In the South-East and South-West at sunrise and sunset, Parry saw, generally, near the horizon, a rich bluish purple, and a bright arch of deep red above, one mingling imperceptibly with the other. About the time of sunset in these regions, the part of the sky within 1° or 2° of the horizon, was of a bright red, above which was a soft light blue, passing into delicate green. At sunset in December, the sky was beautifully red near the Southern horizon, and a soft rich purple to the North. Saussure remarked in his ascent of Mont Blanc, that the evening vapour which tempered the Sun's brightness, and half concealed the immense space he had below him, formed the finest purple belt encircling all the Western horizon; and as the vapour descended and became more dense, this belt became narrower and of a deeper colour, and at last of a blood red. At the same instant, some Clouds darted a light of such brightness, as to resemble meteors or flaming stars.

In our ow Country.

In the Po lar seas.

In the Al

(881.) But the colour of the sky is often influenced by reflection from terrestrial objects. Ross mentions, that while the Sun and Moon were passing in azimuth along the tops of the mountains, the snow which covered them, and which had naturally a yellow tinge, had then the lustre of gold, the reflection of which on the sky produced a green so delicately rich and beautiful, as to pass description. Other causes, also, sometimes operate. Humboldt remarked when the air was clear and the sky of a very deep blue, that the horizon reflected a livid and yellowish light, which he thought resulted from the quantity of sand suspended in the air

The colo of the sk often influenced reflectio from ter trial obje

Effects o suspend sand.

---

* No one more than the Meteorologist requires a knowledge of the combinations of colour, so infinitely varied are the tones of Nature, both in the same and different Countries. Who can venture to imitate by the pencil the endless varieties of red, and orange, and yellow, which the setting Sun discloses, and the magical illusions which all the day diversify the vast and varied space the eye travels over in rising gradually from the horizon to the upper sky. Those who have paid any attention to colours must be aware of the difficulty of describing the various tints and shades that appear, and which are known to amount to many thousands. It would be useful if our Meteorologists would endeavour to record in some way the various colourings of the different modifications, and also their elevations at the time of observation.

Example of a sunset from Howard.

(882.) It may be useful to advert to a single example of a sunset, recorded by Howard. The Sun set, surrounded by a moderate glow of flame colour, and without a spot on the Western sky. An extensive brightness remained in the horizon, which insensibly vanished upwards and towards the North-East and South-West. Opposite to this, and quite distinct in its boundaries, appeared a mass of colour resting on an extensive violet or purplish base, in the horizon, and which, diminishing as it rose, terminated at length in a rose-coloured apex. As this apex passed away, an orange tint in the North-West spread and deepened, and was suddenly surmounted by a fine blush of red, completing a grand pyramid of coloured light, reaching half way to the zenith, and glowing every moment with increased brightness; so that half an hour after sunset, the landscape to the East was actually in a much stronger lighter than after the disappearance of that luminary. At the moment this was in the greatest perfection, the opposite pyramid was no longer visible, and the twilight passing off, the red first vanished, the orange spreading upward, at the same time it grew fainter with the white light of the picture.

Cause of morning and evening Clouds displaying a richer colouring than at noon.

(883.) We may gather from what has been advanced on the absorption of light, and from the necessary arrangement of the dimensions of Clouds in the air, a reason why the morning and evening skies display a richer colouring than when the Sun is in its meridian splendour. The stability of Clouds requires that their horizontal dimensions should, in general, be greater than their vertical. In the morning and evening, the former dimension is so situated, as to call into the greatest activity the absorptive power, when taken in conjunction with the great range of horizontal air; whereas in the middle of the day, not only is there a smaller dimension of the Cloud, but a much less quantity of air acts on the light. The increased rarity of the air in Tropical climes, may afford also a reason why the sunsets there are less brilliant than in Countries more remote from the Equator. The continued low elevation of the Sun in the Polar Regions, will likewise explain the more frequent occurrence of rich and splendid skies in that region. Very much remains to be done to perfect our knowledge of the phenomena of Clouds, and we hope it is a subject which will meet with increased attention from Meteorologists.

Tropical and Polar sunsets.

Halos, Parhelia, &c.

(884.) There are other remarkable exhibitions of colour in the atmosphere connected with the Sun and Moon, which have very much occupied the attention of Philosophers. In a clear sky these luminaries exhibit their discs without any change of colour; but in other conditions of the air, they not only undergo alterations of colour, but are also surrounded with circles and parts of circles of various sizes and forms, and exhibiting diversities of the most singular and remarkable kinds.

Formation of corona.

(885.) When a thin stratified Cloud passes before the Sun or Moon, a portion of the Cloud surrounding the luminary appears much more luminous than the rest, as in fig. 1. pl. xvii., the phenomenon being then denominated a Corona. These coronæ depend, probably, on the existence of a number of particles of water, of equal dimensions, and situated in a proper position with respect to the luminary and the eye. There being so much diversity in the magnitudes of the spherules of water, their dimensions may be expected to vary without limit, and by observation they are accordingly found to do so. Coronæ are very common, and are best seen round the Sun by reflection from the surface of still water. Newton saw in this way, three rings of colour surrounding the Sun, like small rainbows, the innermost being blue next the Sun, red without, and white between. The second ring was purple and blue within, pale red without, and green in the middle. The third ring was pale blue within and pale red without. The diameters of the rings were respectively 5° or 6°, 9½°, and 12°.

Very common. Best seen by reflection from still water.

Newton's example.

Halos round the Sun.

(886.) On other occasions circles more or less brilliant, and of a much larger size, surround the disc of the Sun and Moon, the luminary occupying the centre, as in fig. 2. These are denominated halos. Those belonging to the Sun are generally tinted with colours less bright than the rainbow, and sometimes quite as distinct. These colours, however, are variously disposed. Sometimes the red is next the Sun, and a pale blue on the outside; but at other times indigo and violet are without. Frequently they are red or yellow on the inside, and white on the outside. One halo was seen, the middle of which was white, after which followed red, blue, and green, its outermost border being a bright red. In another case a pale red on the outside was followed by yellow and green, terminating with white. The space included within the halo is frequently of a most intense grey, or of a deeper blue than the rest of the sky, when the atmosphere is misty, or of a transparency more or less perfect. Under some circumstances a second halo is formed, much larger than the first and concentric with it, as in fig. 3. Its colours are very pale, and its whole splendour much less than that of the halo within. Frequently, from peculiar conditions of the atmosphere, neither the first nor second halo is perfectly formed, as fig. 4.

Tinted with colour.

Space within halo frequently an intense grey.

Halos sometimes imperfectly formed.

Halos round the Moon.

(887.) Halos round the Moon are formed sometimes of a luminous white circle, and at other times are tinted with pale red alone, or green and red. The white circle is sometimes well defined on the inner side, so as to make the included space appear dark, while on the other side it passes insensibly into the colour of the sky. A succession of these halos frequently occurs. A corona is sometimes formed within the halo, as fig. 5; and Howard observed a case where the corona was not formed by the Clouds which produced the halo, but by haze probably nearer the Earth.

Succession of halos.

Corona within a halo.

Halos seen in a mist.

(888.) Professor Strehlke of Dantzic, in passing over some fields at midnight in August, 1828, was greatly surprised at the successive appearance and disappearance of halos. Some of the fields were covered with mist, and others perfectly clear. In a field free from mist no halo could be perceived; but in those covered with mist, three, or even four halos were perceived at small distances from each other, with very vivid colours, red being always on the outside. Howard saw a lunar halo of moderate diameter, which, disappearing, gave place to a portion of a very large one. In the Polar Regions Parry remarked that halos almost always began to make their appearance about the time of full Moon.

Vary according to climate.

(889.) Coloured circles are, however, much more rare in the Countries of the North, than in Provence, Italy, and Spain. Under the Torrid zone beautiful prismatic colours appear almost every night. Often in the space of a few minutes they disappear several times. Between the 15th degree of latitude and the equator, small halos surround the Planet Venus, orange, purple, and violet being distinctly perceived. Humboldt, however, never saw any colours around Sirius, Canopus, or Achernar.

Marriotte's theory of their formation.

(890.) Marriotte accounted for the formation of halos from the refraction of prismatic crystals of ice descending through the air in all possible directions, and these receiving the solar rays under every variety of inclination. In certain positions of these prisms, it may be proved that light suffers, in transmission through them, a mininum deviation; and this position is determined by the condition that the refracted ray forms with the two sides of the prism an isosceles triangle; or, which comes to the same thing, the angle of refraction is equal to half the refracting angle; and as the refracting angle is here 60°, the angle of refraction must be 30°, and the angle of incidence about 41°. Hence the deviation is equal to double the angle of incidence, *minus* the refracting angle; or $2 \times 41^\circ - 60^\circ = 22^\circ$, and which, singularly enough, coincides nearly with the semidiameter of the solar halo. In other positions of the prism, the deviation increases very slowly, till it becomes a few degrees greater. Hence the breadth of the circles of colour being considerable, the colours must fall principally on each other, and thus become very indistinctly separated. The external circle may be referred to the effect of two such refractions in succession. This mode of explanation could be put at once to a decisive test, could the diameters of halos be measured with the same exactness as the rainbow; but it is seldom the phenomenon is presented with all the uniformity and precision desirable.[*]

Light of halos refracted.

(891.) Arago made an observation which proves in a certain degree, that the light of halos is refracted, having found that it is always polarized by refraction and not by reflection.

Halos may afford us information respecting temperature of higher regions of the air.

(892.) One useful Meteorological inference may be drawn from these Optical inquiries respecting halos, and that is if the presence of icy particles be necessary for their formation, they may be regarded as furnishing us with some data respecting the temperature of the higher regions of the air.

Indications of weather.

(893.) Halos, from their relation to the modification Cirro Stratus, in which they chiefly occur, are found to indicate wind and rain, and sometimes, at the approach of Winter, snow and frost, at which time the colours are very brilliant. Late in the Spring, Howard has repeatedly observed a large white lunar halo to be followed by hot weather.

Appar forms o halos.

(894.) The apparent form of the halo is that of an irregular oval, wider below than above, the Sun being nearer their upper than their lower extremity. This results from the apparent figure of the sky. Parry measured several, and found all the diameters of each to be equal.

Parheli

(895.) Parhelia consist in the simultaneous appearance of many Suns, images of the true Sun. These images always appear at the same elevation as the true Sun, and are always united to each other by a white circle, likewise horizontal, and whose pole is in the zenith. This circle changes its elevation with the true Sun; and its apparent semidiameter is always equal to the distance of this luminary from the zenith.

Cause o whitene the circ

Of colo parhelia

Parheli someti without halos. Cause.

(896.) The whiteness of the circle here alluded to, results from the refraction of the vertical faces of crystals, supposed to be scattered equally through every variety of azimuth; and to the refraction of vertical prisms must be referred the coloured parhelia which impart so great an interest to the sky. These coloured parhelia are not always confined to the limits of halos, but are sometimes formed a little without them, on account of the deviation of the light which passes obliquely through the vertical prisms, being somewhat greater than that of the light transmitted by those crystals which have their axes perpendicular to the planes of incidence and refraction. So also, Dr. Young observes, the light which passes through the horizontal crystals, at different azimuths, is variously modified, so as to produce the beautiful phenomena of inverted arches touching the halos at their highest points; or the many other diversified combinations of arches which at times almost baffle description.

Inverte arches touchin halos.

A simpl parhelic

(897.) The simplest example of a parhelion is that wherein one fictitious Sun only appears on one side or other of the true Sun, on a suitable Cloud,—perhaps vapour passing to a Cirro Stratus Cloud, as in fig. 6, where S is the true Sun, and S¹ its image; or, as in fig. 7, where the fictitious Sun S¹ is below the real Sun S. Both these are actual examples.

Two pa lia.

(898.) The next degree of complexity is when fictitious Suns, S^1, S^2, are formed on each side of the true Sun S, on a proper Cloud, as in fig. 8, the apparent Suns being probably more or less tinted with the prismatic colours, and with or without a luminous circle passing through them.

(899.) Parry records a case of two parhelia, S^1, S^2, as in fig. 9; that to the Westward being formed on a thick, dark Cloud, was bright and prismatic, the other on the blue sky being scarcely perceptible. A ray of bright yellow light extended horizontally about 3° or 4° on each side of the parhelia, and a stripe of prismatic colours from each of them to the horizon.

Rays of low ligl

Three helia.

(900.) Another modification is when three parhelia, S^1, S^2, S^3, appear, with a circle more or less perfect passing through them, as in fig. 10. Parry, who describes one of this kind, remarks that the prismatic tints were much more brilliant in the parhelia than in any other part of the circle, red, yellow, and blue being, however, the only colours that could be traced, red being nearest the true Sun.

Three helia w peculia brightn

(901.) On another occasion, when some snow-drift prevailed, and three fictitious Suns, S^1, S^2, S^3, appeared, with a portion of another circle above, as fig. 11, the parhelia were at times so bright as to render it painful

---

[*] The following experiment by Sir David Brewster illustrates in a pleasing manner the actual formation of halos.

"Take a saturated solution of alum, and having spread a few drops of it over a plate of glass, it will rapidly crystallize in small flat octohedrons, scarcely visible to the eye. When this plate is held between the observer and the Sun, or a candle, with the eye very close to the smooth side of the glass plate, there will be seen three beautiful halos of light, at different distances from the luminous body. The *innermost halo*, which is the whitest, is formed by the images refracted by a pair of faces of the octohedral crystals, not much inclined to each other. The *second halo*, which is more coloured, with the blue rays outwards, is formed by a pair of faces more inclined; and the *third halo*, which is very large and highly coloured, is formed by a still more inclined pair of faces.

"Each separate crystal forms three images of the luminous body, placed at points 120° distant from each other, in all the three halos; and as the numerous small crystals have their refracting faces turned in every possible direction, the whole circumference of the halos will be completely filled up.

"The same effects may be obtained with other crystals, and when they have the property of double refraction, each halo will be either doubled, when the double refraction is considerable, or rendered broader, and otherwise modified in point of colour, when the double refraction is small. The effects may be curiously varied, by crystallizing upon the same plate of glass crystals of a decided colour, by which means we should have white and coloured halos succeeding each other."

to the eye to look upon them. A horizontal circle of white light passed through the Sun's disc, and across the parhelia S^1, S^2. A column of light also descended from the Sun, as represented in the figure.

(902.) In a similar case with three parhelia, S^1, S^2, S^3, and a surrounding halo, Parry saw many rays of continuous white light proceeding from the Sun S, and extending in various directions beyond the halo. These rays were brighter after they had passed the halo, than in the part within it. This is shown in fig. 12.

(903.) Mr. White saw at Bedford a beautiful combination of this kind. A B, fig. 13, is the Western horizon, and S a portion of the solar disc, appearing like burnished gold above a dark Cirro Stratus Cloud. S^1, S^2, S^3 are three parhelia, and *d e* a column of white light, reaching to the horizon below, and extending indefinitely upwards; *f*, *g*, *h* were fragments of a solar halo, exhibiting the prismatic colours; *i*, *k*, *l* three luminous trains of lights, terminating in points, the train *k* being highly coloured with yellowish red vapour, owing probably to its being situated in the centre of the column of light *d e*. The train *m* terminated abruptly, but was more distinct than the train *n*, which ended in a point.

(904.) We have before remarked that parhelia S^1, S^2 are sometimes formed outside the halo, but it is rare. Parry remarks, that on one occasion, an officer reported the angular distance between the parhelion and the Sun to be 24° 40′, and the radius of the halo 22° 30′. This was regarded for the time as an error, but subsequent observations abundantly confirmed it. On this occasion an inverted portion of another halo touched the usual halo in a point immediately above the Sun, as in fig. 14.

(905.) Sometimes parhelia S^1, S^2 appear on each side the Sun S, with a halo passing through them, and two inverted arches above, one touching the perfect halo, and the other formed above it. Both the fictitious Suns had tails of a whitish colour proceeding from them, as fig. 15.

(906.) A second halo may surround the first, as in fig. 16, with an inverted arch above it, as well as on the interior halo. This was an example seen by Martin Folkes, P. R. S.

(907.) A still more complex form is, however, sometimes presented, as fig. 17, and which was observed by Parry, where S is the true Sun, having an altitude of about 23° above the horizon *h h*, and *t u* an entire horizontal circle of white light, whose plane passes through the Sun. Immediately below the Sun, at S^1, was a very bright and dazzling parhelion, but not prismatic; and on each side, at the intersections S^2, S^3 of a circle S^1, S^2, *d*, S^3, whose radius was $22\frac{1}{2}°$, with the horizontal circle *t u*, prismatic parhelia were formed. In contact with the upper part of the halo was an arch, *x d v*, of an inverted circle, having its centre apparently about the zenith, and very strongly tinted with the prismatic colours. Above this arch was one, *k e l*, apparently elliptical, the point *e* being distant from the Sun about 26°. The portion included between *x* and *v* was prismatic, but the rest white. The space between the two prismatic arches, *x*, *e*, *v*, *d*, was extremely brilliant by the reflection of the Sun's rays from the innumerable minute spiculæ of snow floating in the atmosphere. Surrounding the whole was a circle, *q f r*, having a radius of 45°, strongly prismatic about the points *f q r*, and faintly so in all its other parts. Above this large circle was a small inverted arch, *m n*, strongly prismatic, and having its centre apparently in the zenith. Springing from the points *q* and *r* were arches, *r p* and *q o*, of large circles, very strongly prismatic. In the outer circle, two spots, *y y*, more strongly prismatic than the rest, were perceptible.

Three parhelia with several halos.

(908.) But three fictitious Suns, S^1, S^2, S^3, are at other times very differently disposed, and producing very different phenomena, as in fig. 18. In this case S is the real Sun, having a very bright halo of the ordinary size surrounding it, tinted with the prismatic colours. On its upper limb, a bright fictitious Sun was formed, as S^1, the rays of which produced a second halo of a smoky white colour, well defined in its whole circumference, and double the diameter of the other halo. S^2 and S^3 were other fictitious Suns, the rays from which formed the circles *m n*, *r p*. The rays thrown off also at the intersection of these circles at *n*, formed segments *q*, *r* of a fifth halo, about 120° of which was below the horizon.

Four parhelia with several halos.

(909.) Four parhelia, S^1, S^2, S^3, S^4, appear sometimes disposed, as in fig. 19. This splendid example was seen by Hevelius at Dantzic, 20th February, 1661. Four parhelia were also observed by Mr. Whiston, as in fig. 20. The true Sun S had a halo surrounding it, and two arches touching the halo and each other at V. At M appeared a smaller arch, convex also to the halo. The parhelia S^1, S^2 were formed outside the halo, and from them proceeded narrow, pale whitish streaks of light, resembling tails. These soon extended themselves so far as to meet in a point opposite the Sun, forming a great circle parallel to the horizon. At S^3 there appeared a third fictitious Sun, and shortly after a fourth at S^4. At P there was a small portion of a secondary halo.

Five parhelia.

(910.) Five parhelia, S^1, S^2, S^3, S^4, S^5, are shown in fig. 21, formed at the intersection of the several halos, S being the true Sun. This fine example was seen at Jackson in Tennessee, 19th August, 1825.

Six parhelia. The most complex yet recorded.

(911.) The most splendid parhelion of recent times was that seen at Gotha, on the 12th of May, 1824. The part of the sky occupied by the Sun was covered with small light Clouds, as well as very small white detached Clouds upon the sky opposite, and upon which the parhelion appeared, the phenomenon being always interrupted in the clear blue sky. The true Sun appeared at S, fig. 22, a circle of shining yellow light, S^1, C, S^2, S^3, surrounding it, its interior margin being red, and its opposite green. At S^1, S^2 two parhelia were seen a little out of the halo, and of the same elevation as the real Sun. These parhelia were very bright, and displayed all the colours of the rainbow, the red being as usual nearest the Sun. At S^3 appeared a third parhelion, less bright than the others. From A and B sprung an arc concentric with the halo S^1, C, S^2, S^3, whose radius, S A or S B, was double the radius of the first halo. The upper part of this arc glowed with the most brilliant colours, the red being towards the Sun. The remaining part of this halo dipped under the horizon. From the same points A and B, another arc A D F B proceeded, showing at D and F very lively colours, but at its extremities A and B, as well as in its middle portion D F, it was whitish. In these two arcs, the red colour was nearest the Sun, and the green on the opposite side. During a part of the time, an inverted arc D C F was seen in contact with the first halo at C; but at another interval of the phenomenon, two intersecting arcs appeared to spring from C, as in fig. 23. At this moment the point C displayed extraordinary brilliance, but no image of the Sun. Another circle K G L appeared also with very brilliant colours, touching the circle A H G I B at G, the red being on its outer border turned towards the Sun, and its inner circumference green. This circle was rather smaller than that surrounding the Sun. In the neighbourhood of G, the colours had extraordinary brilliance.

(912.) A large luminous circle, having the zenith Z for its centre, passed through the centre of the true Sun and the parhelia S^1, S^2 parallel to the horizon. Three other parhelia, S^4, S^5, S^6, appeared upon this last circle, the two first being each 90° from the real Sun, and the last 180°, or immediately opposite. Two luminous arches, O P and Q R, seeming to be portions of two great circles, intersected the fictitious Sun S^6 at right angles. Another observer saw these same arches crossing the horizontal arch nearly in a vertical direction, as fig. 24. During the continuance of the phenomenon, a portion of a circle, M S^3 N, was seen for a short time, and afterwards reappeared. This beautiful spectacle first appeared at 6½ hours A. M., and at five A. M. the thermometer was 36½° of Fahrenheit, so that at no great elevation in the atmosphere, the temperature must have been at the freezing point.

Seven parhelia.

(913.) At Kiaihta, in Siberia, on the 4th of February, 1829, at sunrise, the cold being very severe, luminous rays, known in that desolate region by the name of the Sun's ears, were seen on both sides of that luminary. At ten A. M. these rays changed into parhelia, an immense whitish column, similar to a comet's tail, issuing from the Sun towards the West, formed at length a perfect circle round the heavens. In the circumference of this circle were seven images of the Sun, pale and without rays, at nearly equal intervals from the Sun and from each other.

Singular phenomenon seen at Cape of Good Hope.

(914.) A singular phenomenon was seen by Mr. Fallows at the Cape of Good Hope, which Dr. Young regarded as fragments of coronæ, but which Brewster thinks must have been parhelia. On a clear evening, when the Sun's lower limb had just dipped the water's edge, seven luminous appearances of the same shape, but rather less than the real Sun, were perceived. These, at the moment the upper limb of the Sun came in contact with the horizon, appeared as bright points upon the water's edge, at which time one of them vanished instantaneously. This remarkable appearance is illustrated in fig. 25

Parhelia formed on some medium comparatively close to observer.

(915.) Parry observed, that though parhelia seem, to an observer placed nearly on a level with the sea, to be at a considerable distance from the eye, they are nevertheless found on ascending a gentle eminence to be formed on some medium comparatively close, perhaps only one or two miles distant.

Parhelia occur most frequently and exhibit greatest intensity of light at low elevations of the Sun. Hence seen in short days.

(916.) Parhelia occur most frequently, and exhibit the greatest intensity of light, at low elevations of the Sun. This is often particularly observable in the short days, when these phenomena assume a very brilliant appearance soon after sunrise, decrease in splendour towards noon, and resume their brightness as the Sun descends towards the West; continuing, however, distinctly visible the whole time, and being sometimes accompanied by a more or less perfect halo undergoing corresponding variations. Diversified, and most attractive as these beautiful phenomena really are, we must, nevertheless, hasten to the consideration of another part of the subject.

(917.) Not only is the Sun surrounded with beautiful phenomena of this sort, but the Moon also is attended by an appearance of the same interesting kind, denominated Paraselene. Dr. Trail records an interesting example of a wide halo, faintly exhibiting the prismatic colours formed round the Moon as a centre, a small portion of its circumference being cut off by the horizon. This circular band was intersected by two small portions of a larger circle, and which, if completed, would have passed through the Moon parallel to the horizon. At the points of intersection appeared two luminous discs tolerably well defined, equalling the Moon in size, but less brilliant. The Western paraselene had a coma directed from the Moon; that of the Eastern paraselene being much less distinctly marked, and soon lost in the adjoining segment of the larger circle. A representation of this phenomenon is given in fig. 26.

Paraselene, Dr. Trail's example.

Parry's;

(918.) At half-past six P. M. on the 1st of December, Captain Parry saw part of a circular halo, whose radius was 22° 52′ round the Moon. Part of a well-defined horizontal circle of white light, passing through the Moon, extended for several degrees on each side of her, and in the points where this circle intersected the halo, were paraselene. In the part of the halo immediately over the Moon, was another, much brighter, and opposite to it, in the lower part of the circle, another similar, but much more faint. About the same time on the following evening, two concentric circles were observed round the Moon, the radius of the smaller being 38°, and of the larger 46°. Upon the inner circle were four paraselene, strongly prismatic, and situated with regard to the Moon as on the preceding day. There was also a faint horizontal circle of white light passing through the Moon as before.

another of Parry's.

(919.) Parry gives also another case of a halo whose radius was 22° 30′, which had in it three paraselene, very luminous, but not tinged with the prismatic colours; and, on the following day, the same phenomenon occurred, with the addition of a vertical stripe of white light proceeding from the upper and lower limbs of the Moon, and forming with a part of the horizontal circle seen before, the appearance of a cross. This is represented in fig. 27. There was also at times an arc of another circle touching the halo, which sometimes almost reached to the zenith, changing the intensity of its light very frequently, not unlike the Aurora Borealis.

That seen by Hevelius.

(920.) One of the finest examples of paraselene was that seen by Hevelius at Dantzic, on the 30th of March, 1660, about A. M. The Moon A was surrounded by an entire whitish circle B C D E, in which were two mock Moons at B and D, displaying various colours, and shooting out at intervals long whitish beams. About two A. M. another circle surrounded the first, reaching to the horizon. At the summits of each of these circles, inverted, coloured arches were seen, the lower having the least curvature of the two. The exterior circle vanished first, then the largest of the inverted arches at C, and afterwards the other; and lastly, the inner circle B C D E disappeared. The diameter of the inner circle was 45°, and of the exterior 90°. See fig. 28.

Anthelion

Causes.

(921.) Amidst the unbounded diversity of the Clouds, there are some which reflect at times the Sun's image as from a surface of water, the phenomenon being hence called an anthelion. This appearance seems to result from two refractions and an intermediate reflection within the same icy crystal, causing a deviation of about $120^\circ + 22^\circ = 142^\circ$, and sometimes with two intermediate reflections, producing an angle of $60^\circ + 22^\circ = 82^\circ$

only; but it is difficult to account for the appearance of an anthelion exactly opposite the Sun, and for the unusual appearances which have sometimes been delineated as attending it.

Howard's exception of one.

Fine one seen from Shotover Hill.

(922.) Howard has frequently been able to trace the anthelion in greater or less perfection, on the perpendicular sides, or in the recesses between the crown and the foot of a large Cumulo Stratus, the Cloud being opposite to the Sun at a moderate elevation, and the upper sky clear. Under such circumstances, he says, we may sometimes discover at intervals, a broad spot of light, much brighter than the rest of the Cloud, and proceeding now and then to a momentary circular image, which is presently lost again by the change of form or direction of that part of the surface of the Cloud. Swinton, in the fine example which he saw of it from the top of Shotover Hill near Oxford, describes the anthelion to have been as large and bright as the true Sun, but not so well defined.

Glories.

Bouguer's example.

Howard's example.

Haygarth's splendid example.

Dr. Young's theoretical investigation.

(923.) Sometimes when we are standing on elevated ground, and our shadows are thrown on Clouds below, coloured circles, called *Glories*, may be seen surrounding our heads. When Bouguer and his companions were on Pichinca, a high mountain in South America, the Sun was just rising behind, and a white Cloud formed about thirty paces before them. On this Cloud each person saw *his own* shadow projected, but no other. Each shadow was perfectly defined, but the head was adorned with a kind of glory, consisting of three or four small concentric crowns having all the colours of the rainbow vividly displayed, the red being on the outside. At a considerable distance, a large white circle, 67° diameter, surrounded the whole. Howard and his family beheld a similar phenomenon at Folkstone; and he remarked, when any one of the party removed to a distance, that his shadow passed the halo that surrounded them, and appeared by itself, deprived of the glory; but the individual so removed, continued to see the glory surrounding his own shadow; those of the rest appearing to him without it. A beautiful example occurred to Dr. Haygarth, and is described in the IIId Volume of the *Manchester Memoirs*. His shadow was surrounded by coloured coronæ, and next to these were bright arches, wider than those of a rainbow. Dr. Young explains these phenomena by the interference of some of the portions of light regularly reflected within the minute drops of water, with other portions, incident at a different angle, but after an equal number of reflections, coinciding ultimately with them in direction; supposing only the Clouds in question to afford a number of these drops varying but little from each other in diameter. Dr. Young's investigations of this truly beautiful subject are well deserving the deepest attention. The Spectre of the Brocken is well worthy of attention, and is described in many popular Works.

Solar and Lunar Rainbows.

Rainbow.

Solar and lunar.

(924.) The rainbow cannot but be an object of especial interest to the Meteorologist, connected as it is with Clouds and all the phenomena of rain. Its optical properties, however, having been so ably described in another part of the *Encyclopædia*, we shall do little more than refer to some of its more remarkable appearances in this place. Rainbows may be divided into two classes, belonging to the Sun and Moon. With the ordinary appearances of the former we are all familiar though there are phenomena often which deserve in an especial manner the attention of the ardent Meteorologist.

Solar sometimes visible when Clouds are scarcely to be seen.

Only part of a rainbow sometimes seen.

Howard's remarks on formation and propagation of rain.

(925.) Although reflected upon a dark Cloud in its usual formation, as upon canvass, the rainbow seems, nevertheless, at times, to appear when Clouds are scarcely to be seen. Howard records an example of a few light Clouds beginning to appear in different quarters, but none over the place of the bow; nor was the falling mist that afforded it of sufficient density to obscure the sky. Sometimes a small portion only of a rainbow is exhibited on a few light Clouds. As these advance, the arch may increase, and the whole rainbow become at length complete. The other extremity may then fade and become reduced to a pale white, and the whole may eventually be reduced to this state. In an instance of this sort, Howard thought the rain was formed and propagated in the atmosphere with such rapidity as scarcely to afford time for the formation of drops, in the form of Cloud. Frequently small portions of the rainbow may be seen in different places.

Remarks on space between the primary and secondary rainbow.

(926.) When a brilliant rainbow with its complementary one are sometimes exhibited, the space included *within* the proper bow is perceptibly *lighter*, and that *without* it, extending to the outer bow, as much *darker* than the rest of the Cloud. Howard saw on a Nimbus a double rainbow on a ground of purple.

Third rainbow.

Other arches also in addition.

(927.) A third iris between the common ones, and not concentric with them, has also been seen, probably the result of reflection. Within the purple of the common rainbow also, arches have been seen, the first of which exhibited yellowish green, darker green, and purple; the second green and purple; and the third also green and purple. These were seen by Daval, and described by him in the *Philosophical Transactions* for 1749. He remarks, that these splendid additions of colour were not visible near the horizon, although the bow was very bright there. The supernumerary rainbows sometimes seen are particularly deserving the attention of the Meteorologist. Bülfinger saw three within the primary rainbow, the first of which was red, the second blue, green, and red, and the third dark red. A colourless bow may soon be followed by one having the usual colours.

Rainbows seen in the twilight.

Distorted rainbow.

Rainbow on the ground.

Rainbow by reflection.

Red and colourless rainbows.

Haze bow.

(928.) Rainbows have been seen in the twilight by reflection. The rainbow also has been seen distorted, probably by refraction. An hyperbolic rainbow on the ground has been witnessed, and also one inverted on the grass, formed by the drops of rain or dew suspended on spiders' webs in the fields. Two rainbows also have been seen, one by reflection from the sea. Red rainbows likewise occur. On the other hand, bows perfectly colourless have been seen in mists. On the clearing up of a considerable fog, and when the Sun was just visible, a rainbow of this sort was seen, whose breadth was about double that of an ordinary rainbow, and its colour grey. Near the ground the colour was brighter than towards the centre. Near the extremities of the bow were streaks of white of peculiar brightness. A haze bow of distinct and dazzling light was seen by Parry, having its edges softened off, and without any appearance of prismatic colours. The legs of the bow rose out of a bluish haze.

Halley's singular rainbow.

(929.) One of the most singular rainbows on record was that seen by Dr. Halley from the walls of Chester. A B C and D H E, fig. 29, were the primary and secondary rainbows as seen under ordinary circumstances.

Between these was another arch, A F H G C, rising from the intersections of the horizon with the primary rainbow, and in its upper part dividing the secondary bow into three nearly equal parts. This intermediate arch was coloured in the same way as the primary rainbow; but during the progress of the phenomenon, Halley saw the points F, G rise, and the arch F, G gradually contract, till the portions of the two bows between those points were identified. The intermediate and secondary bows having their colours contrary, produced, therefore, white between the points F and G.

Rainbows crossing each other.

(930.) Rainbows have been seen crossing each other nearly at right angles, as fig. 30.

Two primary rainbows with a secondary bow to each.

(931.) Mr. Sturges saw at Alverstoke, in the South-East, a dark Nimbus, at a time when the Sun shone brightly, near the North-West. Two primary rainbows appeared, not concentric, but touching each other, in the South part of the horizon, with a secondary bow to each, also in contact. Both the primary bows were very vivid for a considerable time, and at different times nearly equally so. The two sets of rainbows were unequal in size, the smallest ultimately vanishing, at which time the greater became a semicircle, the Sun being nearly setting. It was a perfect calm, and the sea, acting like a mirror, produced the smaller of the two rainbows by reflection. Edwards describes a rainbow which must have been formed by exhalations from the City of London, when the Sun had been set twenty minutes, and, consequently, the centre of the bow above the horizon. The colours were the same as in the ordinary rainbow, only fainter.

Rainbow formed by exhalations from London.

Lunar rainbow.

(932.) A lunar rainbow is but very rarely seen. It is sometimes white, and at other times its colours differ but little, excepting in intensity, from those of the solar rainbow. It is formed on the Nimbus, like the ordinary rainbow. Its brightness is frequently unequal; and in a case mentioned by Howard, its Northerly portion, near the Earth, had the colours very distinct; but in other parts they were scarcely distinguishable. A secondary arch was also perceptible, and very well defined. Its Northern extremity was coloured like that of the primary bow. The white portion vanished first. Sometimes a part only of the usual colours are lively and distinct. The lunar rainbow may first appear white, and afterwards develope colours.

Meteors.

Meteors.

(933.) But there are still other luminous appearances in the atmosphere demanding the attention of the Meteorologist, but to which we can only very briefly allude here. These are the meteors which occur under so many diversified circumstances, from the feeble shooting star which has but a momentary existence, up to the immense bodies which terrify whole nations by their magnitude, velocity, and splendour.

Shooting stars in the Torrid zone.

(934.) Shooting stars are far more abundant in the Torrid zone than elsewhere. Towards the morning of the 11th of November, says Humboldt, writing of Mexico, thousands of falling stars succeeded each other for four hours, in the Eastern sky, with the greatest regularity from North to South; and his illustrious brother traveller, Bonpland, remarked, that from the beginning of the phenomenon, not a space in the firmament equal to three diameters of the Moon, was to be seen free from these brilliant meteors. All of them left phosphorescent traces from five to ten degrees in length, which lasted seven or eight seconds. Some were seen even a quarter of an hour after sunrise. Humboldt found by collating different observations, that this brilliant appearance was seen over an extent of the Globe comprising 64° of latitude and 91° of longitude;—at the Equator, in South America, at Labrador, and in Germany, a space embracing 921,000 square leagues. Some of the Franciscan Monks situated at Maroa on the banks of the Rio Negro, marked the day on their Ritual.

(935.) Thirty years before the phenomenon witnessed by Humboldt and Bonpland, there was seen at the City of Quito, in the part of the sky above the volcano of Cayambo, so great a number of falling stars, that the mountain was thought to be in flames. The people assembled in the plain of Exido, where a magnificent view presents itself of the summit of the Andes. A procession was already setting out for the Convent of St. Francis, when it was perceived that the blaze in the horizon was caused by fiery meteors which ran along the sky in all directions, at an elevation of about twelve or thirteen degrees. And that this was not entirely a superstitious fear, but justified by past events, may be gathered from the fact, that during the earthquake which occurred in December 1809, at the Cape of Good Hope, "an uncommon number" of shooting stars fell. At Kingston in Jamaica, also, in November 1812, a large meteor appeared a few minutes previous to some alarming and tremendous concussions.

Connect of these phenom with ea quakes.

Small e tric exp sions in pics at of Marc

(936.) Between the Tropics, at the end of March, Humboldt informs us that the Southern region of the atmosphere is illuminated by small electric explosions, phosphorescent gleams, circumscribed by groups of vapour.

Remark number meteors Forster, Brande and Hu boldt.

(937.) According to Forster, the number of falling stars in the month of August in England, is to the number which fall in September as three to two. In all the other months, this phenomenon is three times less frequent than in August. There are months, however, in which Brandes has reckoned in our temperate zone only sixty or eighty falling stars in one night, and in other months their number has risen to two thousand. Whenever one is observed, says Humboldt, which has the diameter of Sirius or Jupiter, we are sure of seeing so brilliant a meteor succeeded by a great number of smaller ones. If the falling stars be very frequent during one night, it is very probable that this frequency will continue during several weeks. According to Brandes, the number of shooting stars which approach the Earth, surpasses those which recede from it;* and from this it appears that during the short time of their appearance, they are under the attractive influence of the Globe. Forster likewise observes that meteors are not seen below Clouds; nor are any, excepting the larger and brilliant kind, usually observed when thin Clouds are present. This may result from their formation requiring another condition of the atmosphere than what is necessary for the formation of Cloud. When a great meteor appeared near Benares, the sky was perfectly serene, nor had the vestige of a Cloud been seen eight days previous, nor were any observed for many days after. Benzenberg and Brandes consider them as belonging to the furthest limits of our atmosphere,

Meteo which proach Earth ceed th which cede fr

Abser Cloud

---

* The actual passage of some of these meteors *upwards*, has led to the conclusion that they are not aerolites. M. Chladni, who at first looked upon them as such, has lately abandoned this supposition.

between the region of the Aurora Borealis and that of the lightest Clouds.

Greater part of velocity of shooting stars an illusion.

(938.) According to Brandes also, although shooting stars have a proper motion of their own, the greater part of their apparent velocity is an illusion, depending on the movement of translation of the Earth.* The continuance of their lucid trains is variable, enduring longer at some times than others. The light of meteors was considered by Lambert as a celestial signal, which might be employed for the determination of terrestrial longitudes.†

Large meteors.

(939.) But those grand and solitary meteors which occasionally occur, attract in the highest degree the attention of mankind. There are many recorded in history, some of doubtful tradition, and others which the hand of Superstition has moulded to her dark and suspicious forms.

Great one seen in 1718—19.

The large one seen all over Great Britain, Ireland, Holland, and the hither parts of Germany, France, and Spain, at the same instant of time, on the 19th of March, 1718—19, and described by the illustrious Halley in the *Philosophical Transactions*, may be referred to as a splendid and satisfactory example.

That recorded by Kepler.

In the *Ephemerides* of Kepler also, is an account of a meteor which was seen all over Germany, November 7th, 1623, O. S., and in Austria was heard to burst with an explosion like thunder. It would be easy to multiply instances.

Their general appearance varies considerably.

(940.) The general appearances of meteors of this kind seem to differ from each other very considerably, nor can we entirely attribute to the excited imaginations of observers, those great diversities by which their descriptions are characterised. It is very true, as Halley once pertinently remarked, that these splendid phenomena too often escape the observation of those best qualified to describe them; yet though destitute of those habits of admirable caution which the Philosopher after long and laborious discipline has acquired, we can see no good grounds for rejecting *in toto* all that has been recorded respecting them. By some it has been stated that they appear first as luminous balls, nearly round; that gradually becoming elliptical, tails are created as they ascend; that moving onwards, they at length undergo, in some part of their course, a remarkable change, resembling bursting; and that then proceeding no longer as an entire mass, they are at length divided into a great number of balls of unequal sizes, followed by trains like the original body. Under this form, the separated fragments may advance with a motion more or less uniform, perhaps emitting sparks, and continuing to afford a light more or less intense; the body either in its entire or disjointed state having described its immense trajectory in the sky, with a velocity so great, as to baffle almost entirely the judgment of the most accurate mind, until at length it is lost in the great concave itself, or proceeds beyond the furthest verge of the visible sky, to amaze and terrify the inhabitants of another land.

of [illegible]

(941.) Respecting the paths of these meteors we have no data to offer beyond the general observation of Blagden, that the major part have been observed to proceed from the North or North-West quarter of the heavens, and to move very nearly in the present magnetic meridian. This remark, however, is too vague to enable us to draw from it any definite conclusions; and we can therefore merely state, that their paths are described in general terms as either vertical or horizontal, but according to Edward Howard as travelling more frequently in the latter direction than the former; that sometimes they ascend and descend obliquely; sometimes move vertically in a part of their course, and horizontally in the remainder; at other times they rise and fall and make lateral deviations from a right line; on other occasions pursue an undulatory course, and sometimes a kind of spiral line; sometimes ascend to a small height and become stationary, which latter condition, however, may be only apparent, and sometimes exhibit distinct vibrations; that their motion appears also independent of the Earth's, being sometimes directly opposite to it; that sometimes they are formed far beyond the limits of our visible horizon, and make their appearance in or near it, ascend as they approach us, and undergo an apparent descent as they recede; and that sometimes they become objects only of telescopic vision, having been examined as such by Kirch* and the elder Herschel. At other times they appear suddenly in the higher regions of the sky, giving no notice of their approach until they dazzle us by their splendour. They are known to have described tracks of 1000 miles.

Capricious and singular forms attributed to them.

(942.) The forms of these meteors have been a fruitful subject for Superstition to dwell on, and ingenuity has been taxed to devise descriptions for them. They have been described as round and elliptical, as columns or pyramids of fire, comets, barrels, bottles, flasks, spears, paper-kites—a form very often named;—as a pear with its large end towards the Earth; truncated cones, trumpets, tadpoles, glass-drops, quoits, torches, javelins, goats, the Roman letter S, contorted Clouds, and many other objects; and from these diversities the numerous appellations given to them by the Ancients were borrowed.

Their trains or tails.

Colour.

(943.) Of their tails, the brightest portion seems to be of the same nature as the body itself, and an elongation of the matter composing it. The other, and commonly the largest portion of it, appears to be matter left behind, far less luminous than the other part;—sometimes described as a dusky red, sometimes of a pure grassy green, the tail seeming to partake of the colour of the body of the meteor; at other times as of a beautiful rose colour, tinged round the edge with blue;

Sparks, and forms.

sometimes emitting whitish and coloured sparks; sometimes long and undulating, sometimes twisted and appearing to lengthen from one end only,—again like a long white cloudy form, which may be gathered together and then slowly divided, one part, perhaps, remaining stationary, and the other moving off into some distant space.

Their excessive light. That of 1718—19.

(944.) Nothing, however, strikes the beholder more than the excessive light these meteors sometimes afford. In the great one of 1718—19, described by Halley, Sir

---

* We thus arrive at a new proof of the motion of our Globe by observing a phenomenon so fleeting and inconstant as a shooting star!

† There would be some difficulty in this on account of our not knowing when to expect them; and supposing a night were selected when many meteors occurred, how should we be able to know that the *same* meteor was observed by separate persons? An example of the difficulty of observing even rockets, the firing of which had been previously arranged, may be gathered from Mr. Herschel's Paper in the *Transactions of the Royal Society* for 1826.

* Kirch was a diligent observer. He saw a meteor, whose light was most intense, dart downwards obliquely, which where it seemed to terminate, left two nodules visible only through his telescope. Herschel followed the great meteor of August 1783, for 20 or 25 seconds, with his telescope, during which it remained almost in one situation, within a few degrees of the horizon, confirming at once its great elevation and its long journey to the South.

Hans Sloane spoke of its light as being of so vivid and dazzling a lustre, as to compel him to turn his eyes several times from it. Hence people have read by the light of meteors; minute objects have been rendered visible on the ground in the darkest night, and larger ones many miles from the eye. The illumination is often so great as totally to obliterate the stars, to make the Moon look dull, and even to affect the spectators like the Sun itself. Many instances have occurred in which meteors have made a splendid appearance in full sunshine.

Colour of their light. Its effect on the Moon.

(945.) The colour of their light is various and changeable, but generally of a bluish cast, which makes it appear remarkably white. The Moon, when a great meteor occurred at Brussels, appeared quite red, but soon recovered its natural light. Meteors have been seen of a singularly pure grass green. That seen by Gassendi was inclosed in a luminous circle of colours like the rainbow. Prismatic colours have been seen in the body, in its tail, and even in the sparks of a meteor, and differently by different persons. By some they have been compared to the hues of gems. Sometimes the body of the meteor appears to consist of lucid and dull parts, perpetually changing, giving an idea of an internal agitation or boiling of the matter, and in other cases seeming like movable chains. It has also been compared to burning brimstone or spirits, to a pellucid ball of fire, and liquid pearl. Sometimes the light of a meteor appears to suffer a sudden diminution and then to revive, giving a notion of successive inflammation. Sometimes meteors and their trains have been seen white till near their extinction, when they have become a bright blue and tinged at their ends with red. Sometimes the light is described as perfectly white, and sometimes as bright blue.

Pure grass green. Prismatic colours. Light variable. Change of colour.

Meteors seen by day.

(946.) Of those seen by day, their observers have described them as running like fire, bursting like a rocket, and vanishing suddenly, leaving at times trains or columns of smoke. The latter phenomenon has been recorded by several observers.

Height of meteors.

(947.) The height of meteors is at present entirely conjectural. Halley computed the great one of 1718—19 to have been fifty miles high, but they must always appear much nearer than they really are from the effect produced by their great light, when seen without intervening objects. Sometimes their elevation is stated at from 20 to 100 miles. That seen by M. Antonio Brucalassi about five A. M. on the 2d of January near Arezzo, appeared only 100 paces from him, and 10 fathoms or less from the ground. M. de Luc has seen meteors from the tops of very high mountains, and in that lofty region they seemed to be at a very great distance. Such meteors as pass like a flash of lightning, must, where observers are prepared, afford great advantages for determining their height, as they must be seen nearly at the same moment of time and in the same place by different observers.

Meteors are attended with explosions. Description of sounds.

(948.) It seems beyond all doubt that these meteors at times are attended with explosions. Perhaps all are so; nor is the absence of sound in a particular locality any evidence that no sound is produced. An immense meteor may pass without any sound over a district, and in one adjoining a noise may be heard. Meteors may be formed in one region, pass over an immense interval, explode, and their fragments finally disappear in another very distant. The resulting sounds have been variously described, as dull, resembling the noise of a carriage like the discharges of musketry and cannon, whizzing, &c. Some of the recorded instances, however, must be received with caution. The explosion that attended the great meteor of 1716—19, rests, however, on very good evidence. It appeared like the discharge of a broadside at some distance; and in Devon and Cornwall it very sensibly shook the glass windows and doors. Mr. Cruwys, F. R. S. at Tiverton, had a looking-glass broken, which being loose, fell out of its frame by the concussion. Though it exploded over Tiverton, the sound was heard in London, notwithstanding an Easterly wind.

That of 1718—19

Their si unknown.

(949.) No adequate idea can be formed of the sizes of meteors. The Moon has very often been adopted as a standard of comparison for judging of their apparent dimensions; but this mode ought rather to be regarded as a general effect of the strong impression produced by such splendid objects on the mind, than as conveying any determinate idea of their size. Blagden, by supposing one to have subtended an angle of 30′, when it passed the zenith fifty miles high, inferred it was half a mile across, and the train ten or twelve times longer than the body. By some their diameters have been stated at more than a mile.

The dura tion of a meteor must be necessari very diffe ently stat

(950.) The duration of a meteor must be very differently stated, partly because some observers must necessarily have it in view a much longer time than others, partly from locality, and partly from one person in the same place having his attention called to it earlier than another. A meteor sometimes passing on in its full splendour becomes suddenly extinct, without any appearance of bursting or explosion. Meteors also have become suddenly extinct, and passing on revived again. Their duration is sometimes so short that good observers find it utterly impossible to state the direction in which it proceeds. Blagden said of a meteor, that he could not tell whether it proceeded *from* or *towards* the South-East.

The velo city of m teors.

(951.) Of their velocity we can give but very vague and uncertain notions. Blagden stated one to have moved twenty miles per second, which exceeds that of sound ninety times, and approaches to that of the Earth in its annual course. At this rate it must have passed over the whole of Great Britain in less than half a minute, and might have reached Rome, which there is some ground for supposing it did, within a minute afterwards. In seven minutes such a meteor would have traversed the whole diameter of the Earth. By others their velocity has been estimated at even thirty or forty miles per second. One seen by Gay Lussac remained stationary for five minutes. One seen November 7th, 1811, passed over 60° in the third of a minute. Meteors sometimes appear to start forward by successive fits.

(952.) The bodies actually discharged from these luminous Meteors, will be noticed under the head of STONES, (METEORIC,) in the *Miscellaneous Division.*

A few other Meteorological subjects which we are compelled to leave unnoticed here, will find their place in our Alphabetical arrangement, and the Reader will be easily guided to them by consulting the *General Index.*

GEORGE HARVEY.

Plymouth, July 31*st*, 1832.

FIGURE OF THE EARTH.

Since Astronomy first assumed the form of a Science, the inquiry into the Figure and dimensions of the Earth has always excited the interest of Philosophers. It can hardly be doubted that in the mind of a reflecting man there would always be a desire to know the nature of the Planet upon which he existed; but without Science of an exalted order, it would be impossible for him to gratify his curiosity. For the Astronomer, however, it was absolutely necessary to know something of the form of the Earth; and Astronomy alone gave the means of determining it. While the only observations of the heavenly bodies consisted in watching the rising and setting of the Sun and Stars, the form of the Earth was a matter of indifference; but when an attempt was made to reduce to a system the motions of the luminaries and Planets, it was necessary as a preliminary step to assume, and even to establish by something approaching to demonstration, a hypothesis on the Figure of the Earth.

At present the determination of the Earth's Figure possesses an interest of which formerly it was altogether destitute. The Astronomers of antiquity knew that the Earth is nearly spherical; they had also some not very correct ideas of its magnitude; and this was sufficient for their purposes. But the sphericity of the Earth, when thus established, was an isolated fact. It was proved by the impossibility of explaining certain phenomena on any other hypothesis; but it was not connected with any general theory which made this Figure a necessary consequence of the properties of matter. But by the discoveries of Newton the Figure of the Earth was shown to depend on the same theory which explains with such wonderful accuracy the motions of the Planets and their satellites. The investigations of the most profound Mathematicians have since been directed to its determination, from the Principles of Gravitation; and the labours of the most able experimenters have been employed in ascertaining it from actual observation; and the comparison of the results of theory and of observation shows that their agreement, though not perfectly exact, is sufficiently so to enable us to assert with confidence, that the Principle of Gravitation is well founded. Indeed, for one part of that Principle, (*viz.* that the attraction of a Planet is not a force directed to its centre, but is the resultant of all the forces directed to every one of its particles,) it may be considered as affording the most satisfactory proof that we can expect ever to have.

Under the head of the Figure of the Earth we propose not only to consider the theoretical form, and to give an account of the principal measures and their results, but also to explain the most remarkable phenomena depending on its Figure; namely, the variation of Gravity on its surface, and the disturbances in its own motion, and the motion of the Moon, occasioned by its deviation from the spherical form. And in connection with this subject we shall give a short account of the experiments which have been made to determine the comparative density of the superficial and the interior parts of the Earth. The whole may be considered as a collection of various classes of observations which have been made for the examination of that part of the Principle of Gravitation which asserts that "the attraction of a mass is the sum of the attractions of every one of its particles."

Section 1.—*History.*

General Principle of Meridian measures.

It was probably by observation of the form of the Earth's shadow, as seen in eclipses of the Moon, that the Figure of the Earth was first ascertained to be nearly spherical; and the necessity of an allowance for *parallax* in the Moon's declination would very soon teach Astronomers that the place of observation was not the centre about which the lunar revolutions were performed. But these remarks would in no degree enable them to form an idea of its magnitude. The method of determining the dimensions by measuring an arc of the meridian has been employed with no alteration of Principle from the time of the Alexandrian Astronomers to the present day. Let A, B, fig. 1., be two places of observation; A C, B C, lines perpendicular to the surface at those points: suppose these perpendiculars to intersect in C; let A F D, F B E, be horizontal lines; G A, H B, parallel lines, representing the directions of the visual rays from the celestial Pole, or from some very distant object, as the Sun or a Star. By observation of the angles H B E, G A D, (the altitudes of the Pole, or the Sun, &c.) their difference is known; that is, the difference of H B E and H K D, or K F B, which is equal to A C B. The length of the arc A B can be measured; knowing then the length of A B, and the angle A C B, and assuming A B to be a circular arc, the length of A C or B C can be immediately calculated. Instead of calculating the length of A C it is rather more convenient to calculate the length A M, which corresponds to an angle A C M of one degree; and this is usually called *the length of a degree on the Earth's surface.* It is plain that this process can be applied only when the vertical plane which passes through the two places, passes also through the body observed; and the observations must either be simultaneous, or must be of such a nature that a small error in the time (which in practice is inevitable) will produce no sensible error in the body's altitude. From these considerations it appears that A and B must be in the same meridian. If we assume the Earth to be spherical, we shall by this method find its radius; or if we perform the same operations in different parts of the Earth, and always find the same value for the radius, we may infer that the Earth is spherical.

This is the method pursued in the earliest measure of which we have any tradition, that of Eratosthenes. For we cannot hold with some writers that any real measure is alluded to by Aristotle, *De Cœlo,* lib. ii., when he

Estimation by Eratosthenes.

speaks of the circumference of the Earth as being 400,000 stadia, according to the opinions of the Mathematicians of his time. Eratosthenes, about 230 B. C., observed that at Syene, in Upper Egypt, the Sun was, as far as he could discover, exactly vertical at noon, on the day of the summer solstice; and that at Alexandria the Sun's zenith distance at the same season was 7° 12′. The former observation (according to Cleomedes) was made by remarking that the edges of a deep well threw no shadow on the bottom, the latter by the use of the *σκάφη*, a hemispherical bowl with a vertical style. These circumstances will be represented in fig. 1., if we suppose B H to be in the same straight line with C B, and G A parallel to B H, and the angle $N\,A\,G = 7° \, 12'$. He supposed Alexandria and Syene to lie in the same meridian, and reckoned their distance at 5000 stadia, which gave the Earth's circumference = 250,000 stadia. The length of the stadium here used is unknown, and it is unnecessary to point out the sources of error in this operation.

By Posidonius.

An estimation was also attempted (as the same author informs us) by Posidonius, who was contemporary with Pompey the Great. It appears to have been intended only as a rough guess, and is, in fact, much inferior in accuracy to that of Eratosthenes. He observed that the star Canopus was seen at Rhodes to just touch the horizon; at Alexandria he estimated its meridian altitude at $7\frac{1}{2}°$: the distance of the places was supposed to be 5000 stadia. This gave for the circumference of the Earth 240,000 stadia. In this measure it is merely necessary to observe that refraction was neglected, not being known; and that no accurate estimation could be formed of the distance of two places separated by the Mediterranean.

By Ptolemy

In the Astronomical Works of Ptolemy (who flourished about A. D. 137) we find no notice of the Earth's dimensions. He assigns as reasons for believing the Earth to be spherical, that eclipses of the Moon, as seen at different places on the Earth, take place at different times with reference to the noon of the places of observation; and that the differences of apparent times are proportional to the distances East or West. This, we believe, is the earliest notice of the Principle of deducing terrestrial longitude from the difference of the apparent times at which an eclipse of the Moon is observed. He remarks also that on going Northward, the number of circumpolar stars is increased, appearances which could not exist if the Earth were plane, or cylindrical. But in his Geography he tacitly assumes the Earth to be spherical, and uses constantly as the length of one degree 500 stadia. This estimation seems to have been made by Marinus the Tyrian, from observations of the latitude of very distant places, and from the rough measures of the distance made by sailors and merchants.

The dark Age which followed the overthrow of the Alexandrian School, put a stop to all speculations on the Figure of the Earth. It was not till the Empire of the Caliphs had extended over the greatest part of the civilized World, and the Works of the Greek Astronomers had been translated and studied by the Arabs, that another attempt was made to measure an arc of the meridian. Abulfeda relates that Abdalla Almamoun, who begun his reign at Bagdad A. D. 814, having fixed on a spot in the plains of Mesopotamia, ordered one company of Astronomers to go Northward and another Southward, measuring the distance by rods, till each should find their alteration of latitude, or alteration in the altitude of the Pole, to be one degree. One party found the distance 56 miles of 4000 cubits, the other $56\frac{2}{3}$ miles; the latter was adopted as preferable to the former. The length of the cubit, however, is not known.

Measure by Almamoun.

By Fern

Seven hundred years elapsed before another estimation was attempted, and the scene was then shifted to Western Europe. Fernel, a Parisian, born in 1485, (according to Lalande, *Mém. Acad.* 1787,) published in 1528 the account of a measure made in the neighbourhood of Paris. On August 25, he observed the Sun's meridian altitude at Paris; he went Northward one degree, as nearly as he could judge, and on August 29 again observed the Sun's meridian altitude. His observations were made with a triangle, (not a quadrant,) of which one side, eight feet in length, was vertical; another side of the same length was movable round the point of connection with the first, and carried sights; the third side measured the distance between the other two, and was graduated as a line of chords to every minute of the quadrant. (This is the instrument which Ptolemy describes as proper for the observation of the Moon's parallax.) On applying to the Sun's altitudes the proper correction for change of declination, he found that his latitude had increased one degree. The distance was calculated from the number of turns made by the wheel of his carriage. The length of an arc of meridian of one degree, thus found, (56,746 toises,) agrees very well with the length given by modern observations, (about 57,060 toises.)

By Snel

The next measure (that of Snell) is distinguished by a very great improvement in the manner of measuring, —the substitution of trigonometrical operations for the actual measurement of the whole distance by the application of rods or perambulators. This method is partly described in our Treatise on TRIGONOMETRY, section 9; and will be illustrated more fully in a succeeding section of the present Essay. The account of Snell's measure was published at Leyden, in 1617, under the quaint title *Eratosthenes Batavus de Terræ ambitûs verâ quantitate, &c. a* Willebrordio Snellio *suscitatus*. He measured a base of 326.4 Rhinland perches, and two bases of verification of 348.1 and 166 perches, (each perch of 12 feet.) The length of the first base was, however, in reality concluded from a base of 87.05 perches; for the calculated length is used, though it differs a little from the measured length. His angles were observed with quadrants and semicircles. Thus he found the meridian distance between Alcmaer and Bergen-op-Zoom = 33,930.2 perches. Their latitudes he found to be 52° 40′ 30″, and 51° 29′. From this he found one degree of meridian = 28,473 perches. Between Leyden and Alcmaer he found 1° = 28,510; finally he fixed upon 28,500. As he was careful to compare his standard with the standards of other nations, this measure was readily reduced to French toises, and it gave 1° = 55,100 toises. A recalculation and reobservation of the latitudes by Muschenbroek in 1729, gave 1° = 57,033 toises. Another measure was effected (we believe in nearly the same locality) by Blaeu, or Cæsius; it was said to agree in its results with Picard's, but we are unacquainted with the details.

In 1637 was published, *The Seaman's Practice, contayning a fundamentall Probleme in Navigation experimentally verified, namely touching the Compasse of the Earth and Sea, and the Quantity of a Degree in our English Measures, &c.;* by Richard Norwood, Reader

By Norwood.

of the Mathematicks. In this Work most of the older measures are mentioned. It is stated, also, that a Mr. Edward Wright had observed the dip at Mount Edgecumbe, and had inferred the semidiameter of the Earth to be 18,312,621 feet. The author then states, that on June 11, 1633, with a sextant of more than five feet, he observed the Sun's meridian altitude near the Tower of London to be 62° 1′; and on June 6, 1635, he found the Sun's altitude at York to be 59° 33′; the difference of latitude 2° 28′. The distance was measured with a chain of 99 feet; the bearings of different parts of the road were observed with a circumferentor, and the measures reduced by a Table. Part of the distance he paced, in which he says he came through custom very near the truth. The number of chains was 9149; from which he found 1° = 61,199 fathoms.

By Riccioli.

About the same time a trigonometrical measure was attempted in Italy by Riccioli. Beginning with a base of 1094 Bolognese paces, he found the meridional distance from a point near Bologna to Modena 20,439 paces; the difference of latitudes he found to be 19′ 25″. The angles were measured with an instrument nearly similar to that of Fernel. From this it appeared that 1° = 63,159 paces, = 61,478 toises, or 65,521 fathoms. This measure has been universally condemned. The Geodetic part was not well conducted, and the Astronomical observations were far below the general science of the Age. It has been remarked, also, that Riccioli was persuaded of the accuracy of the Greek estimations, which (in his interpretation) were considerably greater than the later measures seemed to show. The part of his Works (*Geographia*) which comprehends this measure, contains an interesting account of all the methods of determining the Earth's dimensions which were known at that time, and of all the estimations which preceding Mathematicians had formed.

The method which he appears to have thought superior to all the others, is that of observing from each of two stations the depression of the other; and he instances some observations of his own which give nearly the same value for a degree as that which we have cited. The principle of this method will be readily understood by supposing P and Q, fig. 1, to be two elevated stations, and remarking that if the angles C P Q, C Q P, be observed, P C Q will be found by subtracting their sum from 180°; and the distance P Q being measured, the lengths C P, C Q, are easily calculated.

By Picard.

In 1669 the trigonometrical measure of Picard was commenced; and it was in every respect superior to all that had preceded it. It is true that it was not free from errors: an error of six toises was committed in the measure of the base; and his differences of latitude were vitiated by his ignorance of aberration, &c.; but, by a happy chance, these errors almost balanced each other. The extremities of his arc were Sourdon, (near Amiens,) and Malvoisine, (near Paris.) His base was 5663 toises; his base of verification 3902 toises. The difference of latitude of Malvoisine and Sourdon was found to be 1° 11′ 54″; and when the measure was extended to Amiens, the difference of latitude of Malvoisine and Amiens was found to be 1° 22′ 55″. The corresponding arcs were 68,430 and 78,850 toises; the first gave for the length of an arc of 1°, 57,064 toises, the second 57,057; the mean is 57,060 toises = 60,812 fathoms. The Astronomical observations were repeated in 1739 by Maupertuis, Clairaut, &c.: they found 1° = 57,183 toises.

Huygens's ideas of centrifugal force.

In 1673 appeared the Work of Huygens, entitled *De Horologio Oscillatorio*. In this, for the first time, were found correct notions on the subject of centrifugal force. It does not appear, however, that these were applied to the theoretical investigation of the Earth's form before the publication of Newton's *Principia*.

Newton's investigation of the Earth's form.

In 1666 Newton appears to have first entertained the idea of Gravitation. It is remarkable that, at this time, he seems to have been unacquainted with the measures of Norwood and Snell; and considering the length of a degree, according to the usual estimation, to be sixty miles, he was induced, by the disagreement of his calculations from this estimation, to lay aside his theory of Gravitation. For the Moon's parallax being known, that is the proportion of the Earth's radius to the radius of the Moon's orbit (supposed a circle) being known, the force of Gravity on the Moon was found by Newton's law; and the periodic time was also known; and from these data, and the theorems of Huygens and Newton relating to motion in a circle, it was easy to calculate the radius of the circle in which it moved, and consequently (from the proportion above mentioned) the radius of the Earth: if this were not the same as the radius given by the measures, Newton's law could not be true. The measure of Picard enabled him to establish the theory; and it is this measure that is used in the *Principia* published in 1687. In this wonderful Work a prodigious step was made towards the theory of the Earth's form. Combining the theory of centrifugal forces with the properties of fluids, Newton showed that the Earth must be not spherical but spheroidal; that its equatorial diameter must be longer than its axis of revolution; and he actually calculated the proportion of the diameters, on the supposition that the Earth had been in the state of a homogeneous fluid, to be 229 : 230. With regard to this astonishing investigation we shall merely state, that though defective, it is not erroneous; it is one of the many instances in which Newton has obtained a correct result by means apparently quite inadequate. He showed, also, that Gravity must be less at the Equator than near the Poles; and this served to explain a very remarkable fact that had lately been observed. In 1671 Richer, who had been sent by the French Government to Cayenne for the purpose of conducting a series of Astronomical observations, found that his clock, which had been regulated to mean time at Paris, lost more than two minutes every day. Similar facts were afterwards observed by Varin and Deshayes on the coasts of Africa and America; and in all cases the alteration of the clock's rate was much greater than any that could be caused by the change of temperature.

Variation of Gravity on the Earth's surface.

Newton's explanation of the precession of the Equinoxes.

But the most remarkable of Newton's inferences is, perhaps, his explanation of the precession of the Equinoxes. This motion of the Earth's axis was discovered by Hipparchus, (B. C. 150;) and all succeeding Astronomers had recognised its existence. Eighteen centuries after its discovery, it was shown by Newton to be a consequence of the attraction of the Sun and Moon on the Earth's equatorial protuberance. Having shown that the attraction of a distant body on a satellite would produce a retrograde motion of its nodes, he observes that if we first suppose a number of satellites to revolve in one plane, and then suppose them to be connected in such a manner as to become a solid ring revolving in its plane, we shall still have a retrograde motion of the nodes: and if the Earth be fixed within the ring, the motion of the nodes, though less than before, will still be retrograde; and the transition from this case to that of an oblate spheroid is sufficiently obvious. The calculation which Newton has attempted to found on this reasoning is in some respects erroneous; but the explanation is, perhaps, one of the strongest proofs of genius. Indeed, if at this time we might presume to select the part of the *Principia* which probably astonished, and delighted, and satisfied its readers more than any other, we should fix without hesitation on the explanation of the precession of the Equinoxes.

Huygens's investigation of the Earth's form.

In 1690 was published Huygens's Treatise, *De Causâ Gravitatis.* It contains an investigation of the figure of the Earth, supposing the attraction upon every particle to be directed towards the centre, and to be always the same at equal distances from the centre. This supposition, it will be remarked, is directly opposed to one part of the Principle of Gravitation, namely, that which states that every particle attracts every other particle. The ratio of the axes is found in this manner to be 578 : 579.

J. Cassini's Meridian measure.

In 1684 J. D. Cassini (second of that name) commenced a trigonometrical measure of an arc of meridian in France, taking Picard's base as a foundation and proceeding Southward. It was intended that this should serve as a basis for a map of France; and the more accurate measure which was afterwards executed on the same line was used for that purpose. Some interruption took place, (on the death of the Minister Colbert,) but it was at length finished in 1701. The series of triangles was then extended Northward to Dunkirk, and this part was finished in 1718. A base of 7246 toises was measured near Perpignan, and one of 5464 toises near Dunkirk. The difference of latitudes of Paris and the Southern extremity, Collioure, was found to be 6° 18′ 57″, and the distance 360,614 toises; whence 1° = 57,097. The difference of latitudes of Paris and Dunkirk was found to be 2° 12′ 9″.5, and the distance 125,468 toises; whence 1° = 56,960. It appeared, then, that the degrees shortened in going from the South to the North; and this seemed to indicate that the Earth was a prolate spheroid, the ratio of its axes being nearly 95 : 96. A conclusion in such direct opposition to Newton's theory, now extensively received, excited a great sensation among the Mathematicians of Europe. The accuracy of the measure and the certainty of the conclusion were sustained by Cassini; who, as well as his father and his son, seem to have been firmly convinced that the Figure of the Earth was elongated. To settle the point, a degree of a parallel was measured in 1734, extending from Strasburg to St. Malo. This, also, when compared with the others, seemed to lead to the same conclusion. It was alleged, however, that the difference of longitude of these stations was determined only by some ancient eclipses of Jupiter's satellites, and that no reliance could be placed on them. To escape from this state of doubt, it was determined that an arc of meridian, and if necessary, one of parallel, should be measured near the Equator, in the comparison of which with the arc measured in France, the inevitable errors of observation would produce a smaller effect; and this is the origin of the celebrated expeditions of the French Academicians.

Measure of an arc in Peru.

Every facility being afforded by Louis XV., in May, 1735, MM. Bouguer, Godin, Lacondamine, and others, sailed for South America; they then crossed the Isthmus of Darien, and sailed to Peru. The difficulty of measuring an arc of parallel, and its inutility, (as on any hypothesis it would differ little from an arc of meridian in France,) were so strongly represented by Bouguer, that it was laid aside. But the great valley between the two principal chains of the Andes was found so favourable for operations in the direction of the meridian, that they effected, with the assistance of some Spanish officers, the measure of an arc of three degrees. The Northern limit was a place called Tarqui, 2′ North of the Equator; the Southern extremity, Colchesqui, was in South latitude 3° 4′. A base of 6272 toises was measured in the neighbourhood of Quito, and near the Southern extremity; and a base of verification of 5259 toises near the Northern extremity. No other measure* has been conducted under such extraordinary circumstances of locality. The lowest point of their arc was at an elevation of a mile and a half above the level of the sea; and, in some instances, the heights of two neighbouring signals differed more than a mile. At some places the danger was considered by the inhabitants to be so great, that public prayers were put up in the churches for their safety. The indolence and ill-will of the natives troubled them much; they were even in danger of losing their lives in a popular tumult; and to crown the whole, the instruments by which they were to determine their difference of latitude were found to be not trustworthy, and the corrections of the places of the stars were not to be relied on. The former difficulty they overcame by an ingenious reconstruction of their instruments, the latter by simultaneous observations at the two extremities of the arc. Their final result was that the whole length of the meridian arc, reduced to the level of the lowest station, was 176,945 toises, corresponding to a difference of latitudes of 3° 7′ 1″; and, therefore, that the length of an arc of one degree was 56,767, or reduced to the level of the sea 56,748. The arc was extended about twenty minutes by Godin; but this addition is generally supposed to have been less accurately measured than the other parts. In this expedition an attempt was made by Bouguer to observe the effect of the attraction of Chimborazo; of this we shall speak hereafter. For the complete details of this very interesting measure we must refer the reader to Bouguer's and Lacondamine's accounts; the former is the more amusing and more interesting to speculative Mathematicians, but the latter will be found by practical Astronomers to be the more instructive.

Measure of an arc in Sweden.

Before the return of this party (who, in consequence of their dissensions, separated as quickly as possible, and regained Europe by different ways) another measure had been imagined and completed. Maupertuis, Clairaut, Camus, Lemonnier, and Outhier reached the Gulf of Bothnia in July 1736. They had expected to be able to make use of the islands in the Gulf for the stations of a trigonometrical measure; but they found them so low, and so near the shore, that they were obliged to give up this part of their plan. But the valley of the river Tornea, which passes by the town of the same name, seemed to offer a favourable line of country; and this was accordingly chosen. The stations (as in the Peruvian measure) were on the hills on each side; and the river gave them some facilities for

---

* From this remark we ought, perhaps, to except a part of the survey of an arc of parallel made in the present century, in which the principal chain of the Alps was passed.

History.

the conveyance of their instruments. In the prosecution of their work great inconvenience was sustained from the cold, the birds of prey, &c. but the greatest of all from the tormenting flies and gnats. The fogs also, with which some of the hills were continually enveloped, increased the difficulties of the observations; in some instances they waited ten days on the top of a hill before they could see one of their signals. After sixty-three days of great fatigue they reached the mountain Kittis, which was fixed on for the Northern extremity. The latitudes were observed with a sector made by Graham. On their return to Tornea, the river being frozen, a base was measured on the ice nearly in the middle of the arc, but no base of verification was measured. The result being somewhat different from what they had expected, the latitudes were reobserved, and some angles of the triangles, which had before been omitted, were observed. The final conclusion was that the difference of latitudes was 57′ 29″,6, and the length of the arc 55,023 toises; whence an arc of 1° = 57,422. In this expedition, as well as in that to Peru, observations were made to ascertain the length of the pendulum vibrating seconds; and they all agreed in showing that Gravity increased in going from the Equator towards the Pole. For a complete account of this measure we must refer the reader to Maupertuis, *La Figure de la Terre*.

Before the return of Bouguer and Lacondamine, the whole of the French arc of meridian was remeasured by J. Cassini, his son Cassini de Thury, and Lacaille. The operations of this measure are the subject of the Work entitled *La Méridienne vérifiée*. On measuring new bases and making new observations of every kind, the cause of the original difficulty was soon discovered. The measure of Picard's base was erroneous by about $\frac{1}{1000}$th part of the whole, and this error had affected one part only of the arc. Some inaccuracies both Astronomical and Geodetical were found to exist in Cassini's measure. The late improvements in Astronomy, particularly the discovery of aberration and nutation, enabled the new observers to give much greater exactness to the Astronomical observations. They observed the latitudes of five points, and thus obtained, in fact, four arcs of meridian. Between Perpignan and Rodéz the length of an arc of one degree was found = 57,048 toises; between Rodéz and Bourges 57,040; between Bourges and Paris 57,071; and between Paris and Dunkirk 57,084. In the course of this measure an arc of parallel was measured across the mouth of the Rhone. From a station near Cette in Languedoc, and from Mont St. Victoire in Provence, the explosion of gunpowder at a church between them was observed; and from the difference of apparent times the difference of longitudes was found to be 1° 58′ 19″. The length of the arc of parallel in latitude 43° 32′ included between the two meridians was 76,599.6 toises. The comparison of this arc with the arc of meridian from Perpignan to Rodéz gave an ellipticity $\frac{1}{168}$.

The comparison of any two of the three arcs in Peru, in France, considering the whole as one arc, and in Sweden, showed that the degrees increased in going towards the Pole, and that, consequently, the Earth's Figure was flattened at the Poles. But when all three were considered, a singular difficulty occurred, which we may be permitted to say is not yet wholly removed. The comparison of the Peruvian and French arcs gave an ellipticity of nearly $\frac{1}{314}$; that of the Peruvian and Swedish arcs gave $\frac{1}{213}$ for its value. If, then, the measures were accurate, it was impossible that the Earth's Figure could be elliptic: and Bouguer actually proposed, as the only hypothesis which would satisfy observations, that the increase of the lengths of degrees was proportional to the 4th powers of the sines of latitude, and that the proportion of the axes was 178 : 179. This would indicate a Figure projecting at middle latitudes above the elliptic spheroid with the same axes.

To avoid interruption in our account of several important measures, we have omitted to mention some interesting deductions from the theory of Gravitation made about the same time. These we shall now describe.

Maclaurin's investigation of the Earth's form.

The first important addition to the theory of the Earth was made by Maclaurin. The Academy of Paris proposed as a subject for the Prize Essay in the year 1740, *The Tides*. Three admirable Essays were sent, by Euler, D'Alembert, and Maclaurin: the last is generally considered as one of the most elegant Geometrical investigations that was ever made. Most of the operations can be applied, with very slight alterations, to the investigation of the Figure of the Earth, supposing it a homogeneous fluid; and the author has indicated the principal results which can be obtained by this application. In this Treatise it was proved for the first time, that the oblate spheroid is a form of equilibrium; and the equation was given by which the ellipticity can be found when the proportion of the centrifugal force at the Equator to Gravity is known. This equation is transcendental; but, by an approximate solution when the centrifugal force is small, it was shown that the ellipticity (that is the proportion of the excess of the equatorial diameter above the polar diameter to the latter) is $\frac{5}{4}\times$ the ratio of the equatorial centrifugal force to the equatorial gravity; which in the case of the Earth is $\frac{5}{4}\times\frac{1}{289}=\frac{1}{230}$; and that Gravity at the Pole is greater than Gravity at the Equator, by the same proportion of the whole; and, also, that in going from the Equator to the Pole, the increase of Gravity is as the square of the sine of the latitude. These results are the same as those of the imperfect theory of Newton.

Clairaut's investigation.

In 1743 was published Clairaut's *Figure de la Terre*. This is the most valuable Work that has been written upon this subject. The same theory has since engaged the attention of the most distinguished of the modern Mathematicians, and finally of Laplace; and though the form of the investigations has been much varied, very little has been added to the results. The nature of the equilibrium of fluids is first explained. The only condition which had formerly been assumed as sufficient for the equilibrium of fluids was, that the force at the surface should be perpendicular to the surface, or that the pressure produced by the fluid in two canals of given form, terminated at one extremity in the same point, and at the other extremity in the surface, should be the same. Bouguer first showed that both of these conditions were necessary, or something equivalent to both. Clairaut has shown upon what the possibility of equilibrium depends; and he has applied these principles to the discovery of the form of equilibrium of a fluid on the

Clairaut's theorem.

lowing suppositions: 1st, that the Fluid is homogeneous, with a spheroidal nucleus of different density; 2dly, that the whole mass is fluid and heterogeneous. The form which makes equilibrium possible in all the variety of cases which these suppositions include, is, approximately, an elliptic spheroid; the ellipticity is different according to the law of density, &c., but in all cases the following theorems are true: 1st, the increase of the length of degrees and of Gravity, in going from the Equator to the Poles, is as the square of the sine of latitude; 2dly, the sum of the ellipticity, and of the ratio of the whole increase of Gravity to the equatorial Gravity, is $\frac{5}{2}$ × the ratio of the centrifugal force at the Equator to the force of Gravity. The last of these theorems (one of the most important that has ever been discovered) is usually called by the name of its inventor. It is evident that, in conjunction with the former, it gives the means of determining the Earth's ellipticity from observations of the comparative force of Gravity at any two places.

Nutation discovered by observation and explained by theory.

In 1747 Bradley discovered the nutation of the Earth's axis. This had been alluded to by Newton as a consequence of his theory, but no notice seems to have been taken of his theoretical prediction. As soon, however, as the fact was established, it was treated theoretically by Mathematicians: among the best of the Treatises upon nutation may be reckoned D'Alembert's *Recherches sur la Précession, &c.*

Measure of Boscovich.

In 1750 Boscovich and Le Maire, two Jesuits, measured an arc from Rome to Rimini. Their measures were made with the pace, the measure of the Country; but it was carefully compared with the French toise, so that their results could be expressed in terms of the same standard which had already served for so many measures. A base of 6139.5 toises was measured on the Via Appia; and a base of verification of 6037.6 toises by the sea-side near Rimini. The meridian distance was found = 161,253.6 paces = 123,221.3 toises; and the difference of latitude 2° 9′ 47″, whence 1° = 56,966.3 toises. This, when some corrections were applied, was reduced to 56,979; the mean latitude 42° 59′ The whole of this measure passed over a mountainous country.

Measure of Lacaille.

In 1752 Lacaille, who had been sent to the Cape of Good Hope to make Astronomical observations, finding the circumstances of the country favourable for a trigonometrical survey, measured an arc of 1° 13′ 17″.3, which he found = 69,669.1 toises; whence 1° = 57,037. The length of his base was 6467 toises. See *Mém. de l'Acad.* 1751. This arc presents a remarkable anomaly. According to this measure, a degree in the South hemisphere, whose mean latitude is 33° 20′, is equal to a degree in the North hemisphere, whose mean latitude is about 45°. The known ability of the observer almost forbids the supposition of an error in the observations; and we have no grounds for conjecturing the cause of such a deviation from the law which seems to apply to the other arcs.

The measures described in the next three paragraphs were undertaken, we believe, at the suggestion of Boscovich.

Liesganig's measure.

In 1762 Liesganig, a Jesuit, began the measure of an arc of meridian passing through the Observatory of Vienna. See the *Dimensio graduum Viennensis et Hungarici.* Every care apparently was taken to ensure the correctness of this measure. The Vienna fathom was compared with a French toise furnished by Lacondamine and Lacaille; the iron quadrant of 2½ feet, with which the angles of the triangles were observed, was repeatedly examined in all possible ways; the sector, for observation of latitude, (which we shall afterwards describe,) was on the most improved construction; the observations of latitude were sufficiently numerous; in every triangle, except one, Liesganig assures us, that the three angles were observed; and all the calculations were reexamined. The base (between Neustadt and Neunkirch) was of 6288 toises; the base of verification in Marchfeld was of 6388 toises. The concluded meridional distance of Sobieschiz and Varasdin (the North and South extremities) was 172,796 Vienna fathoms; and the difference of latitudes 2° 56′ 45″.5, whence 1° = 58,655 Vienna fathoms = 57,077 toises. Yet in spite of all these apparent securities, there appears reason for rejecting this measure. The principal objections to it may be seen in Zach's *Correspondance Astronomique, &c.* vol. vii. In the first place, it is certain that the star which Liesganig has put down as μ Draconis is not μ Draconis, but some other star; possibly 85 ι Herculis, which Zach mentions. This would occasion no error, (as the same star was observed at different stations,) except in consequence of taking erroneous reductions. In the next place, Zach (who possessed some of Liesganig's manuscripts, and who recalculated some of the observations) affirms, that many of the observations had been altered to produce greater apparent agreement. And, lastly, it appears from a repetition of part of the survey by the Austrian officers in the beginning of the present century, that in one of Liesganig's triangles it was impossible, and apparently had always been so, to observe one of his stations from another; and, in fact, when the value of one of the angles, as given by him, was compared with the sum of two angles, which ought to be equal to it, observed by the Austrian officers, a difference of 3° was found. This triangle is the last but two to the South; up to this the surveys agree within a few toises, but after this they sometimes differ in the situation which they assign to a station by more than 2500 toises. It would seem that a signal was mistaken; a similar accident happened to Snell; and there is reason to think that it has also occurred in the survey of England made under the direction of the Master-General of the Ordnance. Another arc was measured by Liesganig on the plain of the Theiss, from Kistelech in the North to Czuroch, near Petervaradin, in the South. The length was 59,990 Vienna fathoms; and the difference of latitudes 1° 1′ 34″.5; whence 1° = 58,453 = 56,881 toises. Several circumstances prevent us from attaching much value to this measure; one is, the great number of small triangles which the nature of the country compelled him to use.

Reasons rejecting

Becca measu

About the same time Beccaria, a Jesuit, assisted by another of the same Order, measured a degree in the plain of Lombardy. The measure of Boscovich crossed the Apennines, and its extremities were on the sea-coasts; this of Beccaria (undertaken, as we have mentioned, at the suggestion of Boscovich) was carried over a flat country, and terminated at both extremities at the foot of lofty mountains. It was supposed that if the inequality of the country produced in the measure of a degree any sensible irregularity, the effects, in these two measures, would be of opposite kinds, and that the difference in the length of a degree would be such as to give a good idea of their magnitude. An iron toise, which had been compared by Lacondamine and Lacaille with the toise used in the measure of the arc in Peru, (commonly called the toise of Peru,) was Beccaria's standard. His instruments were in almost every respect similar to those of Boscovich. The length of the base was 6501 toises; the meridional distance from Andratæ, the Northern extremity, to Mons Regalis, (Mondovi,) the Southern extremity, was 64,890 toises. The difference of latitude was found to be 1° 7′ 44″.7; whence 1° = 57,468 toises; a quantity much greater than other measures would have led us to expect. The mean latitude is 44° 57′. An account of this measure was published under the title of *Gradus Taurinensis*. In the surveys made by the French officers during their occupation of this Country, and in the repetition of the observations for the latitudes of the stations by MM. Plana and Carlini, some discrepancies have been found, which would seem to show that the credit of this measure is rather doubtful.

ubts of accuracy

asure of rc in rth erica.

In 1764 Messrs. Charles Mason and Jeremiah Dixon, who had before been engaged by the Royal Society for some important Astronomical observations, were employed in settling the boundaries of Maryland and Pennsylvania in North America. The line which they traced out in the peninsula between Chesapeak Bay and Delaware Bay seemed so favourable for a meridian-measure, that, on their representation, the Council of the Royal Society furnished them with standards and instructions, and procured the loan of a sector belonging to Mr. Penn. An account of the measure is given in the *Phil. Trans.* for 1768. This measure differs from all others made since the time of Norwood in this respect,—that no triangles were used, but the whole line (about 100 miles) was measured with rods. These rods were compared with a five-feet brass rod made by Bird. The whole length was found to be 538,067 feet, and the difference of latitude 1° 28′ 45″; whence 1° = 363,763 feet = 60,627½ fathoms. It had been found by a comparison of standards (*Phil. Trans.* vol. xlii.) that the English fathom $= \frac{107}{114} \times$ French toise; whence one degree was inferred to be 56,904½ toises. But after a new comparison of the toise and fathom, made under the inspection of Dr. Maskelyne, and after applying some small corrections, this was reduced to 60,625 fathoms, or 56,888 toises. The mean latitude was 39° 12′.

The anomalies in these measures were so considerable, that it appeared highly desirable to discover whether the attractions of mountains could have a sensible effect in altering the direction of Gravity. If in consequence of the proximity of a mountain the plumb-line was drawn from the position which it would otherwise have maintained, it is evident that the point of the heavens which corresponded to the zenith of a station, as determined by Astronomical observations, would not be the same as if the mountain did not exist. If, for instance, a mountain were at L, near the point A, in fig. 1, and drew the plumb-line towards L, the apparent direction of Gravity, instead of A C would be A c, and the apparent horizontal line instead of A D would be A d; the difference of latitudes, or the angle A C B, would be changed to A c B, and the length of the radius of curvature of the meridian would be changed from A C to A c. On account of the influence of these effects on the determination of the Figure of the Earth, as well as for the important confirmation which might be given to the Principle of Gravitation, it was to be wished that the attraction of a mountain might be ascertained by direct experiment. This had been attempted by Bouguer and Lacondamine in Peru; but the cold was so intense that it was difficult to make the observations with sufficient accuracy, and other circumstances were not favourable. Instead of observing the zenith distances of a star on opposite (North and South) sides of the mountain, they could only fix on two stations on the South side, one close to the mountain, the other at a distance of 3570 toises from the first, and 505 South of it. The effect of attraction appeared to be 7″.5; but they considered the conclusion almost unworthy of credit. In 1772 (see *Phil. Trans.* 1775) Dr. Maskelyne proposed to repeat the experiment. He pointed out Whernside in Yorkshire as a mountain on the opposite sides of which the attraction would be sensible; or he thought that the defect of matter in the valley between Helvellyn and Skiddaw, (or rather Saddleback,) in Cumberland, producing an effect of the opposite kind, might be sensible in the same kind of observations. Mr. Charles Mason was sent out to examine these, or to look for a hill proper for the purpose: these were finally rejected, and Schehallien was chosen. This is a mountain near Blair Athol, in Perthshire; it is a narrow ridge running East and West, in a comparatively flat country, and about 2000 feet higher than the general level. In 1774 the observations were made. The meridional distance of two stations on the North and South sides was found, by survey, to be 4364.4 feet, which on any estimation of the Earth's dimensions would give for the angle A C B, fig. 1, (C being considered as the centre of the Earth,) a quantity differing very little from 42″.9. The apparent difference of latitude, from Dr. Maskelyne's observations, given either by the 40 observations calculated by Maskelyne, or from the whole mass of 337 calculated by Zach, (*L'Attraction des Montagnes, &c.*) is 54″.6. The difference, or 11″.7, is the sum of the attractions which the mountain exerted in opposite directions on the plumb-line, when placed on opposite sides of the mountain. The mean density of the Earth, calculated on the theory of Gravitation from this attraction, and from an accurate survey of the mountain, was found by Dr. Hutton, (*Phil. Trans.* 1778, 1811, and 1821,) to be about 1.8 × density of Schehallien, or about 5 × density of water.

Attempt to ascertain the attraction of a mountain in Peru.

Observations on the attraction of Schehallien.

The arc of meridian which had been traced so accurately through France, served for a foundation to the surveys for a very accurate map of France. Nothing of this kind had been done in England, excepting a survey of part of the Highlands, commenced in consequence of the Rebellion of 1745. The disastrous wars of the last century prevented our Government from extending the map. In the year 1785, Cassini de Thury presented to the Royal Society a memorial on the uncertainty in the difference of longitude of Greenwich and Paris; and proposed that the English and French Mathematicians in concert should determine, by Geodetic operations, the distance, measured along an arc of parallel. This was assented to, and the English survey was placed under the superintendence of General Roy, the French under that of Count Cassini, (fourth of that name,) Mechain, and Legendre. We believe it may fairly be said that in this, as in other grand experiments, though we began later than our continental neighbours, we conducted our operations with a degree of accuracy of which, till that time, no one had dared to form an idea. For the measure of the first base on Hounslow Heath, in 1784, deal rods

Junction of the observations of Greenwich and Paris.

(which had been used in all preceding measures) were rejected, and glass tubes were used. These were afterwards laid aside, and a steel chain was employed in the measure of a base of verification on Romney Marsh. In 1791 the base on Hounslow Heath was remeasured with the chain. The description of the mode of measuring the bases (*Phil. Trans.* 1785, and *Account of Trigonometrical Survey*, vol. i.) was translated into French by M. Prony. The angles of the triangles were observed with a large theodolite, made by Ramsden; and this is the first instrument with which the spherical excess of the sum of the three angles above 180° (a quantity that rarely exceeds 3″ or 4″) was observed. The French part of this survey is remarkable also, as the first instance in which the newly-invented repeating-circle was used in extensive operations. Whether this invention has contributed to the accuracy of Astronomical determinations, we may be permitted to doubt; but it can hardly be doubted that it is an excellent instrument for Geodetic operations. The chain of triangles formed by the English observers, extended from the neighbourhood of London to Dover, and across the channel to Calais, and some neighbouring stations; the French triangles joined these with the chain of triangles formerly observed in the meridian of Paris, in the neighbourhood of Dunkirk.*

The object originally proposed in this survey was now attained; but it will readily be imagined that advantage was taken of such an admirable commencement for an equally excellent extension. An accurate survey of the whole Kingdom was commenced; several bases of verification were measured, and in the course of the survey, an arc of parallel between Beachy Head and Dunnose was measured in 1794, (by reciprocal observations of azimuth, a method which we shall hereafter describe,) and an arc of meridian from Dunnose to Clifton in Yorkshire, in 1802. The latitudes were observed with a large zenith sector made by Ramsden. The first of these arcs gave for the length of a degree of longitude in the parallel of 50° 37′ 7″.3, 38,818 fathoms; the second gave for the length of a degree of meridian in latitude 52° 2′, 60,820. This arc of meridian was divided into two parts, nearly equal, by the station of Arbury Hill; the arc from Dunnose to Arbury gave for one degree in latitude 51° 25′, 60,864; that from Arbury to Clifton gave for one degree in latitude 52° 50′, 60,766. These partial arcs present the same anomaly as those in France; the degrees appear to diminish in going towards the Pole. (See *Account of Trigonometrical Survey*, and *Phil. Trans.* for various years.)

English arc of parallel.

English arc of meridian.

Origin of the new French measure.

In 1791 the National Convention of France wishing to fix on a new standard of linear measure, determined (in the true spirit of the Revolutionary Philosophy) to select one which could not be considered as belonging to one nation rather than to another, but which might claim to be esteemed a standard for all the World. The length of the pendulum vibrating seconds at a given place had been pointed out by Picard as the best practical standard; but this did not suit the expanded ideas of the French legislators. They considered that the length of the seconds' pendulum varied on varying the place of experiment; but that, assuming the Earth's surface (at least the Geometrical surface at which if channels were made communicating with the sea the water would find its level) to be an exact surface of revolution, the length of the quadrant of meridian passing through every place would be the same. The length of the quadrant of meridian passing through the Observatory of Paris was therefore to be ascertained, and one ten-millionth part of this was to be called the *mètre*. It is almost unnecessary to add, that the idea of replacing a lost standard by means of an extensive Geodetic measure is perfectly chimerical; and that the only practical method (still subject to some uncertainty) is by ascertaining the length of the seconds' pendulum, which it is presumed, in the same place, does not vary from one Age to another. The measure was undertaken by Delambre and Mechain, and is described in the *Base du Système Mètrique;* a Work which cannot be too strongly recommended to the perusal of all who wish to be acquainted with the methods pursued in an extensive survey by the ablest general observers and practical Mathematicians of the Age. The difficulties with which they had to struggle were very great, arising principally from the disturbed state of the Country, and, as they approached to a termination, from the depreciation of the assignats. Fire-signals at night are preferable to all others for the operations of a survey; but these it was impossible to employ, as the people would have supposed them to be counter-revolutionary signals. In the choice of day-signals, and in procuring permission to erect and to observe them, they experienced sometimes the most serious, and sometimes the most ludicrous obstacles. It was generally necessary to receive the sanction of the popular assembly of each town through which they passed; and in many cases Delambre found himself obliged to give to the collected inhabitants a sort of Lecture on Geodesy. When a great part of their labour was completed, they were dismissed from their office for not having sufficiently distinguished themselves by their hatred of Kings. They were, however, allowed to complete the arc which they had originally intended to measure; following the course of the former measures, and using, in many instances, the same signals from Dunkirk to Barcelona. The part South of the Pyrenees was measured by the permission and with the assistance of the Spanish Government. As soon as the details of the measures could be collected, they were laid before a committee consisting of scientific deputies from several continental nations. It was there determined to proceed on the assumption, that the Earth is an exact elliptical spheroid, and to calculate its ellipticity, its dimensions, and the length of the quadrant, from a comparison of the arc newly measured with the arc measured by Bouguer and Lacondamine in Peru. The ellipticity adopted was $\frac{1}{304}$, and the mètre was fixed at 443,296 lines. The latitudes were observed at Dunkirk, Paris, Evaux, Carcassone, and Montjouy, near Barcelona. The arc was thus divided into four partial arcs, of which the middle latitudes were 49° 56′, 47° 31′, 44° 42′, and 42° 17′, and which gave respectively for the length of one degree, in toises, 57,082.7, 57,068.8, 56,977.8, and 56,946.6. This survey was afterwards extended by Biot and Arago to the Island of Formentera, near Minorca; the mean latitude of the additional arc was 40° 1′, and the length of one degree 56,956.4. The mean latitude of the whole arc, from

Figure of the Earth.

Cavendish's experiments on the attraction of leaden balls.

Formentera to Dunkirk, is 44° 51′, and the mean length of the arc of one degree 57,006.6.

In 1798, a beautiful series of experiments was instituted by Mr. Cavendish, for determining the attraction of metallic balls. The observations on Schehallien had shown, that the attraction of a mountain was certainly appreciable; but it required much artifice, and great experimental delicacy, to make the attraction of a sphere of lead, eight inches in diameter, distinctly sensible. This, however, was effected, and so completely that the comparison of the effects of this attraction with the effects of the attraction of the Earth, enabled him to infer the proportion of the Earth's mean density to the density of lead; and of course to the density of water. The result is very nearly the same (*Phil. Trans.* 1798 and 1821) as that given by the Schehallien experiment.

Earth's ellipticity discovered by the motion of the Moon.

Nearly at the conclusion of this century the investigations of Laplace (*Mécanique Céleste*) furnished us with a curious method of determining the ratio of the Earth's axes. He showed that, in consequence of the Earth's oblateness, the Moon's motion would not be the same as if the Earth were spherical; and that *two* of the resulting irregularities would rise to such a magnitude as probably to be sensible. From the accurate observations of the Moon made at Greenwich, the existence of these inequalities has been detected, and their magnitude (about 8″ each) has been ascertained with tolerable certainty. They indicate an ellipticity of nearly $\frac{1}{300}$.

We have mentioned that the ellipticity of the Earth, (assumed to be an elliptic spheroid,) given by a comparison of the degree in Peru with that in France, was not the same as that given by the comparison of the degree in Peru with that in Sweden. The only inference to be drawn from this was, that the assumption was false, and that some such form as that stated by Bouguer must be the true one. No new measures had since been made which could be considered as decisive on this point: the measure in Peru was made with very great care: the accuracy of that in France had been confirmed by the late measure; and, as the only possible explanation, it was thought that the circumstances under which the Swedish measure was made, were not perhaps so favourable to accuracy. To set this at rest the arc was remeasured, and extended in both directions by Svanberg, in the years 1801, 1802, 1803. The details will be found in his very elegant Work entitled *Exposition des Opérations faites en Lapponie, &c.* In this survey the peculiarities of the new Astronomical School of France were pushed to an extent to which the boldest of their proposers had hardly ventured. The French standard and the French graduation alone were used; no instrument but the repeating circle was employed; the labour which English observers would have used in making good single observations was by Svanberg bestowed on the infinite repetition of angles; the imagination was taxed to discover the best manner of combining the observations in order to obtain the result which, according to the theory of chances, would be most probably correct. The methods of calculation were principally taken from Delambre. The base was nearly the same as that measured by the Academicians; the triangles, as far as the survey of the Academicians extended, were the same; those which Svanberg added were not so favourably circumstanced. The latitudes of his extreme stations, Mallorn and Pahtavara, were 65° 31′ 30″.265, and 67° 8′ 49″.83; the distance 180,827 metres = 92,778 toises; whence 1° = 57,196 toises. (Maupertuis had found 1° = 57,422 toises.) The result of this measure seemed at once to destroy the difficulty which had so long troubled Philosophers; in fact, the arcs already mentioned agreed pretty well with the new arc in giving an ellipticity rather less than $\frac{1}{300}$.

Svanberg's arc in Sweden.

History.

But how is the difference of the two measures to be explained? The geodetic measures, as far as they went together, agree very well; the latitude of Tornea, as determined by Maupertuis, agrees perfectly with the observations of Svanberg; the latitude of Kittis was not observed by Svanberg. It is much, very much, to be regretted that the Swedish Astronomer did not repeat the observations at the only place where an important error could be feared.

Zach's observations on the attraction of Mimet.

In 1810 an attempt was made by Baron de Zach to show that the attraction of a mountain called Mimet, near Marseilles, was appreciable. (See his Work, *L'Attraction des Montagnes, &c.*) He observed the latitude of a station on the Southern face of the mountain, and that of the small island Planier: and he calculated the difference of latitudes from the distance found by survey. The attraction of the mountain appeared to produce in the latitude an error of 1″.98. It has been shown, we think satisfactorily, by Arago, (*Conn. des Temps*, 1819, *Additions*,) that the repeating circle used by Zach (as appears from other observations made with it) was not good enough for an operation of such extreme delicacy. We may add, that as the stars observed were all on the same side of the zenith, a change in the constant error of the circle would produce an error in the result without affording any means of discovering its amount.

Arc of meridian measured by Lambton in India.

In the present century an arc has been measured by Colonel Lambton in the Peninsula of India, which, for length and accuracy, must be considered, we think, as exceeding those of all the arcs yet measured. (See *Asiatic Researches* for various years, or *Phil. Trans.* 1818.) The instruments and the methods of calculation were similar to those used in the English survey. The latitude of Punnæ, the Southern station, (near Cape Comorin,) was found to be 8° 9′ 38″.39; that of Daumergidda, the Northern extremity, 18° 3′ 23″.53; the meridional distance 598,609.98 fathoms, or 680 miles. By observing the latitudes of two intermediate stations, this arc was divided into three partial arcs, whose amplitudes were 2° 50′ 10″.54, 4° 6′ 11″28, and 2° 57′ 23″.32; and whose lengths were 171,516.8, 248,188.5, and 178,904.7 fathoms; which give respectively for the length of a degree 60,472.8, 60,487.6, and 60,512.8 fathoms. A comparison of these values with those determined by the French, English, or modern Swedish measures, gives for the ellipticity a quantity rather less than $\frac{1}{300}$. An arc of parallel was also measured in the same manner as the English arc between Dunnose and Beachy Head; but the geographical situation of the place is highly unfavourable to the use of this method.

The first instance, we believe, in which instantaneous fire-signals were used to determine the difference of longitude of two places, for the purpose of comparing it with the distance measured on an arc of parallel, and

Extensive arc of parallel measured in Europe.

thus determining the radius of the parallel of a given latitude, was that in which Cassini de Thury and Lacaille measured an arc across the mouth of the Rhone, and observed the explosion of gunpowder at one intermediate point. In the years 1821, 1822, and 1823, the difference of longitude of Marennes (near Bourdeaux) and Padua was determined by this method. This extensive arc was divided into six partial arcs, and the difference of longitudes* of the extremities of each was ascertained independently of the others. The observers were MM. Brousseaud, Nicollet, Plana, and Carlini. The geographical distance of both extremities from the frontiers of Savoy and Piedmont, had been ascertained by a survey conducted by the French engineers. Considerable difficulty was found in connecting these parts of the survey, as it was necessary to select several stations on the very crest of the Alps. This was at last effected in that part of the chain which lies between the passes of Mont Cenis and Mont Genèvre; accessible stations were found, though one was more than 11,000 feet above the sea. These triangles of junction were surveyed by a mixed commission of Austrian and Piemontese officers. The result (*Conn. des Temps*, 1829, *Additions*, and *Opérations Géodésiques et Astronomiques en Piémont et Savoie*) is that the length of a degree of parallel in latitude 45° 43′ 12″, is 77,865^m·75. A comparison of this arc with the principal arcs of latitude seems to show that the ellipticity is about $\frac{1}{280}$. At the same time the arc measured by

Remeasurement of Beccaria's arc.

Beccaria was remeasured, and the latitudes of the stations reobserved. The result differs from Beccaria's, but not so much as to remove the anomaly in that measure.

The arc of parallel between Beachy Head and Dunnose, measured by General Roy, was used to fix a scale of longitudes in the Ordnance map of England. It was suspected that the scale was erroneous, but it was only in 1823 that this was clearly established. Dr. Tiarks,

Connection of the measure of parallel in England.

by carrying several chronometers backwards and forwards between Dover and Falmouth, found that the difference of their longitudes was incorrect, to the amount of 4″ of time; the difference of longitudes given by the map being smaller than that given by the chronometers. It was necessary, therefore, to diminish the value of a degree of parallel, as determined by Roy's observations; and the degree so diminished agrees much better with those obtained from other measures.

Besides these measures which have been undertaken expressly for the purpose of ascertaining the Earth's dimensions, others have been made in which the principal object was the mapping of the country, and from which the Earth's dimensions have been incidentally deduced, when the latitudes of extreme stations as observed, have been compared with the latitudes as calculated on assumed dimensions. We have great doubts of the accuracy, in general, of the observed latitudes; and we have not, therefore, thought these operations worthy of a particular mention. Several, undoubtedly, ought to be excepted from this remark; we may mention in particular the survey lately made connecting Göttingen and Altona, in which we believe that the latitudes were observed with Ramsden's sector, but of which the details have not reached us.

Moder perime with th pendul for the riation Gravity

In the present century, and at the termination of the last, a great number of expeditions have been undertaken, of which one of the principal objects has been to determine the length of the seconds' pendulum at different places. We cannot here give any detailed account of them, and shall merely mention the following. Observations at places in a great extent of latitude in the Spanish expedition of 1789; (*Conn. des Temps*, 1816, *Additions*;) observations by the French at various places in France and England; (*Base du Système métrique*;) observations made in the voyages of Captains Ross and Parry; (see the accounts of those voyages, and *Phil. Trans.*;) observations by Captain Sabine at a number of places in almost all practicable latitudes, undoubtedly the best series of observations yet made; (*Account of Experiments, &c.*;) observations made in the voyages of Freycinet and Duperrey; (accounts of the voyages, and Additions to the *Conn. des Temps*;) observations made by Captain Kater at several places in Great Britain, and by Captain Hall, Sir Thomas Brisbane, Mr. Goldingham, and others, in various parts of the world. (*Phil. Trans.* various years.) The pendulum experiments, especially those of Captain Sabine, appear to indicate a greater ellipticity than is given by the measures.

In our account of the various measures and experiments which are used to determine the Figure and constitution of the Earth, it is possible that we may have omitted some of inferior note. We believe, however, that we have included all upon which any reliance can be placed for aiding us in a most difficult and delicate inquiry.

Section 2.—Theoretical Investigation of the Form assumed by a Revolving Fluid on the Principle of Gravitation.

Physic theory.

(1.) It will be proper to commence this investigation by a repetition of the explanation given in our Treatise on HYDRODYNAMICS, of the conditions of equilibrium of a Fluid of which different points are acted on by different forces acting in different directions.

(2.) We shall suppose that some point is taken as the origin of a system of rectangular coordinates, and that the coordinates of any point are called x, y, z; and that the force R, which acts on the Fluid at that point, is resolved into three forces parallel, respectively, to the three axes, (see MECHANICS, § V.) which are called respectively X, Y, Z. These forces (or the single force of which they are parts) are of the kind called accelerating forces; they are not pressures, but, like Gravity and all kinds of attraction, they produce pressure by acting upon some mass, and the pressure so produced is proportional to that mass. We ought, in strictness, to state it thus: the force which we call R acting on the mass dm produces the pressure $R\,dm$, and this is resolved into the pressures $X\,dm$, $Y\,dm$, $Z\,dm$, parallel to the three coordinates x, y, z.

Condi the eq brium Fluid.

(3.) Now if the Fluid is at rest, we shall not disturb its rest by enclosing a part of it in tubes. Suppose then that in the fluid mass, fig. 2, we place several tubes extending from the surface to the small quantity of Fluid enclosed in a box at the point A: and now let us consider the state of the Fluid in these tubes, &c. as

---

* The English reader who wishes to be acquainted with the best method of determining differences of longitude by fire-signals, is referred to an admirable paper by Mr. Herschel, *Phil. Trans.* 1826, on the determination of the difference of longitude of Paris and Greenwich.

if the surrounding mass did not exist. The action of the forces on the different parts of Fluid in the tube C D A will produce a pressure on the Fluid at the place A; that in the tube E A, or C B A, will also produce a pressure there. Now the characteristic property of Fluids (HYDRODYNAMICS, § II.) is, that the pressure produced by the Fluid in E A, will be transmitted by the Fluid at A, in such a manner as to cause the same pressure upwards (estimated by the pressure on a given surface) at the bottoms of the tubes C B A, C D A. If, then, the pressures produced by the Fluids in these tubes be less than that produced by the Fluid in E A, the Fluid will be forced up them; if greater, it will descend, forcing a portion of the Fluid up A E; both which conclusions are inconsistent with our supposition of rest. It is necessary, therefore, that they be equal; and thus we obtain as the condition necessary for equilibrium; the pressure produced by the Fluids in all imaginary canals from the surface to any given point of the Fluid must be equal.

(4.) This condition is also sufficient for equilibrium. For if we take small tubes as F G, H G, to any part of the tube E A, the Fluids in these, in consequence of this condition being satisfied, will have no tendency to disturb the Fluid in E A; from which it appears, that the equilibrium of the Fluid in E A does not depend on its being enclosed in a tube: and the same applies to any other point of the Fluid.

Expression for pressure of a Fluid.

(5.) The condition can now be reduced to a mathematical form, for which purpose we must find an expression for the pressure produced by the Fluid in a tube. Take a very small portion of the tube, as B b, and construct a parallelopiped of which B b is the diagonal, and whose sides B c, c d, d b, are parallel to the coordinates x, y, z, respectively. As these sides are the differences between the coordinates that correspond to the point B, and those that correspond to the point b, let them be called dx, dy, dz; and call B b, the increase of the length of the tube in proceeding from B to b, ds; call the section of the tube, expressed in square units of surface, K; and the density of the Fluid in that part of the tube, expressed by the weight of one cubical unit, ρ. Then the solid content of the tube B b is K ds; the weight of the Fluid contained in it is K ρ ds: the action of the force X upon this causes the pressure K ρ X ds in the direction B c. Resolve this (MECHANICS, Art. 29.) into two pressures, one of which is parallel to B b, the other perpendicular to it. The latter of these will only cause a pressure on the sides of the tube, and therefore is to be neglected; the former will cause a pressure in the direction of the tube, and will therefore add to the pressure of the Fluid. Its value is $\mathrm{K}\rho\mathrm{X}\,ds \times \cos b\mathrm{B}c = \mathrm{K}\rho\mathrm{X}\,ds \times \frac{\mathrm{B}c}{\mathrm{B}b}$ $= \mathrm{K}\rho\mathrm{X}\,ds \times \frac{dx}{ds} = \mathrm{K}\rho\mathrm{X}\,dx$. This is the pressure which it causes on the surface K; and therefore on a surface 1 it would cause the pressure $\rho\,\mathrm{X}\,dx$. Similarly it would appear that the pressure caused by the action of the force Y would be $\rho\,\mathrm{Y}\,dy$; and that caused by the force Z would be $\rho\,\mathrm{Z}\,dz$. The sum of these, or $\rho(\mathrm{X}\,dx + \mathrm{Y}\,dy + \mathrm{Z}\,dz)$, is the quantity by which the pressure of the Fluid is increased between B and b; and therefore it is, in common language, the differential of the pressure. The whole pressure is the integral of this, and is therefore $\int\rho\,(\mathrm{X}\,dx + \mathrm{Y}\,dy + \mathrm{Z}\,dz)$.

(6.) Now the condition of equilibrium requires that the pressures produced by the Fluids in the tubes C B A, C D A, should be equal, or (since this is to be the case for tubes of any form) that the pressure should be independent of the form of the tube. Now the form of the tube will be defined by two equations, one of which will express y in terms of x, and the other z in terms of x; so that, assuming at pleasure a value of x, we can find corresponding values of y and z. For every different form of the tube, y and z will be expressed in different functions of x. And since the density at any point is known from a knowledge of its situation, ρ is a function of x. On substituting these values in the quantity $\rho\,(\mathrm{X}\,dx + \mathrm{Y}\,dy + \mathrm{Z}\,dz)$ it will have the shape $\phi\,(x)\,dx$, the integral of which is of the form $\psi\,(x)$; putting a and e for the values of x at A and C, and integrating between these limits, the pressure will be $\psi\,(a) - \psi\,(e)$. Now this expression clearly is not the same for all forms of the function ψ, that is, it is not the same for all forms of ϕ, or it is not the same for all figures of the tube; and therefore when it is necessary to integrate $\rho\,(\mathrm{X}\,dx + \mathrm{Y}\,dy + \mathrm{Z}\,dz)$ in this manner, the equation of equilibrium cannot be satisfied.

Mathematical condition of equilibrium.

(7.) But there is one case in which $\rho\,(\mathrm{X}\,dx + \mathrm{Y}\,dy + \mathrm{Z}\,dz)$ can be integrated without expressing y and z in terms of x; it is when $\rho\,(\mathrm{X}\,dx + \mathrm{Y}\,dy + \mathrm{Z}\,dz)$ is explicitly a complete differential of some function of x, y, and z. In this case, supposing the integral to be $\chi\,(x, y, z)$, and putting a, b, c for the values of x, y, z, at the point A, and e, f, g for those at the point C, the pressure will be $\chi\,(a, b, c) - \chi\,(e, f, g)$. Here the expression is the same whatever be the form of the tube; and thus we get for one condition of equilibrium, that $\rho\,(\mathrm{X}\,dx + \mathrm{Y}\,dy + \mathrm{Z}\,dz)$ must be explicitly a complete differential.

Form of external surface necessary for equilibrium.

(8.) Here we have compared the pressures produced by the Fluids in two tubes drawn from the same point of the surface C. If, however, we take another tube E A from another point of the surface, and call l, m, n the coordinates of E, the expression for the pressure which the fluid in it produces will be $\chi\,(a, b, c) - \chi\,(l, m, n)$. This must be the same as the former expression; hence $\chi\,(l, m, n)$ must be the same as $\chi\,(e, f, g)$. Applying this to all points of the surface we find that, l, m, n being the coordinates of any point of the surface, $\chi\,(l, m, n)$ must be constant; or putting x, y, z instead of l, m, n, and observing that $\chi\,(x, y, z)$ is the integral of $\rho\,(\mathrm{X}\,dx + \mathrm{Y}\,dy + \mathrm{Z}\,dz)$, the external surface will be defined by making this differential $= 0$, or $\mathrm{X}\,dx + \mathrm{Y}\,dy + \mathrm{Z}\,dz = 0$. And this is the second equation of equilibrium.

Relation of forces when the Fluid is homogeneous.

(9.) Suppose the Fluid to be homogeneous, or ρ, the density, to be constant and equal to k; then we must have $k\,(\mathrm{X}\,dx + \mathrm{Y}\,dy + \mathrm{Z}\,dz)$ a complete differential, or $\mathrm{X}\,dx + \mathrm{Y}\,dy + \mathrm{Z}\,dz$ a complete differential. Now it is remarkable that this condition is satisfied by the only attractive force (Gravitation) whose laws are accurately known to us, as well as by the centrifugal force of which we shall presently speak. For, let the mass of one attracting point be dm, its coordinates a, b, c, the coordinates of an attracted point x, y, z, the distance between them r, so that

Satisfied by Gravitation and centrifugal force.

$$r = \sqrt{\overline{x-a}|^2 + \overline{y-b}|^2 + \overline{z-c}|^2}.$$

Then the attraction in the direction of r, on the principle of Gravitation, will be represented by $\frac{dm}{r^2}$; that in the direction of x will be $\frac{dm}{r^2} \times \frac{x-a}{r} = dm \times \frac{x-a}{r^3}$; those in the direction of y and z, $dm \times \frac{y-b}{r^3}$, and $dm \times \frac{z-c}{r^3}$ Hence $X = dm . \frac{x-a}{r^3}$, $Y = dm . \frac{y-b}{r^3}$, $Z = dm . \frac{z-c}{r^3}$, and $X\,dx + Y\,dy + Z\,dz$

$$= dm . \frac{\overline{x-a}.dx + \overline{y-b}.dy + \overline{z-c}.dz}{(\overline{x-a}|^2 + \overline{y-b}|^2 + \overline{z-c}|^2)^{\frac{3}{2}}},$$

which is a complete differential (the integral is $\frac{-dm}{\sqrt{\{\overline{x-a}|^2 + \overline{y-b}|^2 + \overline{z-c}|^2\}}}$). The same will be true for the forces produced by the attraction of any other attracting point; and therefore for the forces produced by the sum of all the attractions of different points. The centrifugal force (as we shall show hereafter) is proportional to the distance of the point on which it acts from an axis, and acts in the direction of a line perpendicular to the axis, and passing through the point; whence it is easily found that, supposing the axis of z to be the axis of rotation, and the force to be $m \times$ distance, the force in the direction of x will be mx, and that in the direction of y will be my, that in the direction of z, 0; therefore $X\,dx + Y\,dy + Z\,dz = m\,(x\,dx + y\,dy)$, which is a complete differential, its integral being $\frac{m}{2}(x^2 + y^2)$.

Form or surface of equal density when the Fluid is heterogeneous.

(10.) If ρ be not constant, and if $X\,dx + Y\,dy + Z\,dz$ be a complete differential, and $= dq$, then the quantity in Art. (7.), which must be a complete differential, is $\rho\,dq$. This can only be true when ρ is a function of q; and, consequently, so long as q does not vary, ρ must remain without variation. That is, if the fluid be heterogeneous, the surface which limits a stratum of any given density is defined by the equation $q = c$. Let p be the pressure; then $dp = \rho\,dq$, and $p = \int \rho\,dq$, which is some function of q, as $\phi\,(q)$; and if q' be the value of q at A, and q'' the value at the surface, p at $A = \phi\,(q') - \phi\,(q'')$. From this (as in Art. 8.) it appears that $\phi\,(q'')$ must be constant, or q'' must be constant, at the external surface; and thus it appears that the external surface, as well as any surface which separates strata of different density, is defined by the equation $q =$ constant. It appears, also, that $p = \phi\,(q')$ — constant, whence q' is a function of p, and ρ, which is a function of q', is also a function of p; that is, where p is the same, ρ is the same. Conversely, where ρ is the same, p is the same, provided* that the Fluid consist of indefinitely thin strata of densities varying from any one to the next in contact with it.

The same equation holds if the density depend on the pressure.

(11.) From this conclusion we derive this remarkable inference, that if we suppose the density to depend on the pressure, the equations of equilibrium will not be in any degree altered. For that supposition would only require that ρ should be the same where p is the same, which is already secured by the conclusion just mentioned.

Attracti… entirely …rected t… centre.

(12.) *Example.* Suppose the only forces which act on each particle of a heterogeneous Fluid to be these; an attraction (not to every other particle but) to the centre, varying inversely as the square of the distance from the centre; and the centrifugal force resulting from rotation round an axis passing through the centre. (This is nearly the same as Huygens's supposition.)

Let A C B, fig. 3, be the axis, C the centre, C M, M N, N P, the three coordinates of a point P, one of which (N P or z) is parallel to the axis; join C N, C P, and draw P Q parallel to N C, which will be perpendicular to A C B. The force $\frac{f}{r^2}$ in the direction P C, represented by P C, may be resolved into P N, N M, M C, that is, the resolved parts parallel to x, y, and z are $-\frac{fx}{r^3}$, $-\frac{fy}{r^3}$, $-\frac{fz}{r^3}$; where r s put for P C, and the forces are considered negative because their action tends to move the particle in such a direction as to diminish x, y, and z. The centrifugal force, if T be the time of revolution, is equal (MECHANICS, § XIV.) to $\frac{4\pi^2}{T^2}$ Q P, or $\frac{4\pi^2}{T^2}$ C N; which may be resolved into $\frac{4\pi^2}{T^2}$ C M, and $\frac{4\pi^2}{T^2}$ M N, or $\frac{4\pi^2}{T^2}x$ and $\frac{4\pi^2}{T^2}y$, in the directions of x and y. These are positive, because their action tends to increase the coordinates x and y of any particle. When the rotation is taken into account by this application of centrifugal force, we may consider the conditions of equilibrium the same as if there were no rotation. Then

$$X = -\frac{fx}{r^3} + \frac{4\pi^2}{T^2}x,$$

$$Y = -\frac{fy}{r^3} + \frac{4\pi^2}{T^2}y,$$

$$Z = -\frac{fz}{r}.$$

From which $dq = -\frac{f}{r^3}(x\,dx + y\,dy + z\,dz)$ $+ \frac{4\pi^2}{T^2}(x\,dx + y\,dy) = -\frac{f\,dr}{r^2} + \frac{2\pi^2}{T^2}d\,(x^2 + y^2)$, and $q = \frac{f}{r} + \frac{2\pi^2}{T^2}(x^2 + y^2)$. The equation to the external surface will, therefore, be

$$\frac{f}{r} + \frac{2\pi^2}{T^2}(x^2 + y^2) = C.$$

Let a be the equatorial radius; at a point in the equator $r = a$, and $x^2 + y^2 = a^2$; consequently $C = \frac{f}{a} + \frac{2\pi^2}{T^2}a^2$, and the equation is $\frac{f}{\sqrt{x^2 + y^2 + z^2}} + \frac{2\pi^2}{T^2} \times (x^2 + y^2) = \frac{f}{a} + \frac{2\pi^2}{T^2}a^2$. If the centrifugal force at

---

* If the strata of homogeneous Fluid were thick, ρ would be the same where p was the same, yet p would not be the same where ρ was the same. For between the upper and lower surface of the stratum ρ would not be altered, but p would have had all values between the value at the upper and that at the lower surface.

the equator $\left(\text{or } \frac{4\pi^2}{T^2} a\right)$ be $m \times$ whole force there $\left(\text{or } m \times \left\{\frac{f}{a^2} - \frac{4\pi^2}{T^2} a\right\}\right)$, we have $\frac{4\pi^2}{T^2} = \frac{m}{1+m} \cdot \frac{f}{a^3}$; and the equation is $\frac{f}{\sqrt{x^2+y^2+z^2}} + \frac{mf}{2(1+m)a} \times (x^2+y^2) = \frac{f}{a} + \frac{mf}{2(1+m)a} = \frac{2+3m}{2+2m} \cdot \frac{f}{a}$, or

$$\frac{1}{\sqrt{x^2+y^2+z^2}} = \frac{2+3m}{2+2m} \cdot \frac{1}{a} - \frac{m}{2+2m} \cdot \frac{x^2+y^2}{a^3}.$$

The polar semiaxis, or b, will be determined by making x and $y = 0$, and $z = b$; then $\frac{1}{b} = \frac{2+3m}{2+2m} \cdot \frac{1}{a}$, or $b = \frac{2+2m}{2+3m} a$. The proportion of the diameters is, therefore, $2+3m \,.\, 2+2m$, or the flattening at the Poles is $\frac{m}{2+3m} \times$ the equatorial diameter. If these were the circumstances of the Earth, m (see MECHANICS, § XIV.) would be $\frac{1}{289}$, and the flattening would be $\frac{1}{581}$.

(13.) It must be observed that the determination of the form assumed by a revolving Fluid on the Principle of Gravitation is not so simple as the solution which we have just exhibited. In fact, one of the forces which acts on each particle (the attraction of every other particle) depends on the form; that is, one of the elements necessary to the determination of the form depends itself on the form. The extreme difficulty which this introduces will prevent us from determining, analytically, the form; and will oblige us to confine ourselves to showing, synthetically, that an elliptic surface satisfies the conditions of equilibrium. For a proof that the elliptic is the only form of equilibrium, we refer the reader to a paper by Legendre, in the *Mémoires de l'Académie*, for the year 1789.

On the Figure assumed by a Homogeneous Fluid.

(14.) We shall show that the surface formed by the revolution of an ellipse will satisfy the condition of Art. (9.) (The condition of Art. (8.), as we have explained in (10.), is already satisfied.) For this purpose we must find the attraction of a spheroid on a point at its surface.

Earth supposed homogeneous.

Attraction of a pyramid on a point in its vertex.

(15.) First it is convenient to premise the expression for the attraction of a pyramid on a point at its vertex. Let V P W, fig. 4, be a pyramid of which the base V W (to which the axis is perpendicular) is very small, its area being $= A$; call the length P V, l; then the area of the section at a distance P v (which we will call s) is $A \times \frac{s^2}{l^2}$; and if another section $v'w'$ be taken at the very small distance ds from the former, the solid content of the included frustrum is $A \cdot \frac{s^2\,ds}{l^2}$; and if k be the density of the matter, (estimated as in (5.)), the mass of the matter in the frustrum is $Ak \cdot \frac{s^2\,ds}{l^2}$. Now by the Principle of Gravitation the force of the attraction of this matter on P will be *proportional* to this quantity divided by the square of the distance, or *proportional* to $\frac{Ak}{l^2} ds$. It is *equal* to this quantity multiplied by some constant;* but as this constant must be the same in all parts of the investigation, we will omit it in every part; and consider the attraction of the matter in $v w'$ on the point P, as represented by $\frac{Ak}{l^2} ds$. The integral of this, or $\frac{Aks}{l^2} + C$, is the attraction of the pyramid; making it vanish when $s = 0$, and then making $s = l$, we have for the whole attraction $\frac{Ak}{l}$.

Spheroid divided into pyramids.

(16.) Now let C M, M N, N P, fig. 5, be the coordinates x, y, z, of a point P in the surface; let the plane A P B pass through C and N P; and refer the points of the surface to three coordinates, r, s, and z, of which r is parallel to A B, s perpendicular to A B, but in the plane A B D, and z the same as before. For the point P, therefore, r is C N, s is O, z is N P. Suppose the spheroid to be divided into wedges, (one of which is represented in fig. 6,) by planes passing through P N; let the plane P Q O make with the plane A P B an angle ϕ, and P q O an angle $\phi + d\phi$. Again suppose this wedge divided into pyramids by planes, passing through P Q q, P T t; and let Q P N or q P N be called θ; T P N or t P N, $\theta + d\theta$. Let P Q, the length of this pyramid, be l. Then the area of a section of the pyramid, perpendicular to P Q, is T $t \times t v$. But $tv = \mathrm{P}t \times d\theta = l\,d\theta$ nearly; and T t (supposing tw perpendicular to P N) is $tw \times d\phi = l \cdot \sin\theta \cdot d\phi$. The area of the section is, therefore, $l^2 \cdot \sin\theta \cdot d\phi \cdot d\theta$; and consequently, by (15.), the attraction of the pyramid is $kl \sin\theta \cdot d\phi \cdot d\theta$.

(17.) This is the attraction of the pyramid in the direction of its length. We may resolve this into two parts parallel to P N and N L: the former will be $kl \sin\theta \cdot \cos\theta \cdot d\phi \cdot d\theta$; the latter $kl \cdot \sin^2\theta\, d\phi \cdot d\theta$. This latter may be again resolved into two, one parallel to C A, and one perpendicular to it; their values are $kl \sin^2\theta \cos\phi \cdot d\phi \cdot d\theta$, and $kl \sin^2\theta \cdot \sin\phi \cdot d\phi \cdot d\theta$.

(18.) The first of these is in a direction contrary to that which tends to impress such a motion as would increase the value of z; and, therefore,

Attraction of pyramid in direction of z
$$= -kl \sin\theta \cdot \cos\theta \cdot d\phi \cdot d\theta$$

In a similar manner

Attraction of pyramid in direction of r
$$= -kl \sin^2\theta \cdot \cos\phi \cdot d\phi \cdot d\theta.$$

And

Attraction of pyramid in direction of s
$$= +kl \sin^2\theta \cdot \sin\phi \cdot d\phi \cdot d\theta.$$

The last of these we shall neglect. For when we

---

* The constant would be different according as we estimated the effects of the attraction by the *pressure* which it caused by acting on a given mass at rest, or the *acceleration* which it created in its motion.

take the attraction of the whole spheroid, there will be a pyramid of equal dimensions, and in a similar position, on the opposite side of the plane A P B, whose attraction in the direction of s will have the same magnitude as this, but will have a different sign: and, consequently, they will destroy each other. If we took the attraction of a part only of the spheroid, this reasoning would not hold.

(19.) Now to get the attraction of the wedge in fig. 6, in the direction of z, we must integrate $k\,d\varphi\,.\int l\,.\,\sin\theta\,.\,\cos\theta\,.\,d\theta$. For this purpose we must express l in terms of θ and φ. Let r', s', z' be the coordinates of Q; a and b the major and minor semiaxes of the generating ellipse. Then (ANALYTICAL GEOMETRY, Art. 102.) $b^2(r'^2+s'^2)+a^2z'^2=a^2b^2$. Now $r'=r-tw\,.\cos\varphi'=r-l\sin\theta\,.\,\cos\varphi$; $s'=tw\,.\,\sin\phi=l\sin\theta\,.\,\sin\varphi$; $z'=z-\mathrm{P}w=z-l\cos\theta$. Substituting these values $b^2(r^2-2lr\sin\theta\cos\varphi+l^2\sin^2\theta)+a^2(z^2-2lz\cos\theta+l^2\cos^2\theta)=a^2b^2$. But as P is a point in the surface, and s there is 0, $b^2r^2+a^2z^2=a^2b^2$. Subtracting this equation from the former, $b^2l^2\sin^2\theta+a^2l^2\cos^2\theta-2b^2lr\sin\theta\cos\varphi-2a^2lz\cos\theta=0$; whence

$$l=\frac{2b^2r\sin\theta\cos\varphi+2a^2z\cos\theta}{b^2\sin^2\theta+a^2\cos^2\theta}.$$

All the integrations must be performed between the values $\theta=0$, and $\theta=$ that value which makes $l=0$; that is from $\theta=0$, to $\theta=$ the arc whose tangent is $\dfrac{-a^2z}{b^2r\cos\phi}$.

(20.) The attraction of the wedge, therefore, in the direction of z

$$=\quad k\,d\varphi\int\frac{2b^2r\sin\theta\cos\varphi+2a^2z\cos\theta}{b^2\sin^2\theta+a^2\cos^2\theta}\sin\theta\,.\cos\theta\,.d\theta$$

$$=d\varphi\int\left\{\frac{-2b^2r\cos\varphi.\sin^2\theta\,.\cos\theta\,.d\theta}{b^2\sin^2\theta+a^2\cos^2\theta}-\frac{2a^2z\cos^2\theta\,.\sin\theta\,.d\theta}{b^2\sin^2\theta+a^2\cos^2\theta}\right\}$$

Making $b^2=a^2(1-e^2)$, the general integral is

$$kr\cos\phi\,.\,d\phi\left\{\frac{1-e^2}{e^2}\sin\theta-\frac{1-e^2}{e^3}\log\sqrt{\frac{1+e\sin\theta}{1-e\sin\theta}}\right\}$$

$$+2kz\,d\phi\left\{\frac{1}{e^2}\cos\theta-\frac{\sqrt{1-e^2}}{e^3}\tan^{-1*}\left(\frac{e}{\sqrt{1-e^2}}\cos\theta\right)\right\}.$$

Taking this from $\theta=0$ to $\theta=\tan^{-1}\left(\dfrac{-a^2z}{b^2r\cos\varphi}\right)=\sin^{-1}\left(\dfrac{-a^2z}{\sqrt{a^4z^2+b^4r^2\cos^2\varphi}}\right)=\cos^{-1}\left(\dfrac{b^2r\cos\varphi}{\sqrt{a^4z^2+b^4r^2\cos^2\varphi}}\right)$,

we have the attraction of the wedge

$$=2kr\cos\varphi\,d\varphi\left\{-\frac{1-e^2}{e^2}\,.\,\frac{a^2z}{\sqrt{a^4z^2+b^4r^2\cos^2\varphi}}-\frac{1-e^2}{e^3}\log\frac{\sqrt{a^4z^2+b^4r^2\cos^2\varphi}-a^2ez}{\sqrt{a^4z^2+b^4r^2\cos^2\varphi}+a^2ez}\right\}$$

$$+2kz\,d\varphi\left\{\frac{b^2r\cos\varphi}{e^2\sqrt{a^4z^2+b^4r^2\cos^2\varphi}}-\frac{\sqrt{1-e^2}}{e^3}\tan^{-1}\frac{b^2er\cos\varphi}{\sqrt{1-e^2}\,\sqrt{a^4z^2+b^4r^2\cos^2\varphi}}-\frac{1}{e^2}+\frac{\sqrt{1-e^2}}{e^3}\tan^{-1}\frac{e}{\sqrt{1-e^2}}\right\}.$$

Now it may be observed, that all the terms, except the two last, are of such a nature, that upon increasing φ by a semi-circumference, or π, their value is the same but the sign is different, and the addition of two such expressions, one corresponding to the arc φ, and the other to the arc $\pi+\varphi$, will therefore destroy both. As we shall shortly integrate with respect to φ, from $\varphi=0$ to $\varphi=2\pi$, we shall in reality effect that addition. We may as well then reject, at once, these useless terms; and thus we find for the effective attraction of the wedge in the direction of z,

$$2kz\,d\varphi\left(-\frac{1}{e^2}+\frac{\sqrt{1-e^2}}{e^3}\tan^{-1}\frac{e}{\sqrt{1-e^2}}\right)\text{ or }2z\,d\varphi\left(\frac{\sqrt{1-e^2}}{e^3}\sin^{-1}e-\frac{1}{e^2}\right).$$

(21.) To find the attraction of the whole spheroid in the direction of z, we must integrate this with respect to φ, from $\varphi=0$ to $\varphi=2\pi$, and we get $4\pi k\left(\dfrac{\sqrt{1-e^2}}{e^3}\sin^{-1}e-\dfrac{1}{e^2}\right).\ z$.

(22.) The attraction of the wedge in the direction of r is

$$k\cos\varphi\,d\varphi\int\left\{\frac{-2b^2r\cos\varphi\,.\,\sin^3\theta\,.\,d\theta}{b^2\sin^2\theta+a^2\cos^2\theta}-\frac{2a^2z\sin^2\theta\,.\cos\theta\,.\,d\theta}{b^2\sin^2\theta+a^2\cos^2\theta}\right\}.$$

The general integral is

---

[*] We use the expression $\tan^{-1}\left(\dfrac{e}{\sqrt{1-e^2}}\cos\theta\right)$ to denote the arc whose tangent is $\dfrac{e}{\sqrt{1-e^2}}\cos\theta$; and, similarly, for other functions.

$$2kr\cos^2\phi\, d\phi\left\{-\frac{1-e^2}{e^2}\cos\theta+\frac{\sqrt{1-e^2}}{e^3}\,.\tan^{-1}\frac{e\cos\theta}{\sqrt{1-e^2}}\right\}$$

$$+\,2kz\cos\phi\, d\varphi\left\{\frac{1}{e}\sin\theta-\frac{1}{e^3}\log\sqrt{\frac{1+e\sin\theta}{1-e\sin\theta}}\right\}.$$

On taking this between the limits $\theta = 0$, $\theta = \tan^{-1}\,.\,\frac{-a^2 z}{b^2 r\cos\varphi}$, and rejecting (as in (20.)) those terms which ultimately produce no effect, we have for the effective attraction of the wedge in the direction of r

$$2kr\cos^2\varphi\,.\,d\varphi\left\{\frac{1-e^2}{e^2}-\frac{\sqrt{1-e^2}}{e^3}\sin^{-1}e\right\}.$$

(23.) To find the attraction of the whole spheroid in the direction of r we must integrate this with respect to φ from $\varphi = 0$ to $\varphi = 2\pi$: we thus get $2\pi k\left(\frac{1-e^2}{e^2}-\frac{\sqrt{1-e^2}}{e^3}\sin^{-1}e\right).\,r$.

(24.) Besides these forces of attraction there is the centrifugal force, which (as in (12.)) is $\frac{4\pi^2}{T^2}r$ in the direction of r. The whole force, therefore, in the direction of r is $2\pi k\left(\frac{1-e^2}{e^2}-\frac{\sqrt{1-e^2}}{e^3}\sin^{-1}e+\frac{2\pi}{T^2k}\right)r$.

(25.) Resolving the force in the direction of r or C N, fig 5, into two in the directions of C M and M N, or x and y, we find that they are the same multiples of x and y which the force in the direction of r is of r. Thus we have the following expressions:

Expressions for the forces on a particle at the surface of the spheroid.

$$X = 2\pi k\left(\frac{1-e^2}{e^2}-\frac{\sqrt{1-e^2}}{e^3}\sin^{-1}e+\frac{2\pi}{T^2k}\right)x = 2\pi\,.\,k\mathrm{A}\,.\,x.$$

$$Y = 2\pi k\left(\frac{1-e^2}{e^2}-\frac{\sqrt{1-e^2}}{e^3}\sin^{-1}e+\frac{2\pi}{T^2k}\right)y = 2\pi k\mathrm{A}\,.\,y.$$

$$Z = 4\pi k\left(\frac{\sqrt{1-e^2}}{e^3}\sin^{-1}e-\frac{1}{e^2}\right)z = 4\pi\,.\,k\,.\,\mathrm{B}z.$$

The elliptic form proper for equilibrium.

(26.) The condition in (8.) now requires that the external surface be defined by the equation $X\,dx + Y\,dy + Z\,dz = 0$, or $2\pi k\mathrm{A}x\,dx + 2\pi k\mathrm{A}y\,dy + 4\pi k\mathrm{B}z\,dz = 0$, or (integrating and dividing by πk) $\mathrm{A}(x^2+y^2) + 2\mathrm{B}z^2 = \mathrm{C}$. But the equation to the surface has already been assumed to be $b^2(x^2+y^2)+a^2z^2 = a^2b^2$. (Analytical Geometry, Art. 102.) If these equations are compatible, the elliptic form is proper for equilibrium, and a comparison of the constants will determine the degree of ellipticity. Now the form of the equations is precisely the same, and, therefore, they will be compatible if the proportion of the coefficients of x^2+y^2 and z^2 is the same (C being undetermined.) This condition requires that $\frac{\mathrm{A}}{2\mathrm{B}} = \frac{b^2}{a^2} = 1-e^2$, or $\mathrm{A} - 2\mathrm{B}(1-e^2) = 0$, or

$$\frac{3(1-e^2)}{e^2}-\frac{3-2e^2}{e^2}\sqrt{1-e^2}\,.\,\sin^{-1}e+\frac{2\pi}{T^2k}=0,$$

Equation for finding the ellipticity.

an equation from which, when T^2k is known, e can be found.

(27.) If $\sin^{-1}e = f$, the equation may be put under this form, (which is more convenient for calculation,)

$$f\,.\cot f(1+3\cot^2 f)-3\cot^2 f-\frac{2\pi}{T^2k}=0.$$

If a curve be constructed of which the abscissa is f, and the ordinate the equation deprived of its last term, it will be found to resemble A E F B, fig. 7. If we draw a straight line, C D, parallel to A B, and at a perpendicular distance equal to $\frac{2\pi}{T^2k}$, the points in which it cuts the curve will have for abscissæ the values of f, which satisfy the equation. From this it appears that if $\frac{2\pi}{T^2k}$ does not exceed a certain limit (.22467), there are two values of f and, consequently, of e, or two forms of ellipsoid, with which equilibrium is possible; if it exceed that limit, equilibrium is not possible.

(28.) We have spoken here as if the velocity of rotation was independent of the form of the spheroid. This would not be the case, if in consequence of want of adaptation of the forces the form of the Fluid should change. Nothing, therefore, can be inferred with regard to the stability of the equilibrium. To investigate this we must make use of the following theorem of Mechanics, (known as *the principle of the conservation of areas*) If any bodies revolve round a centre, and are acted on only by their mutual attraction and by forces directed to the centre, the sum of the products of the mass of each by the projection (on a given plane) of the area which it describes round that centre is constant. In the case before us the particles of the Fluid are acted on only by their mutual attraction, and therefore this theorem applies. Now (without making a complete investigation) it is easily seen that the sum of the products of the mass by the area described does not depend on the length of the axis of revolution, but is proportional to the square of the major axis directly, and the time of revolution inversely. That is, $C' = \frac{a^2}{T}$, or $T = \frac{a^2}{C'}$. And since the quantity of matter is given, $C'' = a^2 b = a^3 \sqrt{1-e^2}$; whence $a^3 = \frac{C''}{\overline{1-e^2}|^{\frac{1}{2}}}$.

$a = \frac{C''^{\frac{2}{3}}}{\overline{1-e^2}|^{\frac{1}{3}}}$; and $T = \frac{C''^{\frac{2}{3}}}{C'.\overline{1-e^2}|^{\frac{1}{3}}}$; $\frac{2\pi}{T^2} = \frac{2\pi . C'^2}{C''^{\frac{4}{3}}} \overline{1-e^2}|^{\frac{2}{3}} = D . \overline{1-e^2}|^{\frac{2}{3}}$ for abbreviation. Substituting this in the equation of (27.), and putting $\overline{\cos f}|^{\frac{4}{3}}$ for $\overline{1-e^2}|^{\frac{2}{3}}$, we have

$$f . \cot f . (1 + 3 \cot^2 f) - 3 \cot^2 f - \frac{D}{k} \overline{\cos f}|^{\frac{4}{3}} = 0,$$

$$\text{or } \frac{1}{\overline{\cos f}|^{\frac{4}{3}}} \{ f \cot f . (1 + 3 \cot^2 f) - 3 \cot^2 f \} - \frac{D}{k} = 0.$$

A given mass, in motion, with a given velocity, has only one form of equilibrium. The equilibrium is stable.

If we construct a curve of which f is the abscissa, and this expression deprived of its last term the ordinate, it will be found to resemble fig. 8, the ordinate becoming infinite when $f = 90°$, or $e = 1$. And, therefore, if we draw C D parallel to A B at the distance $\frac{D}{k}$, it will cut the curve at one point and at no more. It appears, then, that the equation above admits in all cases of one solution and of no more than one; and, consequently, if a fluid mass is revolving round an axis, there is always one elliptic spheroid, and only one, in which it can remain in equilibrium. It will very easily be seen that if it be put in the form of a less flattened spheroid, its angular velocity must be increased, and therefore it will return to the form of the spheroid of equilibrium; if it be made too flat, the angular velocity will be diminished and it will also return to that form. Hence the equilibrium is always stable. We have given this proposition, perhaps, more attention than it deserves, because the preceding proposition has sometimes been stated in such a form as to imply that a mass of Fluid might have two forms of equilibrium, and might have one form of unstable equilibrium; conclusions which are quite incorrect.

(29.) With regard to the Earth considered as a homogeneous Fluid, we do not immediately know k, but we know the force of Gravity at the Equator, and we can calculate the centrifugal force there, and, consequently, know their ratio; let this be m. The whole Gravity at the Equator, by (23.), making $r = a$, and changing the sign, is $2\pi k . \left(-\frac{1-e^2}{e^2} + \frac{\sqrt{1-e^2}}{e^3} \sin^{-1} e - \frac{2\pi}{T^2 k} \right) . a$; the centrifugal force is $2\pi k . \frac{2\pi}{T^2 k} a$;

$$\text{hence } \frac{2\pi}{T^2 k} = m \left(\frac{\sqrt{1-e^2}}{e^3} \sin^{-1} e - \frac{1-e^2}{e^2} - \frac{2\pi}{T^2 k} \right), \text{ and } \frac{2\pi}{T^2 k} = \frac{m}{1+m} \left(\frac{\sqrt{1-e^2}}{e^3} \sin^{-1} e - \frac{1-e^2}{e^2} \right)$$

$$= \frac{m}{1+m} \left(\frac{f . \cos f}{\sin^3 f} - \cot^2 f \right).$$

The equation of (27.) is changed by this substitution into the following:

$$\frac{f \cot f (1 + 3 \cot^2 f) - 3 \cot^2 f}{f \cot f (1 + \cot^2 f) - \cot^2 f} - \frac{m}{1+m} = 0.$$

If we construct a curve whose abscissa is f, and ordinate the first term of this equation, it will have the form of fig. 9, the ordinate being $= 1$ when $f = 90°$. If the line C D be drawn parallel to A B, and at the distance $\frac{m}{1+m}$, since $\frac{m}{1+m}$ is less than 1, it will necessarily cut this curve at some point E, and only at one point.

Only one form corresponding to a given ratio of centrifugal force to Gravity.

One corresponding value of f, and consequently one of e, and no more than one, may therefore be found for any given value of m; that is, the ratio of the centrifugal force at the Equator to Gravity there being known, there is but one elliptic form, which will be a form of equilibrium.

Approximate solution of the equation.

(30.) Where m is so small as in the case of the Earth $\left(\frac{1}{289}\right)$, we may be satisfied with a first approximation. Let $a = b(1 + \epsilon)$: ϵ is what is generally called the ellipticity. Then l in (19.) is

$$\frac{2 r \sin\theta . \cos\varphi + 2 z (1 + \epsilon)^2 \cos\theta}{\sin^2\theta + (1 + \epsilon)^2 \cos^2\theta};$$

and if we neglect the square of ϵ, this is

$$\frac{2 r \sin\theta . \cos\varphi + 2 z \cos\theta + 4 \epsilon . z \cos\theta}{1 + 2 \epsilon \cos^2\theta} = 2 r \sin\theta . \cos\varphi + 2 z \cos\theta + \epsilon (4 z \sin^2\theta \cos\theta - 4 r \sin\theta . \cos^2\theta \cos\varphi),$$

gure of e Earth.

Physical Theory. Earth supposed homogeneous.

The attraction of the wedge in the direction of z is, therefore,

$$-k d\phi \int \{ 2r\cos\phi . \sin^2\theta . \cos\theta . d\theta + 2z\cos^2\theta . \sin\theta . d\theta + \epsilon\,(4z . \sin^3\theta . \cos^2\theta . d\theta - 4r\cos\phi . \sin^2\theta\cos^3\theta\, d\theta) \} .$$

The general integral is

$$-k\,d\phi \left\{ \frac{2}{3} r\cos\phi . \sin^3\theta - \frac{2}{3} z\cos^3\theta + \epsilon \left(4z . \overline{\frac{\cos^5\theta}{5} - \frac{\cos^3\theta}{3}} - 4r\cos\phi . \overline{\frac{\sin^3\theta}{3} - \frac{\sin^5\theta}{5}} \right) \right\};$$

taking this between the same limits as in (20.), and selecting in the same way the effective terms, we find the effective attraction of the wedge $= -k\,d\phi \left\{ \frac{2}{3} z + \frac{8}{15}\epsilon z \right\}$. Integrating this from $\phi = 0$ to $\phi = 2\pi$, we have for the attraction of the spheroid in the direction of z,

$$-2\pi k \left\{ \frac{2}{3} z + \frac{8}{15}\epsilon z \right\} = -\frac{4\pi}{3} k \left(1 + \frac{4}{5}\epsilon\right) z.$$

(31.) The attraction of the wedge in the direction of r is

$$-k\cos\phi . d\phi \int \{ 2r\cos\phi\sin^3\theta . d\theta + 2z\sin^2\theta . \cos\theta . d\theta + \epsilon\,(4z\sin^4\theta\cos\theta\, d\theta - 4r\cos\phi\sin^3\theta\cos^2\theta . d\theta) \}$$

The general integral is

$$-k\cos\phi . d\phi \left\{ 2r\cos\phi \times \overline{\frac{\cos^3\theta}{3} - \cos\theta} + 2z\frac{\sin^3\theta}{3} + \epsilon \left(4z\frac{\sin^5\theta}{5} - 4r\cos\phi . \overline{\frac{\cos^5\theta}{5} - \frac{\cos^3\theta}{3}} \right) \right\}$$

The effective part found in the same manner is

$$-k\cos\phi . d\phi \left\{ \frac{4}{3} r\cos\phi - \frac{8}{15}\epsilon r\cos\phi \right\}.$$

Integrating this from $\phi = 0$ to $\phi = 2\pi$, the attraction of the spheroid in the direction of r is

$$-\pi k \left\{ \frac{4}{3} r - \frac{8}{15}\epsilon r \right\} = -\frac{4\pi}{3} k \left(1 - \frac{2}{5}\epsilon\right) . r.$$

Expressions for the attraction of a point in the surface when the ellipticity is small.

(32.) Applying the centrifugal force $= \frac{4\pi^2}{T^2} r$, and resolving the force in the direction of r into two in the direction of x and y, we get the following expressions,

$$X = -\frac{4\pi}{3} k \left(1 - \frac{2}{5}\epsilon - \frac{3\pi}{kT^2}\right) x.$$

$$Y = -\frac{4\pi}{3} k \left(1 - \frac{2}{5}\epsilon - \frac{3\pi}{kT^2}\right) y.$$

$$Z = -\frac{4\pi}{3} k \left(1 + \frac{4}{5}\epsilon\right) z.$$

The equation to the external surface must, therefore, be $\left(\text{omitting } -\frac{4\pi}{B} k\right)$

$$\left(1 - \frac{2}{5}\epsilon - \frac{3\pi}{kT^2}\right)(x^2 + y^2) + \left(1 + \frac{4}{5}\epsilon\right) z^2 = C.$$

But it has been assumed to be $b^2(x^2 + y^2) + b^2 . (1 + 2\epsilon) . z^2 = b^4(1 + 2\epsilon)$. Making the proportion of the coefficients of $x^2 + y^2$ and z^2 the same,

$$1 + 2\epsilon = \frac{1 + \frac{4}{5}\epsilon}{1 - \frac{2}{5}\epsilon - \frac{3\pi}{kT^2}}, \text{ or } 1 + \frac{8}{5}\epsilon - \frac{3\pi}{kT^2} = 1 + \frac{4}{5}\epsilon; \text{ whence } \epsilon = \frac{15\pi}{kT^2}.$$

(33.) Using m to signify the same thing as in (29.), $m = \dfrac{\frac{4\pi^2}{T^2}(1 + \epsilon)}{\frac{4\pi}{3} k \left(1 - \frac{2}{5}\epsilon\right)(1 + \epsilon)\, b} = \dfrac{12\pi}{kT^2}$ nearly; whence $\frac{\pi}{kT^2} = \frac{m}{12}$, and $\epsilon = \frac{5}{4} m$. If the Earth were a homogeneous fluid, m being $\frac{1}{289}$, ϵ would be $\frac{5}{4} \times \frac{1}{289} = \frac{1}{230}$: and the ratio of the axes would be $1 : 1 + \epsilon$ or $230 : 231$.

Expression for Gravity.

(34.) We have nothing remaining but to investigate the magnitude of Gravity (including the effects of attraction and centrifugal force) at any point of the surface. Since the forces X, Y, Z are at right angles to each other, the force compounded of them all is $\sqrt{X^2 + Y^2 + Z^2}$, (MECHANICS, § VI.) which, taking the expressions in (25.) $= 2\pi k\sqrt{A^2(x^2 + y^2) + 4B^2 z^2}$. But by (26.) $\frac{A}{2B} = \frac{b^2}{a^2}$: whence the force

$= 2\pi k\sqrt{\frac{b^4}{a^4}4B^2(x^2+y^2)+4B^2z^2} = 4\pi k B\sqrt{\frac{b^4}{a^4}r^2+z^2}$. Let fig. 10 represent the section of the spheroid through the point P and the axis; draw PR the normal at P. Then (Conic Sections, Art. 34.) $RN = \frac{b^2}{a^2}CN = \frac{b^2}{-}r$; and $PN = z$; therefore $PR = \sqrt{\frac{b^4}{a^4}r^2+z^2}$, and, consequently, the force is proportional to PR.

Gravity expressed in terms of the latitude.

(35.) An expression in terms of the angle PRN (or the latitude of P) may be thus obtained. Let $PRN = \lambda$; $PR = n$; PN or $z = n\sin\lambda$; CN or $r = \frac{a^2}{b^2}RN = \frac{a^2}{b^2}n\cos\lambda$; and substituting these in the equation to the ellipse, $r^2b^2+a^2z^2 = a^2b^2$, it becomes $n^2\left(\frac{a^4}{b^2}\cos^2\lambda + a^2\sin^2\lambda\right) = a^2b^2$, whence $n = \frac{b^2}{\sqrt{a^2\cos^2\lambda + b^2\sin^2\lambda}}$. If $a = b(1+\epsilon)$ and powers of ϵ higher than the first be neglected, this becomes $n = \frac{b}{\sqrt{1+2e\cos^2\lambda}} = b(1-\epsilon\cos^2\lambda) = b\,.\,\overline{1-\epsilon}\,.\,(1+\epsilon\sin^2\lambda)$: and the force is, therefore, proportional to $1+\epsilon\sin^2\lambda$, or $1+\frac{5}{4}m\,.\,\sin^2\lambda$.

On the Figure assumed by a Heterogeneous Fluid.

(36.) The difficulties attending this investigation are so considerable that it would be useless to attempt a complete solution. We shall confine ourselves to an approximation including all terms depending on the first powers of the ellipticities: the reader who may desire to see an approximation including the terms depending on the squares of the ellipticities, and obtained by a different method, is referred to the *Phil. Trans.* for the year 1826.

Method of proceeding in the investigation for a heterogeneous Fluid.

(37.) We shall assume that the form of each homogeneous stratum is elliptical, and that the ellipticity is different for the different strata; so that if we consider the extent of any homogeneous stratum to be sensible, it will be bounded by surfaces of different ellipticities. We shall then investigate the forces produced by each stratum, and by the whole, upon a point in any position: adding the centrifugal force, we shall form the expressions for X, Y, Z; and as we know (Art. 9.) that $X\,dx + Y\,dy + Z\,dz$ is a complete differential, we shall only assume that $X\,dx + Y\,dy + Z\,dz = 0$ is the equation to the surface limiting every homogeneous stratum. We shall then show that this equation agrees with that assumed in the first instance, provided a certain condition be satisfied; from which we shall infer at once the most important deductions relating to the Figure of the Earth.

(38.) Our first object then must be, to investigate the attraction of a shell, bounded by two spheroidal surfaces of different ellipticities, on a point within it or without it. As this is the same as the difference of attractions of two spheroids whose axes and ellipticities are different, we shall begin with investigating the attraction of a spheroid; and first on a point within it.

(39.) It is convenient to premise, that if two pyramids of different lengths have equal solid angles, (that is, if heir sections at a given distance from the vertex be equal,) their attractions are proportional to their lengths. For the attraction of one such pyramid (15.) is $\frac{A\,k}{l}$; that of another $\frac{A'\,k}{l'}$; their proportion is $\frac{A\,l'}{A'\,l}$; but if their solid angles be equal, $\frac{A}{A'} = \frac{l^2}{l'^2}$; therefore the proportion of the attractions is $\frac{l}{l'}$.

Attraction of a homogeneous spheroid on a point within it.

(40.) Now let fig. 11 be constructed in the same manner as fig. 5, except that P, instead of being at the surface of the spheroid, is in the interior; and produce the planes which are the sides of the pyramid QP to meet the other surface about the point Q. The attraction of the pyramids PQ, PQ′, are in opposite directions, and proportional to their lengths, and, consequently, their combined attraction is that of a pyramid whose length is PQ − PQ′, and whose solid angle is the same. Now, using the same notation as in (19.), and forming the same equation, we have

$$l^2(b^2\sin^2\theta + a^2\cos^2\theta) - 2l(a^2z\cos\theta + b^2r\sin\theta\,.\cos\phi) = a^2b^2 - a^2z^2 - b^2r^2;$$

whence

$$l = \frac{a^2z\cos\theta + b^2r\sin\theta\cos\phi}{b^2\sin^2\theta + a^2\cos^2\theta} \pm \frac{1}{b^2\sin^2\theta + a^2\cos^2\theta}\sqrt{\{(a^2b^2 - a^2z^2 - b^2r^2)(b^2\sin^2\theta + a^2\cos^2\theta) + (a^2z\cos\theta + b^2r\sin\theta\cos\phi)^2\}}$$

$$= \frac{a^2z\cos\theta + b^2r\sin\theta\cos\phi}{b^2\sin^2\theta + a^2\cos^2\theta} \pm \sqrt{R}\text{ suppose.}$$

One of these roots represents PQ; the other represents PQ′ estimated in the direction of PQ, that is, if its sign be changed it represents the length of PQ′. Thus

$$PQ = \sqrt{R} + \frac{a^2z\cos\theta + b^2r\sin\theta\cos\phi}{b^2\sin^2\theta + a^2\cos^2\theta},$$

Physical Theory. Earth supposed heterogeneous.

$$PQ' = \sqrt{R} - \frac{a^2 z \cos\theta + b^2 r \sin\theta . \cos\varphi}{b^2 \sin^2\theta + a^2 \cos^2\theta},$$

whence

$$PQ - PQ' = \frac{2\, a^2 z \cos\theta + 2\, b^2 r \sin\theta \cos\varphi}{b^2 \sin^2\theta + a^2 \cos^2\theta}$$

These two pyramids are now to be treated as if they were a single pyramid of length $PQ - PQ'$; and hence we shall have (calling the density ρ)

$$\text{force in direction of } z = -\rho\, (PQ - PQ') \sin\theta . \cos\theta . d\varphi . d\theta,$$

$$\text{force in direction of } r = -\rho\, (PQ - PQ') \sin^2\theta . \cos\varphi . d\varphi . d\theta.$$

The force in the direction of s may be neglected as before.

(41.) Let $a = b\,(1 + e)$; and neglect e^2, e^3, &c. Then

$$PQ - PQ' = 2\, r \cos\varphi \sin\theta + 2\, z \cos\theta + e\, (4\, z \sin^2\theta \cos\theta - 4\, r \cos\varphi . \sin\theta . \cos^2\theta).$$

The force in the direction of z

$$= -\rho\, d\varphi \left\{ 2 r \cos\varphi . \sin^2\theta . \cos\theta . d\theta + 2 z \cos^2\theta . \sin\theta\, d\theta + e\, (4 z \sin^3\theta . \cos^2\theta . d\theta - 4 r . \cos\varphi \sin^2\theta . \cos^3\theta . d\theta \right\}.$$

Integrating this from $\theta = 0$ to $\theta = \pi$, we have for the attraction of the whole double wedge $LQOQ'L$,

$$-\rho\, d\varphi \left\{ \frac{4\, z}{3} + \frac{16}{15} e z \right\}.$$

Integrating this from $\varphi = 0$ to $\varphi = \pi$, we have, attraction of whole spheroid in the direction of z

$$= -\frac{4\pi}{3} \rho \left(1 + \frac{4}{5} e\right) z.$$

(42.) For the force in the direction of r we must in the same way integrate

$$-\rho \cos\varphi . d\varphi . \left\{ 2 r \cos\varphi . \sin^3\theta\, d\theta + 2 z \sin^2\theta . \cos\theta\, d\theta + e\, (4 z \sin^4\theta . \cos\theta\, d\theta - 4 r \cos\varphi . \sin^3\theta . \cos^2\theta . d\theta) \right\},$$

and we find that the attraction of the whole spheroid in the direction of r

$$= -\frac{4\pi}{3} \rho \left(1 - \frac{2}{5} e\right) r.$$

These expressions are independent of the dimensions of the spheroid, provided that it contain the point, and that the ellipticity have the given value e. If, then, two spheroidal surfaces of equal ellipticity but of different dimensions surround the point, the attraction of the matter included between them, upon that point, is nothing. But this will not apply to our present purpose.

Attraction of a homogeneous spheroidal shell on a point within it.

(43.) Now let the spheroid in fig. 11 be surrounded by another spheroid indefinitely near, and of which the ellipticity is $e + de$. Then if the matter whose density is ρ extend to the first spheroid, its attraction on P in the direction of z is $-\frac{4\pi}{3} \rho z - \frac{16\pi}{15} \rho e z$. If it extend to the second spheroid, its attraction is $-\frac{4\pi}{3} \rho z - \frac{16\pi}{15} \rho e z - \frac{16\pi}{15} \rho z . de$. The difference, or the attraction of the stratum included between them, is $-\frac{16\pi}{15} z \rho\, de$. In the same manner, the attraction of the same stratum in the direction of $r = \frac{\quad}{15} r . \rho\, de$.

Attraction of a series of spheroidal shells of different densities on a point within them.

(44.) Now, if we suppose a great number of such thin strata to rest one upon another, as in fig. 12, it will be evident that their attraction in the directions of z and r is to be found by integrating the expressions in the last article. As ρ and e will both be known from a knowledge of the polar semiaxis of the spheroid to which they belong, that is as ρ and e are functions of b, we can put the attractions in this form:

$$\text{Attraction of assemblage of strata in direction of } z = -\frac{16\pi}{15} z \int \rho \frac{de}{db} . db.$$

$$\text{Attraction in direction of } r = \frac{8\pi}{15} r \int \rho \frac{de}{db} . db.$$

The function $\int \rho \frac{de}{db} db$ we shall denote by $\chi(b)$; and if b' be the axis of the inner stratum (which, however, must include or contain P), and b'' that of the exterior stratum, the value of the integral $\int \rho \frac{de}{db} db$ in the present instance will be $\chi(b'') - \chi(b')$; and then the attractions of the assemblage of strata in the directions of z and r are respectively $-\frac{16\pi}{15} z\, (\chi(b'') - \chi(b'))$, and $\frac{8\pi}{15} r\, (\chi(b'') - \chi(b'))$.

(45.) The attraction of a spheroid on a point without it is not found so directly. It will be shown to bear a known proportion to the attraction of another spheroid on a point in a different situation within it; from which, with the assistance of the expressions obtained in (41.) and (42.), its value can be found. For this purpose we must investigate the attraction of a small prism in the direction of its length on a point without it. Let A B

Attraction of a prism on a point without it.

fig. 13, be a prism, the area of whose section is very small and $= \text{A}$; upon the axis produced draw P C, a perpendicular; let $\text{CA} = a$, $\text{CB} = b$, $\text{PC} = c$, $\text{CQ} = x$; at the distances x and $x + dx$, let sections be made; the solid content intercepted is $\text{A} . dx$; and if ρ be the density, the quantity of matter is $\rho . \text{A} . dx$; the distance from P is $\sqrt{c^2 + x^2}$, and therefore the attraction is $\frac{\rho . \text{A} . dx}{c^2 + x^2}$ in the direction PQ, the resolved part of this in the direction C Q is $\frac{\rho . \text{A} . dx}{c^2 + x^2} \times \frac{x}{\sqrt{c^2 + x^2}} = \rho . \text{A} . \frac{x\,dx}{(c^2 + x^2)^{\frac{3}{2}}}$; by integration we get the attraction of the prism $= \text{constant} - \frac{\rho . \text{A} .}{\sqrt{c^2 + x^2}}$; and taking this between the limits $x = a$, $x = b$, it is

$$\rho . \text{A} . \left(\frac{1}{\sqrt{c^2 + a^2}} \frac{1}{\sqrt{c^2 + b^2}}\right) = \rho . \text{A} . \left(\frac{1}{\text{PA}} - \frac{1}{\text{PB}}\right)$$

(46.) Now, in fig. 14, let A B be an ellipsoid, of which the three semiaxes are a, b, c; and let the coordinates of the point P be r, s, z. Parallel to the axis of b and c take two sections whose distances from C are f and $f + df$; and divide the included space into prisms by sections parallel to the axes of a and c, of which two are at the distances g and $g + dg$ from C B; let TT′, the length of that prism, be $2h$. Then the area of its section is $df . dg$; also $\text{PT} = \sqrt{\overline{r-f}|^2 + \overline{s-g}|^2 + \overline{z-h}|^2}$, and $\text{PT}' = \sqrt{\overline{r-f}|^2 + \overline{s-g}|^2 + \overline{z+h}|^2}$, whence (by the last article) the attraction of the prism on P in the direction P N′ is

$$\rho . df . dg \left\{\frac{1}{\sqrt{\overline{r-f}|^2 + \overline{s-g}|^2 + \overline{z-h}|^2}} - \frac{1}{\sqrt{\overline{r-f}|^2 + \overline{s-g}|^2 + \overline{z+h}|^2}}\right\}.$$

This is to be integrated, first with respect to g from $g = -\text{RV}$ to $g = \text{RW}$, which will give the attraction of the slice, and then with respect to f from $f = -a$ to $f = +a$, which will give the attraction of the whole ellipsoid on P in the direction PN′.

Expression to be integrated for the attraction of a homogeneous spheroid on a point without it.

(47.) Let $f = ma$, $g = nb$, $h = pc$. The general equation to the ellipsoid is $\frac{f^2}{a^2} + \frac{g^2}{b^2} + \frac{h^2}{c^2} = 1$, or $m^2 + n^2 + p^2 = 1$; and at the points V and W, $h = 0$, and $\frac{f^2}{a^2} + \frac{g^2}{b^2} = 1$, or $m^2 + n^2 = 1$, whence the extreme values of n are $\pm \sqrt{1 - m^2}$. Also $df = a\,dm$, $dg = b\,dn$. Hence the attraction of the ellipsoid is

$$\rho a b \int dm \int dn \left\{\frac{1}{\sqrt{\overline{r-ma}|^2 + \overline{s-nb}|^2 + \overline{z-pc}|^2}} - \frac{1}{\sqrt{\overline{r-ma}|^2 + \overline{s-nb}|^2 + \overline{z+pc}|^2}}\right\},$$

where the first integration is to be made from $n = -\sqrt{1 - m^2}$ to $n = +\sqrt{1 - m^2}$, and the second from $m = -1$ to $m = +1$.

(48.) In the same manner the attraction of an ellipsoid whose semiaxes are a', b', c' in the same direction on a point whose coordinates are r', s', z', is

$$\rho . a' . b' . \int dm \int dn \left\{\frac{1}{\sqrt{\overline{r'-ma'}|^2 + \overline{s'-nb'}|^2 + \overline{z'-pc'}|^2}} - \frac{1}{\sqrt{\overline{r'-ma'}|^2 + \overline{sn-b'}|^2 + \overline{z+pc'}|^2}}\right\},$$

where the integrals are to be taken between the same limits as before.

(49.) Now the terms within the brackets will be precisely equal in the two expressions, if the following equations hold,

$$a'r' = ar, \quad \text{or} \quad \frac{r'}{a} = \frac{r}{a'} : \text{ let this } = \mu.$$

$$b's' = bs, \quad \text{or} \quad \frac{s'}{b} = \frac{s}{b'} \qquad = \nu.$$

$$c'z' = cz, \quad \text{or} \quad \frac{z'}{c} = \frac{z}{c'} \qquad = \pi.$$

Relation between the attraction of a spheroid on a point without it, and the attraction of another spheroid on a point within it.

Also, $m^2 a'^2 + n^2 b'^2 + p^2 c'^2 + r'^2 + s'^2 + z'^2 = m^2 a^2 + n^2 b^2 + p^2 c^2 + r^2 + s^2 + z^2$; which equation, putting $1 - m^2 - n^2$ for p^2 and $\alpha - \mu^2 - \nu^2$ for π^2, will become

$$c'^2 + m^2 (a'^2 - c'^2) + n^2 (b'^2 - c'^2) + \alpha c^2 + \mu^2 (a^2 - c^2) + \nu^2 (b^2 - c^2)$$
$$= c^2 + m^2 (a^2 - c^2) + n^2 (b^2 - c^2) + \alpha c'^2 + \mu^2 (a'^2 - c'^2) + \nu^2 (b'^2 - c'^2).$$

And as m and n are variable, this can only be satisfied by taking

$$a^2 - c^2 = a'^2 - c'^2$$
$$b^2 - c^2 = b'^2 - c'^2$$
$$\alpha = 1."$$

The last gives $\mu^2 + \nu^2 + \pi^2 = 1$; that is $\frac{r^2}{a'^2} + \frac{s^2}{b'^2} + \frac{z^2}{c'^2} = 1.$

When all these equations are satisfied, the terms within the brackets will be the same, and as the integrals are to be taken between the same limits, the attraction of the first spheroid on the first point perpendicular to a principal section, is to the attraction of the second spheroid on the second point perpendicular to the corresponding section as $a\,b$ to $a'\,b'$, that is as the area of the section of the first to the area of the section in the second.

(50.) The utility of this proposition arises from this circumstance, that if the first point be *without* the first ellipsoid, the second point will be *within* the second ellipsoid, the attraction of which has already been found. For $a^2 - c^2 = a'^2 - c'^2$, or $a^2 - a'^2 = c^2 - c'^2$; similarly $b^2 - b'^2 = c^2 - c'^2$; hence the spheroids will not cut one another (if concentric and similarly situated.) Also since $\mu^2 + \nu^2 + \pi^2 = 1$, or $\frac{r'^2}{a^2} + \frac{s'^2}{b^2} + \frac{z'^2}{c^2} = 1$, the second point is on the surface of the first spheroid; and similarly the first point is on the surface of the second spheroid; therefore, the surface of the second spheroid is without that of the first, and, therefore, the second point is completely surrounded by the second surface.

(51.) This proposition we have demonstrated in its most general form, because the demonstration is thus made somewhat easier. We shall now return to the case which more immediately concerns us, where the semi-axes of the attracting spheroid are b, $b\,(1+e)$, and $b\,(1+e)$, and the coordinates of the attracted point r and z, s being 0.

(52.) Let b', $b'\,(1+e')$, r', and z', be the corresponding quantities in the imaginary spheroid and attracted point; then we must have $b'^2\,(1+e')^2 - b'^2 = b^2\,(1+e)^2 - b^2$; or neglecting e^2, e'^2, $b'^2\,e' = b^2\,e$, and $e' = \frac{b^2}{b'^2}e$. Also $\frac{z^2}{b'^2} + \frac{r^2}{b'^2\,(1+e')^2} = 1$, or $\frac{z^2}{b'^2} + \frac{r^2}{b'^2 + 2\,b^2\,e} = 1$, or $\frac{z^2 + r^2}{b'^2} - \frac{2\,b^2\,r^2}{b'^4}\,e = 1$; or (taking the reciprocal) $\frac{b'^2}{z^2 + r^2} + \frac{2\,b^2\,r^2}{(z^2 + r^2)^2}\,e = 1$, whence $b'^2 = z^2 + r^2 - \frac{2\,b^2\,r^2}{z^2 + r^2}\,e$, and $b' = \sqrt{z^2 + r^2} - \frac{b^2\,r^2}{(z^2 + r^2)^{\frac{3}{2}}}\,e$.

Then the attraction of the fictitious spheroid on the fictitious point in the direction of z, by (41.), is $-\frac{4\,\pi}{3}\,.\,\rho \times \left(1 + \frac{4}{5}\,e'\right).\,z' = -\frac{4\,\pi}{3}\,\rho\left(1 + \frac{4}{5}\,e'\right)\frac{b}{b'}\,.\,z$; and, therefore, by (49.), the attraction of the real spheroid on the real point is $\frac{b^2\,(1+e)^2}{b'^2\,(1+e')^2} \times -\frac{4\,\pi}{3}\,\rho\left(1 + \frac{4}{5}\,e'\right)\frac{b}{b'}\,z, = -\frac{4\,\pi}{3}\,.\,\rho\,.\,z\,.\,\frac{b^3}{b'^3}\left(1 + 2\,e - \frac{6}{5}\,e'\right)$. And the attraction of the fictitious spheroid on the fictitious point in the direction of r by (42.) is $-\frac{4\,\pi}{3}\,\rho\left(1 - \frac{2}{5}\,e'\right)r' = -\frac{4\,\pi}{3}\,\rho\,.\left(1 - \frac{2}{5}\,e'\right).\,\frac{b\,(1+e)}{b'\,(1+e')}\,r$; therefore the attraction of the real spheroid on the real point is

$$\frac{b^2\,(1+e)}{b'^2\,(1+e')} \times -\frac{4\,\pi}{3}\,\rho\,.\left(1 - \frac{2}{5}\,e'\right).\,\frac{b\,(1+e)}{b'\,(1+e')}\,.\,r = -\frac{4\,\pi}{3}\,\rho\,.\,r\,.\,\frac{b^3}{b'^3}\,.\left(1 + 2\,e - \frac{12}{5}\,e'\right).$$

(53.) Putting for $\frac{b^3}{b'^3}$ its value $\frac{b^3}{\overline{z^2 + r^2}|^{\frac{3}{2}}}\left(1 + \frac{3\,b^2\,r^2}{(z^2 + r^2)^2}\,e\right)$, and for e' its value $\frac{b^2}{z^2 + r^2}\,e$, we find

Expressions for the attraction of a homogeneous spheroid on a point without it.

attraction of spheroid in the direction of z

$$= -\frac{4\,\pi}{3}\,\rho\left\{\frac{z}{(z^2 + r^2)^{\frac{3}{2}}}\,.\,b^3\,(1 + 2\,e) + \frac{9\,r^2\,z - 6\,z^3}{5\,(z^2 + r^2)^{\frac{7}{2}}}\,.\,b^5\,.\,e\right\};$$

attraction of spheroid in the direction of r

$$= -\frac{4\,\pi}{3}\,\rho\left\{\frac{r}{(z^2 + r^2)^{\frac{3}{2}}}\,.\,b^3\,(1 + 2\,e) + \frac{3\,r^3 - 12\,r\,z^2}{5\,(z^2 + r^2)^{\frac{7}{2}}}\,.\,b^5\,e\right\}$$

(54.) From this we find the attraction of a thin stratum bounded by two spheroidal surfaces in the same manner as in (44.). If we suppose the spheroid in fig. 14 to be surrounded by a concentric spheroid, whose axis and ellipticity are $b + d\,b$ and $e + d\,e$, we shall have, in the direction of z,

Attraction of a spheroidal homogeneous shell on a point without it

attraction of large spheroid

$$= -\frac{4\,\pi}{3}\,\rho\left\{\frac{z}{(z^2 + r^2)^{\frac{3}{2}}}\left\{b^3\,(1 + 2\,e) + d\,.\,\overline{b^3\,(1 + 2\,e)}\right\} + \frac{9\,r^2\,z - 6\,z^3}{5\,(z^2 + r^2)^{\frac{7}{2}}}\,(b^5\,e + d\,.\,b^5\,e)\right\},$$

attraction of small spheroid

$$= -\frac{4\,\pi}{3}\,\rho\left\{\frac{z}{(z^2 + r^2)^{\frac{3}{2}}}\,.\,b^3\,(1 + 2\,e) + \frac{9\,r^2\,z - 6\,z^3}{5\,(z^2 + r^2)^{\frac{7}{2}}}\,b^5\,e\right\}.$$

The difference, or the attraction of the included stratum,

$$= -\frac{4\pi}{3}\rho . \left\{\frac{z}{(z^2+r^2)^{\frac{3}{2}}} . d . \overline{b^3(1+2e)} + \frac{9r^2z-6z^3}{5(z^2+r^2)^{\frac{7}{2}}} d . b^5 e\right\}$$

(55.) From this, by reasoning precisely similar to that in (44.), we find that the attraction of an assemblage of strata of different densities, each of which is bounded by spheroidal surfaces, concentric and similarly situated, as in fig. 16, on a point without it, in the direction of z, is

$$-\frac{4\pi}{3}\left\{\frac{z}{(z^2+r^2)^{\frac{3}{2}}}\int\rho . d . \overline{b^3(1+2e)} + \frac{9r^2z-6z^3}{5(z^2+r^2)^{\frac{7}{2}}}\int\rho . d . b^3 e\right\}.$$

The integrals in this expression must in general be taken from $b=0$ to $b=$ some assigned value. Let $\int\rho . d . \overline{b^3(1+2e)}$, corrected so as to vanish when $b=0$, be called $\phi(b)$; let $\int\rho . d . b^5 e$ be called $\psi(b)$; then the attraction in the direction of z

Attraction of a series of spheroidal shells of different densities on a point without them.

$$= -\frac{4\pi}{3}\left\{\frac{z}{(z^2+r^2)^{\frac{3}{2}}}\phi(b) + \frac{9r^2z-6z^3}{5(z^2+r^2)^{\frac{7}{2}}} . \psi(b)\right\}.$$

Similarly the attraction in the direction of r

$$= -\frac{4\pi}{3}\left\{\frac{r}{(z^2+r^2)^{\frac{3}{2}}}\phi(b) + \frac{3r^3-12rz^2}{5(z^2+r^2)^{\frac{7}{2}}}\psi(b)\right\}.$$

(56.) We can now express the force which acts upon any point P, in any one of the strata in such a system as we have described, fig. 17. We must use the expressions that we have just found, taking the integrals from $b=0$ to $b=$ C D, D P being the spheroidal surface of equal density that passes through P, and the expressions of (44.), taking the integrals from $b=$ C D to $b=$ C A.

(57.) Let C D $=\beta$, C A $=$ b; let the corresponding ellipticities be ϵ and e. Then the whole forces acting on P (taking into account the centrifugal force) are
force in the direction of r

$$= -\frac{4\pi}{3}\left\{\frac{r}{(z^2+r^2)^{\frac{3}{2}}}\phi(\beta) + \frac{3r^3-12rz^2}{5(z^2+r^2)^{\frac{7}{2}}}\psi(\beta)\right\} + \frac{8\pi}{15}r . \{\lambda(\text{b}) - \chi(\beta)\} + \frac{4\pi^2 r}{\text{T}^2},$$

force in the direction of z

$$= -\frac{4\pi}{3} . \left\{\frac{z}{(z^2+r^2)^{\frac{3}{2}}}\phi(\beta) + \frac{9r^2z-6z^3}{5(z^2+r^2)^{\frac{7}{2}}}\psi(\beta)\right\} - \frac{16\pi}{15} . z\{\chi(\text{b}) - \chi(\beta)\}.$$

And if we resolve the former into forces in the direction of x and y, and observe that $r^2 = x^2 + y^2$, we shall finally obtain

Attraction of a heterogeneous spheroid on one of its particles.

$$\text{X} = -\frac{4\pi}{3}\left\{\frac{x}{(x^2+y^2+z^2)^{\frac{3}{2}}}\phi(\beta) + \frac{3x(x^2+y^2)-12xz^2}{5(x^2+y^2+z^2)^{\frac{7}{2}}}\psi(\beta) - \frac{2}{5}x\{\chi(\text{b}) - \chi(\beta)\} - \frac{3\pi}{\text{T}^2}x\right\}.$$

$$\text{Y} = -\frac{4\pi}{3}\left\{\frac{y}{(x^2+y^2+z^2)^{\frac{3}{2}}}\phi(\beta) + \frac{3y(x^2+y^2)-12yz^2}{5(x^2+y^2+z^2)^{\frac{7}{2}}}\psi(\beta) - \frac{2}{5}y\{\chi(\text{b}) - \chi(\beta)\} - \frac{3\pi}{\text{T}^2}y\right\}.$$

$$\text{Z} = -\frac{4\pi}{3}\left\{\frac{z}{(x^2+y^2+z^2)^{\frac{3}{2}}}\phi(\beta) + \frac{9z(x^2+y^2)-6z^3}{5(x^2+y^2+z^2)^{\frac{7}{2}}}\psi(\beta) + \frac{4}{5}z\{\chi(\text{b}) - \chi(\beta)\}\right\}.$$

(58.) Now we have explained in (10.) and (37.) that the equation to the surface bounding a stratum of equal density, must be $\text{X}\,dx + \text{Y}\,dy + \text{Z}\,dz = 0$; and that this condition is sufficient. But our whole investigation has gone on the supposition that the surface bounding a stratum of equal density is a spheroid, whose semi-axis and ellipticity are β and ϵ, and which is, therefore, defined by the equation $\frac{x^2+y^2}{\beta^2(1+\epsilon)^2} + \frac{z^2}{\beta^2} = 1$, or $\frac{x}{1+2\epsilon}dx + \frac{y}{1+2\epsilon}dy + z\,dz = 0$. The single question then now remains:—is this consistent with the equation $\text{X}\,dx + \text{Y}\,dy + \text{Z}\,dz = 0$? or can the coefficients have the same proportions? In this inquiry we are not to take into account the squares or higher powers of ϵ, as they have been uniformly neglected.

(59.) Assuming the coefficients in the two differential equations to have the same proportion, we get this equation,

$$0 = \frac{2\epsilon . \phi(\beta)}{(x^2+y^2+z^2)^{\frac{3}{2}}} - \frac{6}{5}\frac{\psi(\beta)}{(x^2+y^2+z^2)^{\frac{5}{2}}} - \frac{6}{5}\{\chi(\text{b}) - \chi(\beta)\} - \frac{3}{\text{T}^2},$$

Earth supposed heterogeneous.

in which we have omitted the terms $\epsilon \,.\, \psi(\beta)$, $\epsilon \,.\, \{\chi(\mathrm{b}) - \chi(\beta)\}$, and $\epsilon \,.\, \frac{3\pi}{\mathrm{T}^2}$, because an inspection of the quantities by whose integration the functions are produced will show that though $\phi(\beta)$ is not small, yet $\psi(\beta)$ and $\chi(\beta)$ depend entirely upon e for their value, and, therefore, $\epsilon \,.\, \psi(\beta)$ and $\epsilon \,.\, \chi(\beta)$ are in fact of the second order with regard to ϵ. And $\frac{3\pi}{\mathrm{T}^2}$, which is a multiple of the centrifugal force, is to be estimated of the same order as ϵ, because the ellipticity is immediately occasioned by it, and, therefore, $\epsilon \,.\, \frac{3\pi}{\mathrm{T}^2}$ is also of the second order.

(60.) Again, the quantity $x^2 + y^2 + z^2$, which is in the denominator of the first two terms, differs from β^2 only by $\frac{(x^2 + y^2)(2\epsilon + \epsilon^2)}{\beta^2 (1 + \epsilon)^2}$, that is by a quantity of the same order as ϵ, and, therefore, it may be considered in this equation as equal to β^2. The equation now becomes

$$0 = \frac{2\epsilon \,.\, \phi(\beta)}{\beta^3} - \frac{6}{5} \,.\, \frac{\psi(\beta)}{\beta^5} - \frac{6}{5}\{\chi(\mathrm{b}) - \chi(\beta)\} - \frac{3\pi}{\mathrm{T}^2};$$

or putting b for β,

$$\frac{2e \,.\, \phi(b)}{b^3} - \frac{6}{5}\frac{\psi(b)}{b^5} - \frac{6}{5}\{\chi(\mathrm{b}) - \chi(b)\} - \frac{3\pi}{\mathrm{T}^2} = 0:$$

and if this equation is possible, the equilibrium is possible.

Equilibrium is possible, with the form assumed.

(61.) Differentiating this equation twice, so as to eliminate $\psi(b)$ and $\chi(b)$, both which contain e, and observing that as $\phi(b)$ is multiplied by e, we may consider it as $= \int \rho \,.\, d\,(b^3)$, instead of $= \int \rho \,.\, d\,(b^3 \,.\, \overline{1 + 2e})$, we find

$$b^3 \phi(b) \,.\, \frac{de}{db} + 3\,\psi(b) - 3\,e \,.\, b^2 \phi(b) = 0,$$

$$\frac{d^2 e}{d b^2} + \frac{2\rho b^2}{\int \rho b^2 db} \,.\, \frac{de}{db} + \left(\frac{2\rho b}{\int \rho b^2 db} - \frac{6}{b^2}\right) e = 0.$$

Upon expressing ρ in terms of b it will be possible to solve this equation, and to obtain e in terms of b. The solution will contain two arbitrary constants, whose values may be determined by making the expression satisfy the original equation. Hence equilibrium is possible.

(62.) Using the letter m (as in the investigation of the form assumed by a homogeneous fluid) to denote the ratio of the centrifugal force at the Equator to the force of Gravity there, and observing that at the surface $\beta = \mathrm{b}$, $x = \mathrm{b}\,(1 + \mathrm{e})$, $y = 0$, $z = 0$, we have

$$m = \frac{\frac{3\pi}{\mathrm{T}^2}\mathrm{b}\,(1 + \mathrm{e})}{\frac{\phi(\mathrm{b})}{\mathrm{b}^2 (1 + \mathrm{e})^2} + \frac{3}{5}\frac{\psi(\mathrm{b})}{\mathrm{b}^4 (1 + \mathrm{e})^4} - \frac{3\pi}{\mathrm{T}^2}\mathrm{b}\,(1 + \mathrm{e})};$$

Equation to be used for investigation of the Earth's form.

and neglecting the terms of the second order, $m = \frac{3\pi}{\mathrm{T}^2} \,.\, \frac{\mathrm{b}^3}{\phi(\mathrm{b})}$; whence $\frac{3\pi}{\mathrm{T}^2} = \frac{m\,\phi(\mathrm{b})}{\mathrm{b}^3}$. The equation of (60.), in the form in which we are compelled to use it for investigation of the Earth's constitution, is, therefore,

$$\frac{2e \,.\, \phi(b)}{b^3} - \frac{6}{5} \,.\, \frac{\psi(b)}{b^5} - \frac{6}{5}\{\chi(\mathrm{b}) - \chi(b)\} - \frac{m\,\phi(\mathrm{b})}{\mathrm{b}^3} = 0.$$

We have already remarked in (11.) that this equation also holds if we suppose the density of the fluid to depend on the pressure. We may further remark that if we suppose a solid nucleus to exist, similar in general constitution to what we have assumed to be the state of the Earth, but having for its different strata any arbitrary densities and ellipticities, and then if we suppose fluids of different densities to be suffered to arrange themselves freely round this nucleus, the same expressions will hold for the forces, as if the whole were fluid, (the integrals being taken as well for the solid as for the fluid part,) and the equation of this article will apply in the same manner with regard to the fluid parts. And, therefore, the equations respecting the surface (which are in fact the only important ones, the others being only useful in conducting us to them) are equally true whether the whole be supposed to be fluid, or a fluid heterogeneous mass be supposed to surround such a nucleus.

Equation simplified when applied to the surface.

(63.) At the surface $b = \mathrm{b}$; and the equation of the last article becomes $(2\mathrm{e} - m)\frac{\phi(\mathrm{b})}{\mathrm{b}^3} - \frac{6}{5} \,.\, \frac{\psi(\mathrm{b})}{\mathrm{b}^5} = 0.$

(64.) One of the most remarkable applications of this equation is to be found in the expression for Gravity at any part of the Earth's surface. If in (57.) we put b for b, and $\frac{m\,\phi(\mathrm{b})}{\mathrm{b}^3}$ for $\frac{3\pi}{\mathrm{T}^2}$, we have for the forces acting on a point at the Earth's surface

$$X = -\frac{4\pi}{3}\left\{\frac{x}{(x^2+y^2+z^2)^{\frac{3}{2}}}\phi(\mathrm{b}) + \frac{3x(x^2+y^2) - 12xz^2}{5(x^2+y^2+z^2)^{\frac{7}{2}}}\psi(\mathrm{b}) - x\frac{m\phi(\mathrm{b})}{\mathrm{b}^3}\right\}.$$

$$Y = -\frac{4\pi}{3}\left\{\frac{y}{(x^2+y^2+z^2)^{\frac{3}{2}}}\phi(\mathrm{b}) + \frac{3y(x^2+y^2) - 12yz^2}{5(x^2+y^2+z^2)^{\frac{7}{2}}}\psi(\mathrm{b}) - y\frac{m\phi(\mathrm{b})}{\mathrm{b}^3}\right\}.$$

$$Z = -\frac{4\pi}{3}\left\{\frac{z}{(x^2+y^2+z^2)^{\frac{3}{2}}}\phi(\mathrm{b}) + \frac{9z(x^2+y^2) - 6z^3}{5(x^2+y^2+z^2)^{\frac{7}{2}}}\psi(\mathrm{b})\right\}.$$

Expression for Gravity at the Earth's surface.

The whole force or $\sqrt{X^2+Y^2+Z^2}$, putting r^2 for x^2+y^2, and neglecting terms of the second order, is

$$\frac{4\pi}{3}\left\{\frac{\phi(\mathrm{b})}{r^2+z^2} + \frac{3}{5}\cdot\frac{r^2-2z^2}{(r^2+z^2)^3}\psi(\mathrm{b}) - \frac{r^2}{(r^2+z^2)^{\frac{1}{2}}}\cdot\frac{m\phi(\mathrm{b})}{\mathrm{b}^3}\right\}.$$

Now the equation to the external surface is $\frac{r^2}{\mathrm{b}^2(1+\mathrm{e})^2} + \frac{z^2}{\mathrm{b}^2} = 1$, whence $r^2 + z^2 = \mathrm{b}^2 + 2\,\mathrm{e}\,r^2$; or if λ be the latitude, we may assume (nearly enough to the truth for substitution in the small terms) $r^2 = \mathrm{b}^2 . \cos^2\lambda$; whence $r^2 + z^2 = \mathrm{b}^2(1 + 2\,\mathrm{e} . \cos^2\lambda) = \mathrm{b}^2(1 + 2\,\mathrm{e} - 2\,\mathrm{e}\sin^2\lambda)$. Hence $r^2 - 2z^2 = \mathrm{b}^2(1 - 3\sin^2\lambda)$, omitting e, as this expression is used only to multiply a small term; and $\frac{r^2-2z^2}{(r^2+z^2)^3} = \frac{1-3\sin^2\lambda}{\mathrm{b}^4}$. Also $\frac{r^2}{(r^2+z^2)^{\frac{1}{2}}} = \mathrm{b}(1-\sin^2\lambda)$. Substituting, we get for the whole force

$$\frac{4\pi}{3}\left\{\frac{\phi(\mathrm{b})}{\mathrm{b}^2}(1 - 2\,\mathrm{e} + 2\,\mathrm{e}\sin^2\lambda) + \frac{3}{5}\cdot\frac{\psi(\mathrm{b})}{\mathrm{b}^4}(1 - 3\sin^2\lambda) - \frac{m\phi(\mathrm{b})}{\mathrm{b}^2}(1 - \sin^2\lambda)\right\}$$

$$= \frac{4\pi}{3}\cdot\frac{\phi(\mathrm{b})}{\mathrm{b}^2}\cdot\left(1 - 2\,\mathrm{e} - m + \frac{3}{5}\cdot\frac{\psi(\mathrm{b})}{\mathrm{b}^2\phi(\mathrm{b})}\right)\cdot\left\{1 + \overline{2\,\mathrm{e} - \frac{9}{5}\,\frac{\psi(\mathrm{b})}{\mathrm{b}^2 . \phi(\mathrm{b})} + m} . \sin^2\lambda\right\}.$$

Let

$$\frac{4\pi}{3}\cdot\frac{\phi(\mathrm{b})}{\mathrm{b}^2}\cdot\left(1 - 2\,\mathrm{e} - m + \frac{3}{5}\cdot\frac{\psi(\mathrm{b})}{\mathrm{b}^2\phi(\mathrm{b})}\right) = \mathrm{E};$$

Gravity expressed in terms of the latitude.

then the expression for Gravity is

$$\mathrm{E}\left\{1 + \left(2\,\mathrm{e} - \frac{9}{5}\cdot\frac{\psi(\mathrm{b})}{\mathrm{b}^2 . \phi(\mathrm{b})} + m\right)\sin^2\lambda\right\};$$

from which it appears that, in going from the Equator to the Poles, Gravity increases as the square of the sine of latitude.

(65.) The coefficient of the square of the sine of latitude is $2\,\mathrm{e} - \frac{9}{5}\cdot\frac{\psi(\mathrm{b})}{\mathrm{b}^2 . \phi(\mathrm{b})} + m$. Now from (63.) we get $\frac{9}{5}\cdot\frac{\psi(\mathrm{b})}{\mathrm{b}^2 . \phi(\mathrm{b})} = 3\,\mathrm{e} - \frac{3m}{2}$. Substituting, the coefficient of $\sin^2\lambda$ is $\frac{5m}{2} - \mathrm{e}$; and Gravity is now expressed by $\mathrm{E}\left(1 + \overline{\frac{5m}{2} - \mathrm{e}} . \sin^2\lambda\right)$, a remarkably simple expression, all functions, and, in fact, every thing depending on the internal constitution of the spheroid having disappeared. It appears from this, that if by observations of the force of Gravity at different latitudes we can express it by a formula of this kind $\mathrm{E}(1 + \mathrm{F}\sin^2\lambda)$, then e, the ellipticity of the Earth's surface, will $= \frac{5m}{2} - \mathrm{F}$. This is the celebrated theorem known by the name of *Clairaut's Theorem*.

Clairaut's theorem.

(66.) Another remarkable application of the equation of (63.) occurs in the expression for the attraction of a point exterior to the spheroid. The forces in the directions of r and z will be found by putting b for b in the expressions of (55.); resolving these into forces in the directions of x, y, and z, and calling them X′, Y′, Z′, we have

Attraction of heterogeneous spheroid on a point without it.

$$X' = -\frac{4\pi}{3}\cdot\left\{\frac{x}{(x^2+y^2+z^2)^{\frac{3}{2}}}\phi(\mathrm{b}) + x\,\frac{3(x^2+y^2) - 12z^2}{5(x^2+y^2+z^2)^{\frac{7}{2}}}\psi(\mathrm{b})\right\}.$$

$$Y' = -\frac{4\pi}{3}\cdot\left\{\frac{y}{(x^2+y^2+z^2)^{\frac{3}{2}}}\phi(\mathrm{b}) + y\,\frac{3(x^2+y^2) - 12z^2}{5(x^2+y^2+z^2)^{\frac{7}{2}}}\psi(\mathrm{b})\right\}.$$

$$Z' = -\frac{4\pi}{3}\cdot\left\{\frac{z}{(x^2+y^2+z^2)^{\frac{3}{2}}}\phi(\mathrm{b}) + z\,\frac{9(x^2+y^2) - 6z^2}{5(x^2+y^2+z^2)^{\frac{7}{2}}}\psi(\mathrm{b})\right\}.$$

Physical Theory. Earth supposed heterogeneous.

Substituting for $\frac{3 . \psi (b)}{5}$ the value $\left(e - \frac{m}{2}\right) . b^2 . \phi (b)$ found in (63.), and making $\frac{4 \pi}{3} . \phi (b) = M$, we have

$$X' = - M \left\{ \frac{x}{(x^2 + y^2 + z^2)^{\frac{3}{2}}} + x \frac{b^2 (x^2 + y^2 - 4 z^2)}{(x^2 + y^2 + z^2)^{\frac{7}{2}}} \left(e - \frac{m}{2}\right) \right\}.$$

$$Y' = - M \left\{ \frac{y}{(x^2 + y^2 + z^2)^{\frac{3}{2}}} + y \frac{b^2 (x^2 + y^2 - 4 z^2)}{(x^2 + y^2 + z^2)^{\frac{7}{2}}} \left(e - \frac{m}{2}\right) \right\}.$$

$$Z' = - M \left\{ \frac{z}{(x^2 + y^2 + z^2)^{\frac{3}{2}}} + z \frac{b^2 (3 x^2 + 3 y^2 - 2 z^2)}{(x^2 + y^2 + z^2)^{\frac{7}{2}}} \left(e - \frac{m}{2}\right) \right\}.$$

It appears, then, that the attraction of a spheroid upon a body without it is not in the direction of a line joining the body with the centre of the spheroid; (for if it were, X′, Y′, Z′ would be proportional to x, y, z respectively;) and, in consequence, the motion of the satellite of a spheroidal body will not be the same as if the body were spherical. The irregularity occasioned by this difference is sensible in the motion of our own Moon, and in those of Jupiter's satellites; and as it depends on $e - \frac{m}{2}$, it gives us the means of ascertaining the value of e without any knowledge of the internal constitution of the Earth.

Resulting inequality in the Moon's motion.

(67.) We cannot here go through the whole process of calculating the inequality of the Moon produced by the Earth's ellipticity, but we can indicate the principal steps. Let the axis of x be supposed to be directed to the first point of Aries, that of y to the point in the Equator whose right ascension is 90°, and that of z to the pole of the Equator. Now take a new system of coordinates, that of x being the same as before, that of y' in the plane of the Ecliptic directed to the first point of Cancer, and that of z' directed to the pole of the Ecliptic. Resolve the three forces X′, Y′, Z′ in these three directions. From the Moon let fall a perpendicular on the plane of the Ecliptic, and join the Earth's centre with the foot of the perpendicular, and resolve the forces just found into one in the direction of the joining line, one in the direction of the perpendicular, and one at right angles to both these. Let θ be the Moon's longitude, ω the obliquity of the Ecliptic. Then it will be found that the last-mentioned forces are $X' \cos \theta + (Y' \cos \omega + Z' \sin \omega) \sin \theta$, $Z' \cos \omega - X' \sin \omega$, and $X' \sin \theta - (Y' \cos \omega + Z' \sin \omega) \cos \theta$. Adopting the notation in the Treatise on PHYSICAL ASTRONOMY, Part III., and substituting for x, y, z the values $\frac{1}{u} \cos \theta$, $\frac{1}{u} (\sin \theta . \cos \omega - s \sin \omega)$, $\frac{1}{u} (\sin \theta . \sin \omega + s \cos \omega)$, we find the terms depending on the Earth's ellipticity which are to be added to $m' V$, $m' T$, and $m' \frac{d \Omega}{d z}$. (See PHYSICAL ASTRONOMY.) They are rather complicated, but the only terms which produce any sensible effect are in $m' T$, $- M \left(e - \frac{m}{2}\right) . 2 b^2 u^4 . \sin \omega . \cos \omega . \cos \theta . s$; and in $m' \frac{d \Omega}{d z}$, $M \left(e - \frac{m}{2}\right) \times 2 b^2 u^4 \sin \omega . \cos \omega . \sin \theta$. If we treat these terms like the others in the Treatise alluded to, it will easily be found that the resulting inequality in the Moon's latitude, expressed in seconds, (considering the sum of the masses of the Earth and Moon = 1) is $- \frac{4 . \overline{60}|^3}{\pi} . \overline{e - \frac{m}{2}} . \left(\frac{\text{Earth's period}}{\text{Moon's period}}\right)^2 \left(\frac{\text{Earth's radius}}{\text{Moon's distance}}\right)^2 . \sin \omega . \cos \omega . \sin \theta = - \overline{e - \frac{m}{2}} . 4891'' . \sin \theta$ nearly. The perturbation in longitude is not so easily calculated.

Law of density which makes the equation for the ellipticity of the different strata integrable.

(68.) We shall conclude this investigation with remarking that the differential equation of (61.) may be put in a simpler form by assuming $\int \rho b^2 d b = p$, and $p e = v$; substituting these values,

$$\frac{d^2 v}{d b^2} - \frac{6 v}{b^2} - v \frac{b}{p} . \frac{d p}{d b} = 0.$$

A form of ρ which makes this easily integrable, (first pointed out, we believe, by Legendre,) and which probably represents pretty well the law of density in the interior of the Earth, (giving a density gradually increasing to the centre,) is $\rho = A \frac{\sin q b}{b}$, A and q being constant. The general value of v is found to be $C (\sin \overline{q b + C'} + \frac{3}{q b} \cos \overline{q b + C'} - \frac{3}{q^2 b^2} \sin \overline{q b + C'})$, and determining the constants by substitution in the equations from which this differential equation is derived, it is found that e, or $\frac{v}{p}$, =

$$\frac{5 m}{2} . \frac{\left(1 - \frac{q b}{\tan q b}\right)^2}{2 - q^2 b^2 - \frac{q b}{\tan q b} - \frac{q^2 b^2}{\tan^2 q b}} . \frac{1 - \frac{3}{q^2 b^2} + \frac{3}{q b . \tan q b}}{1 - \frac{q b}{\tan q b}}.$$

Figure of the Earth.

To get the ellipticity of the surface we must put b for b, and if $f = 1 - \frac{q\,\mathrm{b}}{\tan q\,\mathrm{b}}$, it is found that $e = \frac{5m}{2} \cdot \frac{1 - \frac{3f}{q^2 \mathrm{b}^2}}{3 - f - \frac{q^2 \mathrm{b}}{f}}$. The value $q = \frac{5}{6} \cdot \frac{\pi}{\mathrm{b}}$ gives a law of density that probably represents nearly the Earth's density.

The probable error, arising from neglect of the higher powers of the ellipticity, may be inferred from those in the extreme cases.

(69.) We shall now consider the probable magnitude of the error which we have incurred by neglecting the square of the ellipticity. We have investigated, accurately, two cases which may be considered as extremes in the series of laws of density, within which the law of the Earth's density is included. One of these is, the case of a homogeneous Fluid; the other is that of (12.), in which the assumption of attraction directed only to the centre, amounts to the same as (on the principle of gravitation) the assumption that the matter near the centre is infinitely more dense than that near the surface. We shall examine, then, how far, in these two cases, the two principal results of our investigation (the ellipticity of form, and Clairaut's theorem) are true; and if we find them nearly true in these cases, we shall conclude that they are nearly true in the case of a density gradually increasing to the centre.

If the Fluid be homogeneous, the form is accurately elliptic

(70.) First as to the ellipticity of figure. When the Fluid is homogeneous, it appears by the investigation extending from (14.) to 26.), that the figure is *accurately* that of an elliptic spheroid. When the attraction of the particles is neglected in comparison with the attraction to the centre, it appears from (12.) that the equation to the external surface, using r for the distance of any point from the centre, is

$$\frac{1}{r} = \frac{2+3m}{2+2m} \cdot \frac{1}{a} - \frac{m}{2+2m} \cdot \frac{x^2+y^2}{a^3}, \text{ or } \frac{1}{r} = \frac{1}{b} - \left(\frac{a}{b} - 1\right) \cdot \frac{x^2+y^2}{a^3} = \frac{1}{b} - \frac{e}{b^3(1+e)^3}(x^2+y^2).$$

Let r' be the corresponding line in an elliptic spheroid with the same axes for the same values of x and y; then proceeding from the equation $\frac{x^2+y^2}{a^2} + \frac{z^2}{b^2} = 1$, it will be found that

$$r' = b\sqrt{\left\{1 + \frac{a^2-b^2}{a^2 b^2} \cdot (x^2+y^2)\right\}} = b\sqrt{\left\{1 + \frac{2e+e^2}{1+2e+e^2} \cdot \frac{x^2+y^2}{b^2}\right\}}.$$

Expanding the expressions for r and r' as far as terms of the order e^2, it is found that $r' - r = \frac{3}{2b^3}e^2 \cdot (x^2+y^2) \cdot (b^2 - \overline{x^2+y^2})$. This is greatest when $x^2+y^2 = \frac{b^2}{2}$, or at latitude 45° nearly; its value is then $\frac{3e^2}{8}b$. If $b = 4000$ miles, and $e = \frac{1}{580}$, (the ellipticity of the Earth that would correspond to this supposition,) this would be 24 feet, a quantity quite insensible. We may conclude, then, that the theoretical figure of a heterogeneous Fluid, on the principle of Gravitation, would (since r is less than r') be somewhat flatter at latitude 45° than the elliptic spheroid, but that if the circumstances were those of the Earth, the difference would be insensible in measures of degrees.

If the Fluid be infinitely dense at the centre, the form does not sensibly differ from an elliptic spheroid.

(71.) Secondly, as to the law of Gravity at the surface. In the homogeneous ellipsoid it has been found (35.) that, putting λ for the latitude of any point, the Gravity there is proportional to $\frac{1}{\sqrt{\sin^2\lambda + \overline{1+e}|^2 \cos^2\lambda}}$. Expanding this so as to include the second power of e, it may be put under the form $(1 - e + e^2)\ \{1 + e\sin^2\lambda\ \frac{3e^2}{2}\sin^2\lambda\cos^2\lambda\}$, or Gravity is proportional to $\{1 + e\sin^2\lambda - \frac{3e^2}{2}\sin^2\lambda \cdot \cos^2\lambda\}$. Now as Clairaut's theorem is commonly understood, Gravity is proportional to $\{1 + \overline{\frac{5m}{2} - e} \cdot \sin^2\lambda\}$. We must then investigate accurately the relation between e and m. In the equation of (29.) make $f = \frac{1}{\cot f} - \frac{1}{3} \cdot \frac{1}{\cot^3 f} + \frac{1}{5} \cdot \frac{1}{\cot^5 f} - \frac{1}{7} \cdot \frac{1}{\cot^7 f}$, and we find at length $\frac{m}{1+m} = \frac{4}{5}e\left(1 - \frac{57}{70}e\right)$, whence $\frac{5m}{2} = 2e - \frac{1}{35}e^2$, and $\frac{5m}{2} - e = e - \frac{1}{35}e^2$. Consequently, according to Clairaut's law, Gravity should be expressed by $1 + \left(e - \frac{e^2}{35}\right)\sin^2\lambda$; it actually is expressed by $1 + e\sin^2\lambda - \frac{3e^2}{2}\sin^2\lambda\cos^2\lambda$. We ought then to increase Gravity in the homogeneous spheroid by equatorial Gravity × $e^2\sin^2\lambda\left(\frac{3}{2}\cos^2\lambda - \frac{1}{35}\right)$ in order to make it follow Clairaut's law. For circumstances similar to those of the Earth, e must be taken $= \frac{1}{230}$, and the quantity to be added is about

If the Fluid be homogeneous, Clairaut's law is nearly true.

Physical Theory. Earth supposed heterogeneous.

$\frac{\text{equatorial Gravity}}{35300} \times \sin^2\lambda\left(\cos^2\lambda - \frac{2}{105}\right)$. This is nearly a maximum when $\lambda = 45°$, and it then is nearly $= \frac{\text{equatorial Gravity}}{140000}$, a quantity barely sensible in the most accurate pendulum experiments.

When the attractive force is wholly directed to the centre, it appears (see 12.) that the resolved parts of Gravity are

$$f\left\{\frac{x}{r^3} - (2e - 6e^2)\frac{x}{b^3}\right\}, \quad f\left\{\frac{y}{r^3} - (2e - 6e^2)\frac{y}{b^3}\right\}, \quad f\frac{z}{r^3}$$

Adding the squares of these, observing that $\frac{1}{r} = \frac{1}{b}\left\{1 - e\,.\,\frac{x^2 + y^2}{b^2} + 3e^2\frac{x^2 + y^2}{b^2}\right\}$, and extracting the square root, it is found that Gravity is proportional to

$$1 - 4e\frac{x^2 + y^2}{b^2} + 14e^2\,.\,\frac{x^2 + y^2}{b^2} + e^2\left(\frac{x^2 + y^2}{b^2}\right).$$

Now from the consideration that $\sin\lambda = \frac{\text{force in direction of } z}{\text{Gravity}}$, we find $\frac{x^2 + y^2}{b^2} = (1 + 4e)\cos^2\lambda - 2e\cos^4\lambda$; and thus we obtain at length that Gravity is proportional to

$$1 + \overline{4e + 9e^2}\sin^2\lambda - 9e^2\sin^2\lambda\cos^2\lambda.$$

But from (12.) $\frac{a}{b} = \frac{2 + 3m}{2 + 2m}$, whence $e = \frac{m}{2 + 2m}$, and $m = 2e + 4e^2$, $\frac{5m}{2} = 5e + 10e^2$, $\frac{5m}{2} - e = 4e + 10e^2$, and therefore Gravity, according to Clairaut's formula, ought to be expressed by

$$1 + \overline{4e + 10e^2}\,.\,\sin^2\lambda.$$

If the density be infinitely great at the centre, Clairaut's law is nearly true.

We ought, therefore, to increase the actual Gravity by equatorial Gravity $\times\, e^2\sin^2\lambda\,(9\cos^2\lambda + 1)$, in order to bring it under Clairaut's law. The maximum value of this is nearly $\frac{9e^2}{4} \times$ equatorial Gravity; which, if $e = \frac{1}{580}$, is about $\frac{\text{equatorial Gravity}}{150000}$; a quantity as small as that found before.

Conclusions with regard to heterogeneous spheroid.

(72.) We may conclude, then, that the following theoretical results may be considered as sufficiently accurate for a heterogeneous fluid mass in the circumstances of the Earth.

The external surface has the form of an elliptic spheroid.

At the latitude λ Gravity is proportional to $1 + \left(\frac{5m}{2} - e\right)\sin^2\lambda$, (where m is the proportion of centrifugal force at the Equator to Gravity at the Equator, and $1 : 1 + e$ is the proportion of the axes.)

Disturbance produced by a small mass near the Earth's surface.

(73.) If a mass of different density were placed any where in the Fluid it is plain that it would disturb all the laws that we have found. For a calculation of its effects we shall refer to a paper by Dr. Young, in the *Phil. Trans.* for 1819, from which we extract the following results.

Prop. A. If a plumb-line be drawn aside by a small mass not far below the Earth's surface, the distance of the points where the greatest deviations are produced, is to the depth of the mass, as $\sqrt{2}$ to 1.

B. The sine of the greatest deviation $= ,385 \times \frac{a}{c^2}$ $\left(\text{where } a = \frac{\text{disturbing mass}}{\text{Earth's mass}}, \text{ and } c = \frac{\text{depth}}{\text{Earth's radius}}\right)$.

C. The greatest elevation of the general surface above the sphere $= \frac{a}{c}$.

D. Gravity at the highest point will be increased by $\frac{a}{c^2} - \frac{2a}{c}$.

E. At the place where the greatest deviation of the plumb-line is produced, the proportional increase of Gravity is to the deviation (estimated as an arc to radius 1) as $\sqrt{2}$ to 1.

We have conducted the theoretical investigation of the Earth's form by an analysis which, though far from elegant, is sufficiently powerful to master this subject, and sufficiently simple to be understood after a common acquaintance with the Differential Calculus. The analysis of Laplace we have thought it desirable to exclude, where it is possible to succeed without its assistance. The difficulty of understanding the fundamental points of that calculus, and the obscurity which, to those who have given most attention to it, has always appeared to hang upon many of its applications, (see *Phil. Trans.* 1812, &c. and *Cambridge Transactions*, vol. iii.) will serve for our apology. We have thus lost some of Laplace's results, (especially those relating to the form of a Fluid spread over an irregular solid;) but we have thought it better to give them up at once, than to compose a treatise which, to the greater part of our readers, would be (and that without necessity) unintelligible. The reader who wishes to be acquainted with a calculus the most singular in its nature, and the most powerful in its applications that has ever appeared, is referred for explanation and example to our Essay **Electricity**, or to the Vth Book of the *Mécanique Céleste.*

Section 3.—On the Manner of determining the Figure of the Earth by Geodetic Measures.

The investigations which we have just given seem to show that if the Earth had been originally fluid, and if the different liquids of which it consisted had been allowed to settle into a state of rest, and if it had then become solidified, and had afterwards been subjected to no alteration of shape, its external form would be nearly that of an oblate spheroid. The ellipticity of the spheroid, however, is not determined; it has only appeared that if the Earth were supposed to have been a homogeneous Fluid, (a thing in the highest degree improbable,) and the attraction of each molecule proportional to its mass, the proportion of the equatorial axis to the polar axis would be 231 : 230; if the whole attraction were directed to one attractive point at the Earth's centre, or if, on the same theory of universal attraction, the density at the centre were infinitely greater than that at any other point, the proportion would be 581 : 580; and if (as seems *à priori* most probable) the density increased gradually to the centre, and if every particle attracted with a force proportional to its mass, the proportion of the axes would be between these two.

Now it is plain that none of these suppositions correspond exactly to the state of the Earth's surface. The irregularities in its external form are considerable. The height of the mountains in some parts is perhaps equal to $\frac{1}{7}$ of the difference between the polar and equatorial semiaxes. The depth of the sea in many places is possibly much greater. Still the examination of the Earth's surface will serve to verify the correctness of the general principle of Gravitation. We may expect that there will be a considerable approximation to the spheroidal form, subject to irregularities of which, in some cases, the causes cannot be discovered, and in other cases a probable explanation can be given by reference to the form of the neighbouring mountains or the surrounding country. If (as some Philosophers have supposed) the interior of the Earth be yet fluid within a small distance of the surface, it is impossible that the general form of the Earth can differ very much from that of a fluid mass.

The theory will apply, approximately, to the Earth's form.

The extent of the watery covering of the Earth is a circumstance highly favourable to the agreement of the calculated and observed forms of the Earth. We may consider the sea as a Fluid, acted on by the attraction of the solid part of the Earth, (whose form does not much differ from that of equilibrium,) and by the centrifugal force, and the reciprocal attraction of its own particles. The irregularities in the Earth's attraction will be very much smaller than those of the Earth's form; and, consequently, the irregularity which they produce in the form of the sea will be very much smaller than the irregularities in the form of the land. If, then, we refer our measures, which must necessarily be made on land, to the surface of the sea, we may expect an agreement of the theoretical form and the ascertained measures to very considerable exactness.

It is natural, therefore, that in making the comparison we should begin by discussing the properties of the spheroid. By combining with them a consideration of the practical exactness which it is possible to attain in the different measures, we shall be able to choose the kind of measure which is best adapted to our purpose. And by calculating from different combinations of measures the length of the Earth's axes and the value of its ellipticity, we can infer, from the agreement or discordance of the results, the correctness or incorrectness of our original assumptions.

Differences of latitude found astronomically.

We have explained in the first section the general principle upon which the Earth's form is ascertained by measures. If the distance between two points can be found, and if the angle can be found which is included between the verticals drawn at these points, the distance of the intersection of those verticals can be found; and this is the same as the radius of curvature of the curve joining those points. The lengths of the extensive arcs which have been used for this purpose, have always (with one exception) been ascertained by geodetic operations, for a general idea of which we refer the reader to the Essay on **Trigonometry**, § IX., and which we shall explain with greater minuteness in the following section. For the mere measure, the general direction of the chain of triangles, or the direction of the line joining the extreme points, is a matter of perfect indifference. But there are practical considerations which require us to fix on one of two directions. The latitudes of the places P and Q, fig. 18, whether on the same meridian or not, are the complements of the angles $p\,P\,s$, $q\,Q\,s$, respectively, which are included by the verticals at the places and the lines drawn to the celestial Pole. And if S be any star which can be observed at both places the angle $s\,P\,p = s\,P\,S + S\,P\,p$, and $s\,Q\,q = s\,Q\,S + S\,Q\,q$; considering, therefore, the angles $s\,Q\,s$, $s\,P\,s$, as equal, the difference of latitudes is the same as the difference of $S\,P\,p$, $S\,Q\,q$. That is, it is the same as the difference of the zenith distances of the same star at the two places, and can, therefore, easily be found. Now if the places P and Q be on the same meridian, their verticals will intersect in some point D, and the difference of latitudes, which is the difference of $s\,Q\,q$ and $s\,P\,p$, or ($P\,r$ being parallel to $Q\,q$) the difference of $s\,P\,r$ and $s\,P\,p$, is equal to $r\,P\,p$, or Q D P, the angle contained by the verticals. The length P Q being known from measures, and the angle P D Q, or the difference of latitude, being found by observations of the zenith distances of a star, the length of P D or Q D, or the radius of curvature, is found.

Again, if T and V, fig. 19, be two places on different meridians, and if planes be drawn through these places, and through the axis A C of the Earth, the angle made by these planes (or the difference of longitude) may be determined astronomically. For in consequence of the inclination of the planes, the place T will be brought by the Earth's motion under the celestial meridian passing through some known star sooner than the place V;

re of Earth.

Determination by Geodetic Measures.

Difference of longitude found astronomically.

and as the Earth's rotatory motion is uniform, the difference of time will serve to measure the angle.* If, then, we compare by any means the clocks at the two places, and observe the times indicated by these clocks at the passage of the same star over the meridians, the angle between the planes can be ascertained. Now if instead of T we have a place *t*, whose latitude is the same as that of V, and if we draw V W, *t* W, perpendicular to the axis, the angle between the planes will be the same as the angle V W *t*. The distance V *t* being measured, and the angle V W *t*, or the difference of longitude being found, the length of V W, or *t* W, or the radius of a parallel, is found.

Either of these measures then will give the length of a line that will assist materially in determining the Earth's form and dimensions. But they cannot easily be combined. Both have been extensively used; but the difference of latitude can be ascertained with so much greater accuracy than the difference of longitude, that measures of the former kind have generally been relied on.

Now in practice it is found extremely difficult to determine with accuracy the direction of any one line with respect to the meridian, or the azimuth of any station with respect to any other station. We must, therefore, always consider that we are liable to a small uncertainty in the direction of a side of one of the triangles, and, consequently, in the general direction of the chain of triangles, which depends entirely on this line. And we must choose the direction so that a small error may produce the smallest possible effect in the line to be measured.

The general direction of the chain of triangles ought to be either in the meridian or perpendicular to it.

Now, in fig. 20, let P Q be the meridian, P the first extremity of the chain of triangles, X the last; let X, *x*, Y, *y*, be in the circumference of a circle whose radius is P. Draw X Q, *x q*, Y R, *y r*, arcs of parallels. From the uncertainty in the direction of the triangles, it is uncertain perhaps whether X or *x* is the true situation of the last station. It is uncertain, therefore, whether the point in the meridian P Q, whose latitude is the same as that of the last station, is Q or *q*. But it is plain that this uncertainty is much less than it would be if Y or *y* were the situation of the last station; and that by bringing the position as near as possible to the meridian P Q, the uncertainty Q *q* may be made as small as we please. The same, it will readily be seen, is true with respect to an arc measured nearly in the direction of a parallel.

It appears, therefore, that we must determine on measuring an arc either in the direction of a meridian, or in that of a parallel; and that when we have chosen between these, we must make the general direction of the chain of triangles coincide as nearly as possible with that of the line that we have chosen.

We shall now, from the properties of the spheroid, express the length of the lines above described in terms of the axes and ellipticity of the spheroid.

Radius of parallel in a spheroid, expressed in terms of the latitude.

Let fig. 21 be the generating ellipse of the spheroid, in the position in which its plane passes through the place P; P M the normal; P N, P W, perpendiculars to the axes. Let B C = *a*, A C = *b*. Then (CONIC SECTIONS, Art. 34.) $\mathrm{N\,M} = \frac{b^2}{a^2}\,\mathrm{C\,N}$. Also P *s* being parallel to the axis, or in N P produced, and M P being produced to *p*, the angle *p* P *s* or N P M is the colatitude, and P M N the latitude of P; call this L. Then $\mathrm{N\,P} = \mathrm{M\,N}\tan\mathrm{L} = \frac{b^2}{a^2}\,\mathrm{C\,N}\,.\tan\mathrm{L}$. Now (CONIC SECTIONS, Art. 26.) $\mathrm{P\,N}^2 = \frac{b^2}{a^2}(a^2 - \mathrm{C\,N}^2)$ or $\frac{b^4}{a^4}\,\mathrm{C\,N}^2\,.\tan^2\mathrm{L} = \frac{b^2}{a^2}(a^2 - \mathrm{C\,N}^2)$, or $b^4\,.\,\mathrm{C\,N}^2\,.\tan^2\mathrm{L} = a^4 b^2 - a^2 b^2\,.\,\mathrm{C\,N}^2$, whence

$$\mathrm{C\,N}^2 = \frac{a^4}{b^2\tan^2\mathrm{L} + a^2} = \frac{a^4\cos^2\mathrm{L}}{b^2\sin^2\mathrm{L} + a^2\cos^2\mathrm{L}} = \frac{a^4\cos^2\mathrm{L}}{b^2 + (a^2 - b^2)\cos^2\mathrm{L}},\ \text{and}\ \mathrm{C\,N} = \frac{a^2\cos\mathrm{L}}{\sqrt{\{b^2 + (a^2 - b^2)\cos^2\mathrm{L}\}}}.$$

Let $a = b\,(1 + e)$; $\mathrm{C\,N} = b\,\frac{(1 + 2\,e + e^2)\cos\mathrm{L}}{\sqrt{1 + (2\,e + e^2)\cos^2\mathrm{L}}}$. If we suppose *e* so small that its square may be neglected, $\mathrm{C\,N} = \frac{b\,(1 + 2\,e)\cos\mathrm{L}}{\sqrt{1 + 2\,e\cos^2\mathrm{L}}} = b\cos\mathrm{L}\,(1 + 2\,e - e\cos^2\mathrm{L})$; or $b\cos\mathrm{L}\,(1 + e + e\sin^2\mathrm{L})$. This is the value of P W, the radius of the parallel passing through P.

Degree of parallel in terms of the latitude.

If then D be the difference of longitude expressed in seconds, of two places on the same parallel, and L their latitude, the length of the arc between them is $b\,.\cos\mathrm{L}\,(1 + e + e\sin^2\mathrm{L})\,\mathrm{D}\sin 1''$; $\mathrm{D}\sin 1''$ being the length of the arc, which with radius 1 subtends the angle D″. The length of the arc corresponding to a difference of longitude of 1° is $b\cos\mathrm{L}\,(1 + e + e\sin^2\mathrm{L})\,.\,3600\,.\sin 1''$; this is called *a degree of parallel.*

Radius of curvature of meridian in a spheroid, expressed in terms of the latitude.

The radius of curvature of the meridian is found by the expression $-\frac{\left\{1 + \left(\frac{d\,y}{d\,x}\right)^2\right\}^{\frac{3}{2}}}{\frac{d^2 y}{d\,x^2}}$, where $x = \mathrm{C\,N}$, $y = \mathrm{N\,P}$. But $y^2 = \frac{b^2}{a^2}(a^2 - x^2)$, or $b^2 x^2 + a^2 y^2 = a^2 b^2$; whence $\frac{d\,y}{d\,x} = -\frac{b^2 x}{a^2 y}$, and $\frac{d^2 y}{d\,x^2} = -\frac{b^4}{a^2 y^3}$; and the radius of curvature $= \frac{1}{b^4 a^4} \times (a^4 y^2 + b^4 x^2)^{\frac{3}{2}}$. But we have just found $x^2 = \mathrm{C\,N}^2$ or $\mathrm{P\,W}^2 = \frac{a^4\cos^2\mathrm{L}}{b^2\sin^2\mathrm{L} + a^2\cos^2\mathrm{L}}$; and

---

* This angle may also be ascertained in other ways, of which we shall speak hereafter.

$y^2 = \mathrm{P\,N}^2 = \mathrm{N\,M}^2 \tan^2 \mathrm{L} = \frac{b^4}{a^4}\,\mathrm{C\,N}^2 . \tan^2 \mathrm{L} = \frac{b^4 \sin^2 \mathrm{L}}{b^2 \sin^2 \mathrm{L} + a^2 \cos^2 \mathrm{L}}$; whence the radius of curvature

$$= \frac{1}{b^4 a^4} \times \left(\frac{a^4 b^4}{b^2 \sin^2 \mathrm{L} + a^2 \cos^2 \mathrm{L}}\right)^{\frac{3}{2}} = \frac{a^2 b^2}{(b^2 \sin^2 \mathrm{L} + a^2 \cos^2 \mathrm{L})^{\frac{3}{2}}}.$$

If $a = b\,(1 + e)$, the radius of curvature $= \frac{b\,(1 + 2e + e^2)}{(1 + \overline{2e + e^2} . \cos^2 \mathrm{L})^{\frac{3}{2}}}$; or if e is so small that e^2 may be neglected, the expression becomes $b\,(1 + 2e - 3e\cos^2 \mathrm{L})$, or $b\,(1 - e + 3e\sin^2 \mathrm{L}.)$

If then λ and λ' are the latitudes of two stations on the same meridian, and if the difference between λ and λ' be not great, the included arc may be considered as a circular arc whose radius is the radius of curvature, corresponding to the middle point between them, or $b\left(1 - e + 3e\sin^2 \frac{\lambda + \lambda'}{2}\right)$. And if $\lambda' - \lambda$ be expressed in seconds, the length of the arc, subtending the angle $\lambda' - \lambda$, in a circle whose radius is 1, will be $(\lambda' - \lambda)\sin 1''$, and, therefore, the arc of meridian or the circular arc equal to it, will be $b\left(1 - e + 3e\sin^2 \frac{\lambda + \lambda'}{2}\right) . (\lambda' - \lambda) \sin 1''$.

Degree of meridian in terms of the latitude.

The length of the arc corresponding to a difference of latitudes of 1° is $b\left(1 - e + 3e\sin \frac{\lambda + \lambda'}{2}\right) . 3600 \sin 1''$; this is called *a degree of latitude.*

If, however, the arc be considerable with respect to the radius, the following process must be used. If two normals be drawn at points whose latitudes are L and L + d L, they will intersect at the distance $b\,(1 - e + 3e\sin^2 \mathrm{L})$. Let s be the arc of meridian, ds that part included betwen the latitudes L and d L, then $ds = d\mathrm{L} \times b\,(1 - e + 3e\sin^2 \mathrm{L}) = b\,d\mathrm{L} \times \left(1 + \frac{e}{2} - \frac{3e}{2}\cos 2\mathrm{L}\right)$, and $s = b \times \left(1 + \frac{e}{2}\,\mathrm{L} - \frac{3e}{4}\sin 2\mathrm{L}\right)$. This expression gives the length of the arc from the Equator to the point whose latitude is L; if then we put λ and λ' successively in place of L, and take the difference of the expressions, we shall have for the length of the arc included between the latitudes λ and λ',

$$b\left(\overline{1 + \frac{e}{2}} . \overline{\lambda' - \lambda} - \frac{3e}{4} . \overline{\sin 2\lambda' - \sin 2\lambda}\right) = b\left(\overline{1 + \frac{e}{2}} . \overline{\lambda' - \lambda} - \frac{3e}{2}\cos \overline{\lambda' + \lambda}\sin \overline{\lambda' - \lambda}\right)$$

$$= b\left(\overline{1 + \frac{e}{2}} - \frac{3e}{2} . \cos \overline{\lambda' + \lambda} . \frac{\sin \overline{\lambda' - \lambda}}{\lambda' - \lambda}\right) . (\lambda' - \lambda).$$

Here (as in all expressions given by integration) it is supposed that $\lambda' - \lambda$ is measured by its proportion to the radius; if expressed in seconds, we ought to put $(\lambda' - \lambda)\sin 1''$, and thus the length

$$= b\left\{\overline{1 + \frac{e}{2}} . - \frac{3e}{2} . \cos \overline{\lambda' + \lambda} . \frac{\sin \overline{\lambda' - \lambda}}{\lambda' - \lambda}\right\} \times (\lambda' - \lambda)\sin 1''.$$

From the former expression it will be seen that in an oblate spheroid a degree of meridian (found by making $l' - l = 3600$) near the Pole, is greater than one near the Equator, and that, generally, on increasing the latitude the degrees increase. The general fact of the oblateness of the Earth will, therefore, be proved by the augmentation of degrees in approaching the Pole; a diminution would show that the Earth's form was prolate.

The length of the axis, and the oblateness, may thus be found from two measures. Suppose λ and λ' the latitudes of the extreme points of one arc, whose length, as determined by measures, $=$ A; suppose μ, μ', and B, the extreme latitudes and measured length of another arc. Then

Ellipticity determined from two measures of meridian arcs.

$$\frac{\mathrm{A}}{(\lambda' - \lambda)\sin 1''} = b\left(1 - e + 3e\sin^2 \frac{\lambda' + \lambda}{2}\right).$$

$$\frac{\mathrm{B}}{(\mu' - \mu)\sin 1''} = \left(1 - e + 3e\sin^2 \frac{\mu' + \mu}{2}\right).$$

$$\therefore \frac{\mathrm{A}}{(\lambda' - \lambda)\sin 1''} - \frac{\mathrm{B}}{(\mu' - \mu)\sin 1''} = 3eb\left(\sin^2 \frac{\lambda' + \lambda}{2} - \sin^2 \frac{\mu' + \mu}{2}\right).$$

The value of b will be found nearly enough by neglecting e in either equation; thus $b = \frac{\mathrm{A}}{(\lambda' - \lambda)\sin 1''}$ or $= \frac{\mathrm{B}}{(\mu' - \mu)\sin 1''}$. Considering this then as known, e

$$= \frac{\frac{\mathrm{A}}{(\lambda' - \lambda)\sin 1''} - \frac{\mathrm{B}}{(\mu' - \mu)\sin 1''}}{3b\left(\sin^2 \frac{\lambda' + \lambda}{2} - \sin^2 \frac{\mu' + \mu}{2}\right)}.$$

Now, if an error should be committed in measuring either A or B, the influence of this error on the value of e would

Determination by Geodetic Measures.

depend entirely on the magnitude of the divisor $3\,b\left(\sin^2\frac{\lambda'+\lambda}{2}-\sin^2\frac{\mu'+\mu}{2}\right)$ It would be greatest when the divisor was least; and *vice versâ*. The most favourable combination, or that which would make $\sin^2\frac{\lambda'+\lambda}{2}-\sin^2\frac{\mu'+\mu}{2}$ greatest, would be one arc of which the middle was under the Equator, and another of which the middle was at the Pole. The latitudes of the middle points, or $\frac{\lambda'+\lambda}{2}$ and $\frac{\mu'+\mu}{2}$, being then, respectively, 90°, and 0, the quantity $\sin^2\frac{\lambda'+\lambda}{2}-\sin^2\frac{\mu'+\mu}{2}=1$. If the middles of the two arcs have nearly the same latitude, the divisor will be so small, and the consequent influence of errors so great, that no dependence can be placed on the value of e so determined. In general, the arcs should be separated by as wide an interval as possible. No advantage, however, is gained by measuring an arc beyond the Equator; as, on any supposition upon which investigations can be made, the degrees of meridian in South latitude ought to be equal to the degrees of meridian in the same North latitude. It is scarcely necessary to mention that if the arcs are long, and measured with accuracy, two equations should be made of the form

$$\frac{A}{(\lambda'-\lambda)\sin 1''}=b\left\{\overline{1+\frac{e}{2}}\,.\,-\frac{3\,e}{2}\,.\cos\overline{\lambda'+\lambda}\,.\,\frac{\sin\overline{\lambda'-\lambda}}{\lambda'-\lambda}\right\},$$

and should be rigorously solved for the determination of b and e.

An arc of meridian, and one of parallel, may also be combined for the same purpose. For from a measured arc of meridian we shall have the equation

$$A=b\left(1-e+3\,e\sin^2\frac{\lambda'+\lambda}{2}\right)(\lambda'-\lambda)\sin 1''.$$

Ellipticity determined from a measure of a meridian arc and a measure of an arc of parallel.

And if D be the difference of longitude (in seconds) between two places on the same parallel, whose latitude = L, and if the measured distance = C, we shall have the equation

$$C=b\cos L\,(1+e+e\sin^2 L)\,D\sin 1''.$$

Whence

$$\frac{A}{(\lambda'-\lambda)\sin 1''}-\frac{C}{D\cos L\sin 1''}=b\,e\left(3\sin^2\frac{\lambda'+\lambda}{2}-\sin^2 L-2\right),$$

and

$$e=\frac{\frac{A}{(\lambda'-\lambda)\sin 1''}-\frac{C}{D\cos L\sin 1''}}{b\left(3\sin^2\frac{\lambda'+\lambda}{2}-\sin^2 L-2\right)}=\frac{\frac{C}{D\cos L\sin 1''}-\frac{A}{(\lambda'-\lambda)\sin 1''}}{b\left(2+\sin^2 L-3\sin^2\frac{\lambda'+\lambda}{2}\right)}.$$

As before, b may be taken $=\frac{A}{(\lambda'-\lambda)\sin 1''}$, or $=\frac{C}{D\cos L\sin 1''}$. The denominator will be greatest when $\sin L$ is nearly $=1$, and $\sin\frac{\overline{\lambda'+\lambda}}{2}=0$, or when the arc of parallel is near the Pole, and that of meridian near the Equator. It will be least when $\sin^2 L$ is nearly equal to $3\sin^2.\frac{\lambda'+\lambda}{2}-2$; such a combination ought therefore to be avoided. If both arcs be measured in nearly the same latitude, the divisor is $2-2\sin^2 L$, or $2\cos^2 L$. For such measures a place near the Equator should be chosen.

In the comparison of two arcs of meridian, it appears that the greatest divisor is $3\,b$; in the comparison of one arc of meridian and one of parallel, the greatest divisor is also $3\,b$. It would, at first sight, appear that these combinations were equally advantageous. But, in fact, the difference of longitudes cannot be ascertained with so great exactness as the difference of latitudes, and larger errors may be expected in the numerator when the arc of parallel is used, than when only arcs of meridian are employed. On this account the principal reliance is placed on the comparison of meridian arcs. We believe that two arcs of parallel have never been compared; but it is plain that if they could be measured with sufficient exactness, two arcs of parallel might be used to determine the axis and ellipticity.

Elements of Earth's form may be corrected from new measures.

Instead, however, of using two measures in the way which we have described, every new measure, when the elements of the Earth's form have been approximately determined, may be employed for the purpose of correcting previous determinations. This method is now extensively used, as it bears great analogy with the process commonly employed in correcting other astronomical elements; we shall therefore describe it here. By methods which we shall discuss in the next section, when two points are connected by a chain of triangles, and the latitude of one is known, the latitude of the other can be calculated with assumed dimensions of the Earth. But this latitude may also be observed; if the observed latitude differs from that calculated, it shows that the assumed dimensions are erroneous. Suppose, now, b and e to be the assumed axis and ellipticity; $b+\delta b$, and $e+\delta e$, the real axis and eccentricity; λ' the calculated latitude of the second point, $\lambda'+\delta\lambda'$ the observed latitude. Then the first calculation being made for a spheroid, we have

$$\text{Measured arc} = b\left(1+\frac{e}{2}-\frac{3e}{2}\,.\cos\overline{\lambda'+\lambda}\,.\,\frac{\sin\overline{\lambda'-\lambda}}{\lambda'-\lambda}\right)\times(\lambda'-\lambda)\sin 1''.$$

And as the same arc corresponds to the observed latitudes on the spheroid really existing we have (omitting $\delta\lambda'$ in $\cos\overline{\lambda'+\lambda}\,.\,\frac{\sin\overline{\lambda'-\lambda}}{\lambda'-\lambda}$, in which it makes no sensible difference)

$$\text{Measured arc} = (b+\delta b)\left\{1+\frac{e+\delta e}{2}\left(1-3\cos\overline{\lambda'+\lambda}\,.\,\frac{\sin\overline{\lambda'-\lambda}}{\lambda'-\lambda}\right)\right\}(\lambda'-\lambda+\delta\lambda')\sin 1''.$$

Taking the difference, and neglecting the products of δb, δe, $\delta\lambda'$,

$$0=\{(\lambda'-\lambda)\delta b+b\,\delta\lambda'\}\,.\left(1+\frac{e}{2}-\frac{3e}{2}\,.\cos\overline{\lambda'+\lambda}\,.\,\frac{\sin\overline{\lambda'-\lambda}}{\lambda'-\lambda}\right)\sin 1''$$
$$+\,b\,(\lambda'-\lambda)\left(\frac{1}{2}-\frac{3}{2}\,.\cos\overline{\lambda'+\lambda}\,.\,\frac{\sin\overline{\lambda'-\lambda}}{\lambda'-\lambda}\right).\,\delta e\,.\sin 1''.$$

Whence

$$0=\frac{d\lambda'}{\lambda'-\lambda}+\frac{db}{b}+\frac{1-3\,.\cos\overline{\lambda'+\lambda}\,.\,\frac{\sin\overline{\lambda'-\lambda}}{\lambda'-\lambda}}{2+e-3e\,.\cos\overline{\lambda'+\lambda}\,.\,\frac{\sin\overline{\lambda'-\lambda}}{\lambda'-\lambda}}.$$

Form of equations of condition.

Or (as e is small)

$$0=\frac{\delta\lambda'}{\lambda'-\lambda}+\frac{\delta b}{b}+\left(\frac{1}{2}-\frac{3}{2}\,.\cos\overline{\lambda'+\lambda}\,.\,\frac{\sin\overline{\lambda'-\lambda}}{\lambda'-\lambda}\right)\delta e.$$

Every measure gives an *equation of condition* of this form; these are to be used in the same manner as similar equations in other astronomical investigations. A similar process can be extended to arcs of longitude.

Deviations from the elliptic form.

Hitherto, in the whole of this section, we have supposed the Earth's form to be a perfect spheroid. We shall now consider the indications which, using the same observations and the same measures, would show the existence of some deviation from that form.

Dissimilarity of Northern and Southern hemispheres.

If the Northern and Southern hemispheres of the Earth were dissimilar, the radii of curvature in corresponding North and South latitudes would be unequal, and therefore the lengths of degrees in corresponding North and South latitudes would not be the same. Conversely, if it is found that the length of a degree in any North latitude is not the same as that in equal South latitude, we must conclude that the Northern and Southern hemispheres are not similar.

Earth's form not a solid of revolution.

If the Earth were not a Solid of revolution, the different meridians would be different curves, and, therefore, at the same latitude, but in different longitudes, the degrees of meridian would be unequal. The parallels, also, would not be circles, and, consequently, different degrees of longitude on the same parallel would have different lengths. An inequality then either in the degrees of latitude or in those of longitude, depending on the difference of longitude, will show that the Earth's form is not one of revolution.

Form generated by the revolution of a curve differing from the ellipse.

But the Earth's form, even though perfectly symmetrical, may be formed by the revolution of some figure differing from the ellipse. The generating curve for instance, as A Q D, fig. 21, may project between A and D above the ellipse which has the same axes. This deviation of form would be thus discovered. It is plain that at A and D the curvature is diminished, or the radius of curvature increased; and at Q the curvature is increased, and the radius of curvature diminished. Consequently, the length of degrees near A, and near D, is greater, and near Q it is less, than in the elliptic spheroid. In the spheroid the degrees at Q are longer than those at D, and shorter than those at A. Consequently, the difference of the length of degrees at Q and D is diminished; and the difference of those at Q and A is increased. The ellipticity (as is easily seen in the formulæ above) is found by dividing the difference of degrees in different latitudes by a coefficient depending only on the latitudes. This process is properly applicable only to an elliptic spheroid; but if we use it for such a curve as A Q D, it is clear that an ellipticity greater than the true value will be found where the difference of degrees is greater than in an ellipse, and less than the true value where the difference is less. Consequently, by comparing two arcs measured at D and Q, and using the elliptic formula, we should get an ellipticity smaller than the truth; by comparing those measured at Q and A we should get a value greater than the truth. Conversely, if the comparison of arcs near the Equator, and arcs in middle latitudes, give a smaller value of the ellipticity than the comparison of arcs in middle latitudes, and arcs near the Pole, we shall be entitled to conclude that the Earth's form projects at middle latitudes beyond the elliptic spheroid which has the same axes. If the difference be of the contrary kind, we may conclude the Earth's form to be more flattened at middle latitudes than the ellipse which has the same axes.

Indicated by the comparison of three meridian arcs.

The same deviation from the elliptic form might also be discovered thus. By a projection at Q above the elliptic form, the degree of parallel passing through Q, would be made greater than in the ellipse at the same latitude. Suppose the latitude of Q to be 45°, and suppose that two meridian arcs were measured of which the middle points were in latitudes 0°, and 45°, respectively. For $\frac{A}{(\lambda'-\lambda)\sin 1''}$ in the equatorial arc put f, and in the other f'; and for $\frac{C}{D\cos L\sin 1''}$ put g. Then the values of the ellipticity found by comparing each of

Or by the comparison of two meridian arcs with an arc of parallel.

Figure of the Earth.

the meridian arcs with the arc of longitude would be as follows:

$$\text{by the Equatorial arc } \frac{2}{5} \cdot \frac{g \cdot f}{b},$$

$$\text{by the other } 2\ \frac{g - f'}{b}.$$

Now g and f are greater than in the ellipse, and f' is less. The ellipticity therefore given by comparing the arc of parallel with the Equatorial arc of meridian, might, or might not, be too great; but that given by comparing it with the other arc would certainly be much too great. That is, a larger value of ellipticity would be found by comparing the arc of parallel with the arc of meridian in latitude 45°, than by comparing it with one measured across the Equator. If then we find, on comparing an arc of parallel nearly in latitude 45° with arcs of meridian near the Equator, and near latitude 45°, and applying the elliptic formulæ, that the first comparison gives a smaller value for the ellipticity than the second, we may conclude that the Earth's surface at latitude 45° is further from the centre than if the form were that of an elliptic spheroid.

Having thus explained the mode of using measures of meridians and parallels for the determination of the Earth's Figure, we shall now proceed to give an account of the principal measures which have been made.

Section 4.—Measures of Arcs of Meridian.

It will not be expected that we should lay before our readers a complete account of all the measures that have been made. Our limits will not allow this; nor is it by any means necessary. It is our object to give such information as will enable any one to understand the calculations of the several arcs, to appreciate their exactness, and to estimate their importance as conducing to our knowledge of the Earth's form. We shall touch lightly on those measures, which though on a large scale, have not been conducted with the extreme care requisite in such delicate operations, but we shall describe fully the methods, and explain accurately the theories of those which have been adopted, almost by general consent, as the only ones proper to determine the Figure of the Earth. For details we must refer to the original accounts.

Of the rough estimations of the Greek Astronomers, and the somewhat less rough measure of the Arabian Caliph, we have given in the first section as full an account as they deserve. The still more accurate measures of Fernel and Norwood have received sufficient attention. As specimens of attempts made before good instruments were invented, or refined theories formed, they are curious; and their results are not so inaccurate as might, at first sight, be expected. But the great principle of triangulation was then unknown; and little reliance can be placed on the measures in which this was not adopted. We shall commence with a general account of the methods followed in those measures in which triangulation has been used.

Meridian Measures

Preparations for measure of base.

The first part in order of calculation (though not always the first in order of time) is the measure of a base. The method which has generally been pursued is something like this. The extremities being chosen, (the requisites of which are, a sufficient distance, as four or five miles on a pretty level plain, and the power of seeing the same two signals, or at least one, at each extremity,) a telescope, mounted like a transit instrument, is placed at one extremity, and an observer, by means of it, is enabled to direct an assistant to fix stakes in a straight horizontal line, or rather in a vertical plane, on the whole length of the base line. These serve as guides in the actual measure. The base is sometimes measured roughly with a common chain, to prevent any serious error of omission in the subsequent measure, and to point out the places at which it is necessary (in some methods) to fix posts for the accurate measure.

Rods used for base-measure.

For this purpose fir-rods were universally employed till the commencement of the English survey. From some experiments made by General Roy, it appeared that they were subject to considerable alterations of length from moisture; they were laid aside, and glass tubes (and ultimately a steel chain) employed. But the reader must not suppose that these alterations had never been observed before, or that the base-measures anterior to this time were affected by the errors which they would occasion. It was usual in the former measures to keep an iron rod of a toise (a little more than a fathom) in length, as the real standard, and to compare it several times a day with the wooden rods with which the work was actually performed. As the length of the rods in general was several times that of the iron toise, brass pins were fixed at distances as nearly as possible equal to the length of the standard, upon which fine dots were made. The comparison was made by means of *beam-compasses*, (a long rod having at one end a fixed point perpendicular to its length, and at the other a point attached to a frame movable along the rod by means of a micrometer-screw.) The beam-compasses being so adjusted by the standard, that the distance between their points was exactly a known length, the fixed point was applied to one of the dots on the wooden rod, and if the movable point would not touch another it was moved by the micrometer-screw till it came in contact, and thus the difference of length was ascertained with great accuracy. This continual comparison was very troublesome, but we apprehend that little has been gained in point of accuracy by the use of the subsequent methods. When this was done, it is plain that the measured length was the same as if it had been effected with the metallic standard; and, consequently, the same corrections for the expansion or contraction of the metal from change of temperature were necessary.

Manner of placing the rods.

Several rods being provided, they were sometimes laid on the ground, but more frequently were supported on trestles. The end of the first was adjusted to the extremity of the base by a plumb-line; the others were in some instances brought in contact; but more frequently they were placed so as to leave a small interval, which was measured by a small graduated tongue or slider attached to one, and which was moved till it touched the next. Sometimes all were placed horizontal by a carpenter's square, or a spirit-level; then, if the ground was not level, it was necessary to suspend a plumb-line from the extremity of one, and to make it pass over a given point of the next. Sometimes they were inclined so as always to bring the ends in contact; then the inclination was measured, and allowance made for it afterwards. One principle was adopted in every instance, (except that of the English chain-measure,) that at least two rods should be in their places when a third was applied. Of the different methods, we cannot say that any one is preferable to the others.

The arc being thus measured, and the reduction for inclination applied, (if the rods were inclined,) and the correction for temperature being also applied, we have the sum of a series of lines similar to the short lines in fig. 22, measured with the standard bar at the standard temperature. Each of these lengths ought now to be reduced to the projection on some surface (the level of the sea has always been chosen) by lines drawn in the direction of Gravity. If r be the Earth's radius or the radius of the surface of the sea, (which is known nearly enough,) h the elevation, the measured lengths must be multiplied by the fraction $\frac{r}{r+h}$, or $1-\frac{h}{r}$, or they must be diminished by the part $\frac{h}{r}$ of the whole. If the surface slopes uniformly, the mean height may be taken; if it is very irregular, it may be divided into several parts. The reduced length $a\,b$, fig. 22, of the base A B, is now found; if the length of the chord be required, it is easily found by subtracting $\frac{A\,B^3}{24\,r^2}$.

Reduction for elevation above the sea.

Signals.

The signals at the principal stations have generally been flagstaffs, poles supported by piles of stones, pyramids of wood, broad plates of wood or metal with a hole through which the sky was visible, or Bengal lights; placed for the purpose on the same spot as the instrument with which the angles were observed. Sometimes advantage has been taken of church spires, windmills, &c., near which the quadrant or theodolite could be placed; a reduction is then necessary, to make the angle such as it would have been if the instrument had been placed exactly on the signal. Thus, in fig. 23, suppose E and F signal stations, from which the signal G has been observed; the instrument cannot be placed at G, but is placed at g; the length Gg, and the angle GgE, GgF, are observed. The real angle E G F is greater than the observed angle EgF by G Fg − G Eg. And $\sin GFg = \frac{Gg}{GF} \sin GgF$, which is easily calculated, as an approximate knowledge of G F is sufficient. Similarly G Eg is calculated. Thus the angle is found which would have been observed at G.

Measure of angles between signals.

The instruments which have been used for measuring the angles are quadrants, theodolites, and repeating-circles. When we consider the various errors to which quadrants are liable, it seems strange that the use of whole circles should not have been sooner introduced. But these evils (like most others) can be evaded if sufficient labour is bestowed upon them. The principal errors to which they are liable are, inequality in the parts of the graduation; and eccentricity, by which a further apparent inequality is created, and the proportion which the whole arc bears to the circumference is vitiated. The last defect was discovered and measured by placing the quadrant in a situation where the horizon was clear, and observing the apparent angular distance from an object A to another B, from B to C, and so on to A again, when the sum of all ought to equal 360°. The first was found by measuring the same angle on different parts of the quadrant, or by some equivalent method. When these points were attended to, we doubt whether the defects peculiar to the quadrant produce errors of any importance. The English theodolite and the French repeating-circle are undoubtedly superior, chiefly because the art of making instruments is improved. In respect of accuracy we should be inclined to prefer the theodolite; but the portability of the repeating-circle is a most valuable quality, especially in the survey of a mountainous country.

Verification quadrant.

Angles duced t horizon angles.

With the quadrant and the repeating-circle, the angle contained between two signals was observed; with the theodolite, the horizontal angle was observed, and not the angle actually subtended by the signals, except both were in the horizon. In some of the earlier surveys, the true angles, unreduced, were used, and the length of the opposite sides was calculated, and this process was continued through the whole chain of triangles. For the subsequent calculations, however, it was necessary to reduce them to horizontal angles. Here it is plain that the sides of the triangles were the actual lengths from one station to another, measured in straight lines, which would be in general inclined to the horizon. But in most instances the observed angles have been reduced to horizontal angles by the approximate method given in TRIGONOMETRY, Art. 181.; sometimes by rigorous calculations of the triangle, whose angles are at the zenith, and the two signals. Then the triangles were generally calculated as plane ones. The accuracy of the English survey made the difference between plane and spherical triangles sensible; and the English reduced the spherical triangle to a plane one, whose sides were the chords joining the stations, or rather the projections of the stations on the spheroid, whose surface is the level of the sea, by the formula in TRIGONOMETRY, Art. 182. The French calculated the triangles by Legendre's formula, given in TRIGONOMETRY, Art. 183. The first of these methods has been used in the whole of the English survey, and in that of India; the second has commonly been employed on the Continent since the year 1780. The spherical excess, it must be observed, is the same on a spheroid as on a sphere, where the latitudes and difference of longitudes of the stations are the same; of this we shall give a demonstration when we treat of the determination of differences of longitude.

Calcul of trian

Deter tion of muth o signal.

The next step is, to determine the direction of one of the sides with regard to the meridian. The general principle is this. The error of a clock or chronometer with respect either to solar or to sidereal time, may be found by means of a transit-instrument, or by observations of equal altitudes, or by absolute altitudes if the latitude of the place be well known. It is easy to calculate the azimuth of a star or the Sun at any given time; and, consequently, (the clock-error being known,) at any given clock-time. And if the star or sun be used when near the horizon, the angle made with another object will not be much affected by the uncertainty of refraction. At a signal station, therefore, the angle made by another signal with some celestial body near the horizon is observed, and the time noted; by applying the clock-error the true time is found; the azimuth at the instant is calculated; and by adding or subtracting the observed angle the azimuth of the station is found. The Sun, at rising or setting, or some circumpolar star, as Capella, passing the meridian below the Pole, has generally been used. The azimuth of Polaris, at its extreme digressions, has been observed with a theodolite; or the distance of Polaris from a signal, when apparently nearest to it or furthest from it.

with a repeating-circle. The former method requires extremely good adjustment of the theodolite; the latter, a very precise knowledge of the latitude and the refraction. The following method seems preferable where it is practicable. A temporary mark is fixed as nearly as possible in the meridian. A transit-instrument is adjusted upon it, and the transits of stars at different Polar distances are observed. The deviation of the transit-instrument, or the azimuth of the mark, can be determined thus with extreme accuracy. By means of the theodolite or repeating-circle, the angle between this mark and one of the signals can be observed, and thus its azimuth can be found. The Baron de Zach has suggested the observation of what he calls circum-meridian observations of the Sun. When the Sun is near the meridian his motion in azimuth is nearly uniform, and can easily be calculated. Repeated observations can be made; and the time being noted, his azimuth can be calculated more easily than when he is in any other part of his course. It is necessary that the clock-error be determined by transits of the Sun; for the Solar Tables (Delambre's or Carlini's) are not sufficiently exact to give his azimuth at a time determined by transits of stars, and the observation of equal altitudes is not sufficiently accurate. If night-signals can be used, the observation of a circumpolar star under the Pole would possess the same advantages without the same liabilities to error.

Calculation of arc of meridian.

We are now able to calculate the distance of the parallels which pass through the extreme stations of the chain of triangles. This, in the light in which we have considered these measures, is the sole object of the survey; but in point of fact nearly all the measures of arcs have been parts of surveys for mapping the country. Perhaps it is owing to this circumstance that the method of parallels and perpendiculars has been so much used. In the first extensive survey of France (of which Picard's arc was the beginning, and the arc measured and remeasured by J. Cassini and Cassini de Thury a continuation) an imaginary meridian line was drawn through Paris, and lines perpendicular to it were drawn across the kingdom at intervals of 60,000 toises, and chains of triangles were carried as nearly as possible along them; which were the foundation of the grand survey of France. In the English survey, meridian lines were traced through eight of the principal stations; and though the course of the triangles was not particularly directed by them, the places of all the stations were referred to them.

Method of parallels and perpendiculars.

It is plain that no method of determining the situation of a place could be more convenient than to give the distance from the fundamental point along a given line to the foot of the perpendicular passing through the point in question, and to give the length of that perpendicular; it is in fact the same as giving the rectangular coordinates x and y of the point. It is also convenient for the meridian measure. The only point of importance to be attended to is, that the perpendiculars be not so long that the difference between the spherical length of the sides, and their length when projected on the tangent plane, (or rather the tangent cylinder, which touches the sphere in the line to which the points are referred) become sensible. This was secured in the mapping surveys by using several lines of reference instead of one; and in the chain of triangles used for a meridian measure there is no fear that the perpendiculars will be too long.

Distance of feet of perpendiculars calculated.

Now let fig. 24 represent such a chain of triangles with the perpendiculars drawn from the stations upon the meridian passing through A one extremity. The length of A B, and its azimuth, (or the angle B A b,) are known, and therefore, A b and b B can be found; and similarly A c and c C. Through B draw g B h parallel to b A. The angle A B h is equal to B A b, and C B A and C B D have been observed; hence D B g = A B h + C B A + C B D − 180° is known. Also D B is known; and hence D g and g B can be calculated. Adding D g to g d or B b, which has been calculated, we have D d; and adding g B to b A we have A d. These can also be determined from the position of C by the length and direction of the line C D; and if the two results differed it would be proper to take the mean. Then the meridian distance and perpendicular for F, would be found from those at C and D; and so on to the end. It must be observed that g B h is not the meridian passing through B, and therefore D B g is not the azimuth of D as seen from B; it differs from it by an angle termed *the convergence of meridians*, of which we shall speak hereafter. We may also remark that there is no inconsistency in taking into account the spherical excess, while we neglect here the difference between the lengths of lines on a sphere or spheroid, and the corresponding lines on a cylinder; the former varies, *cæteris paribus*, as the square of the sides, and the latter as the cube, and therefore, when the triangles are very small in comparison with the Earth's radius, the latter is smaller in proportion to the quantities retained than the former.

Difference between perpendicular and small circle.

Now let F be the last of the stations. The distance A f is not the distance between the parallels passing through A and F. For produce A f to P the Pole of the Earth, and describe a small circle, F f', of which P is the centre. Then A f' is the real distance between the parallels, and $f f'$ must be subtracted from the ascertained length A f. This quantity may be calculated in the following manner. F f is part of a great circle, (since it is produced in a vertical plane,) F f' is part of a parallel. In fig. 25, we have represented the chain of triangles on the surface of the sphere, or spheroid; with the plane of the great circle F f G M, and that of the small circle F f' G N, intersecting in the straight line F m G. Fig. 26 represents the plane of the circle P A; m is the point at which the radius of the great circle and the small circle intersect. Now $f f' = m f . \tan f m f' = m f . \tan f K e = m f .$ tan latitude of f; or $= m f .$ tan latitude of F (the difference being very small.) But $m f$ is evidently the versed sine of the arc of F f to radius K f, and therefore

$$= \frac{\overline{\mathrm{F}f}|^2}{\text{Earth's diameter}};$$

consequently,

$$f f' = \frac{\overline{\mathrm{F}f}|^2 . \text{ tan lat. of F}}{\text{Earth's diameter}}.$$

We believe that this would be the easiest way of making the calculation. But it has generally been done thus. From the approximate knowledge of the Earth's dimensions find the arc of a great circle in degrees and minutes corresponding to the length F f. Consider P F f as a right-angled spherical triangle, of which the side P f will be determined by this formula,

$$\cos \mathrm{P}f = \frac{\cos \mathrm{PF}}{\cos \mathrm{F}f} \text{ (Trigonometry, Art. 105.)}$$

Take the difference between P F and Pf in degrees, and from the assumed radius of the Earth convert it into fathoms. This method appears troublesome, it requires logarithms of 7 places; that above would not require logarithms of more than 4 places.

Convergence of meridians.

We may now easily see what is meant by the convergence of meridians. In fig 24, or 25, join P F by an arc of great circle. Then P F is not perpendicular to Ff, and therefore in fig. 24 it is not parallel to Pf. The angle is easily found by solution of the same spherical triangle, P Ff, thus, $\cos \mathrm{PF}f = \dfrac{\tan \mathrm{F}f}{\tan \mathrm{PF}}$. (Trigonometry, Art. 109.) If now (as frequently happens) the azimuth of B had been observed at A, and that of E at F, and it was desired to know how nearly one coincided with the result calculated from the other, the process to be used would be this. Since fF E is known, (by the antecedent calculations,) and A Ff is known, (by the solution of the spherical triangle just given,) their sum P F E is known; and this is the angle to be compared with the observed azimuth.

Delambre's method of calculating arcs of meridian.

The method invented by Delambre, and used in the measure of the French arc commenced in 1792, and in most of the continental surveys since that time, is certainly more elegant, and, perhaps, in some respects, more convenient than that which we have described. The triangles were calculated as spherical triangles, and therefore the spherical excess was computed for no other purpose than to discover the sum of the errors in the observation of the angles. When the side a, and the two adjacent angles B, C, of a triangle are known, and its area roughly calculated, from which the spherical excess x is found, then $\mathrm{A} = 180 + x - \mathrm{B} - \mathrm{C}$, and

$$\mathrm{Sin}\, b = \frac{\mathrm{Sin}\, a \,.\, \sin \mathrm{B}}{\sin \mathrm{A}}, \quad \mathrm{Sin}\, c = \frac{\mathrm{Sin}\, a \,.\, \sin \mathrm{B}}{\sin \mathrm{A}},$$

where by Sin a we mean the sine in the circle whose radius $= \mathrm{R} =$ Earth's radius. Now $\mathrm{Sin}\, a = a \dfrac{\mathrm{Sin}\, a}{a}$; and a is a quantity whose logarithm is found easily from the common tables, and $\log \dfrac{\mathrm{Sin}\, a}{a}$ is a quantity that varies very slowly, and can be taken from a very small table constructed for the purpose. Now the general problem is this. Given the Earth's dimensions to tolerable accuracy, the length of A B, fig. 27, the angle P A B, and the latitude of A, to find the difference of latitudes of A and B, the distance of the parallels, the difference of longitudes, and the angle P B A. Draw A Q the normal at A, B S that at B. As the Earth's form is not spherical, these normals will not (in general) meet the axis P S in the same point. Join B Q, A S; and suppose that a sphere described from the centre Q with radius 1, cuts the lines Q P, Q A, Q B, in p, a, b. The angle at P, or the difference of longitudes will be the same as the angle at p; that observed at A will be the same as that at a, since each is the inclination of the planes A Q P, A Q B; but the angle observed at B will not be the same as the angle $p\,b\,a$. For suppose the angle measured with a theodolite; its axis must be vertical; that is, it must be in the direction B S; consequently the angle which it measures is the angle made by the planes B S A, B S P; whereas $p\,b\,a$ is the angle made by the planes B Q A, B Q P. We have now to inquire, Are the planes B S A, B Q A, equally inclined to the plane B P Q S? In general they are not; but we can investigate their difference thus. Draw A a' perpendicular from A on the meridian plane P B; and from a' draw $a's'$, $a'q'$, perpendicular to B S, B Q. This is more clearly represented in fig. 28. Then the plane A a' s' is perpendicular to B S, and therefore the tangent of the angle observed at B is $-\dfrac{\mathrm{A}a'}{a's'}$. Similarly the tangent of the angle $p\,b\,a$ is $-\dfrac{\mathrm{A}a'}{a'q'}$. Hence $\tan p\,b\,a = \tan$ angle at $\mathrm{B} \times \dfrac{a's'}{a'q'}$. These will be absolutely equal when $a'q' = a's'$; or when the elevation of A actually observed at B is equal to the depression which would be observed if the axis of the theodolite were in the line B Q; that is, if A be very near the horizon of B. The error of the assumption, that $p\,b\,a =$ the angle observed at B, depends therefore entirely on this circumstance, that a perpendicular at A, when observed at B, does not appear perpendicular. This, however, is not discoverable by the senses when assisted by the best instrument; and, therefore, we may at once assume that $p\,b\,a$ is equal to the azimuth of A as observed at B. Now, in the spherical triangle $b\,a\,p$, we have given $p\,a =$ colatitude of A; $b\,a\,p =$ observed azimuth; $a\,b = \dfrac{\mathrm{A\,B}}{\mathrm{A\,Q}}$, whose determination therefore requires a knowledge of A Q as well as of A B (if the form be assumed to be elliptical A Q = P V, in fig. 10,

Azimuth at second station may be calculated as on a sphere.

$$= \frac{\mathrm{C\,N}}{\mathrm{R\,N}} \,.\, \mathrm{P\,R} = \frac{a^2}{b^2} \,.\, \mathrm{P\,R}$$

$$= \frac{a^2}{\sqrt{a^2 \cos^2 \lambda + b^2 \sin^2 \lambda}} = b\,(1 + 2\,e - e \cos^2 \lambda),$$

if we neglect powers of the ellipticity) and a small table of the value of log A Q at different latitudes must be made: it varies very slowly. Then solving the triangle as a spherical triangle, for which the method in Trigonometry, Art. 186. was generally used by Delambre, and is shorter than the accurate computation, we have the azimuth $\mathrm{PBA} = p\,b\,a$; and the distance $a\,b''$ of the parallels passing through a and b; whence the distance $\mathrm{A}\,b' = \mathrm{A\,Q} \times a\,b''$ is found. For a survey of meridian lines these two determinations (the azimuth of A as seen from B, and the distance in linear measure between their parallels) are all that are necessary; but as it is always desirable, and in mapping necessary, to determine the latitudes and longitudes of the stations, on assumed dimensions of the Earth, the following must also be calculated. The difference of longitudes B P A, which is the same as $b\,p\,a$; and the difference of latitudes, which is obtained by dividing the distance between the parallels by the radius of curvature of the meridian at the middle point, or (in the ellipse)

or

$$b\left(1 - e + 3\,e \sin^2 \frac{\lambda + \lambda'}{2}\right).$$

We will remark here, once for all, that the theory of the shortest lines that can be traced on an ellipsoid between two points has no application to the sides of Geodetic triangles, as some writers have supposed. The lines which determine the azimuths, &c. are the lines which represent the rays of light passing from one signal to another; and light does not move in the shortest curves that can be traced on ellipsoids, but in straight lines. In consequence of this, (as may be observed in the theory just given,) the truth or falsehood of some of our propositions will depend on the relative elevation of the signals. And in all the more delicate parts of the theory, we must consider the signals as being elevated above the curved surface. Thus Delambre treated the subject; and thus it had been treated long before in some masterly Papers by Dalby, in the *Phil. Trans.* for 1791 and 1795, which are transcribed in the first volume of the *Account of the Trigonometrical Survey*. If we chose to take into account the terrestrial refraction, and to suppose that refraction always bends the light towards such a *shortest line*, we ought to correct our results by about $\frac{1}{12}$th of the difference between them and those obtained by the theory that we have rejected; but such a refinement would be ridiculous.

Theory of shortest lines does not apply in Geodetic theorems.

Determination of difference of latitudes by observation.

We have here given every thing necessary for determining the distance between the parallels passing through the extreme stations of the chain of triangles; and the Geodetic part is completed. We now come to the Astronomical determination of the latitudes at the extremities; a determination on the accuracy of which the exactness of the whole operation depends, and whose difficulties far exceed all the difficulties of the other determinations

Small [illegible] in the [illegible] [illegible] is of no consequence.

From the description of the general principle which we have given in the Ist section, and from the formulæ in the IIId section, it will appear that if the difference of latitudes of the extreme stations be accurately determined, the radius of curvature at the middle point will be known; and, if a small error be committed in fixing on the absolute latitudes, (from which the latitude of the middle point is found,) it will have no sensible effect on the resulting dimensions of the Earth. For if we take the expression which gives the ellipticity by comparison of two measured arcs,

$$e = \frac{\dfrac{A}{(\lambda' - \lambda) \sin 1''} - \dfrac{B}{(\mu' - \mu) \sin 1''}}{3\, b \left(\sin^2 \dfrac{\lambda' + \lambda}{2} - \sin^2 \dfrac{\mu' + \mu}{2} \right)},$$

in which the numerator is certainly small, and the denominator is not generally small, it is evident that the value of the denominator will not be much altered by a small alteration in $\frac{\lambda' + \lambda}{2}$; for instance, if

$$\frac{\mu' + \mu}{2} = 0, \text{ and } \frac{\lambda' + \lambda}{2} = 45^\circ,$$

an error of 1 in $\frac{l' + l}{2}$ would only alter the denominator from $3\, b \sin^2 45^\circ$ to $3\, b \sin^2 44^\circ 59'$. But an error in $\lambda' - \lambda$ will produce a very serious effect in the numerator; as if $\lambda' - \lambda = 1^\circ$, an error of $1'$ will alter $\frac{A}{(\lambda' - \lambda) \sin 1''}$ from $\frac{A}{3600 \sin 1''}$ to $\frac{A}{3540 \sin 1''}$, or will increase it by $\frac{1}{60}$th part; and if $\frac{A}{(\lambda' - \lambda) \sin 1''}$ exceeds $\frac{B}{(\mu' - \mu) \sin 1''}$ by only $\frac{1}{360}$th part, it will from the effects of the error exceed it by $\frac{7}{360}$th part, or the resulting ellipticity will be seven times as great as before. In estimating, then, the accuracy of the observations for determining the latitudes, we have no need to inquire into the exactness of the determination of the absolute latitudes, but only into that of the difference of latitudes.

An error in the difference of latitudes is very important.

General description of the zenith-sector.

The instrument with which the difference was commonly determined in the surveys previous to 1787 is the zenith-sector. With this instrument the zenith-distance of stars that pass near the zenith can be ascertained with great accuracy. At the two extremities of an arc the same stars were observed at their meridian passage; and, without any knowledge of their declination, the difference of their zenith-distances was found; which is equal to the difference of the Astronomical latitudes. As much of the credit of several of the measures depends on the capability of this instrument, we shall give a general description of it, and of the method of using it. In fig. 29, A B is a bar of iron with a cross-piece C D, the whole in one piece. The top, A, is formed in such a way that the instrument can be turned half round in azimuth when suspended at the top, and that the bottom can be moved freely in the directions D C, or C D. It might be made as represented in the figure; or it might move on a hinge for its ordinary motion, and in a swivel for its azimuthal motion. The bracket, or other support, E, on which it rests, is attached to some firm part of the building. To the bar, A B, is firmly attached a telescope, F G. At a point, *a*, near A, is attached a plumb-line, *a* H; sometimes it is fastened at a point of attachment which is movable, in order that, by moving the point of suspension, the plumb-line may be made to pass over a fine dot at *a*. The limb, CD, is graduated, sometimes on a circular arc, of which *a* is the centre, and sometimes on a straight line. L D is a screw passing through a block strongly connected with the floor, and acting with its point against the end D of the piece C D; and M N O is a string and weight pressing the sector against the point of the screw.* The method of using it is this. By transits, or equal altitudes, a clock is regulated to solar or sidereal time; and then, the time at which celestial bodies pass the meridian being known, the meridian line is easily found with tolerable correctness. A cord is stretched across the room, and this serves well enough (as great accuracy is not necessary) to direct the astronomer in fixing guides which will compel the sector to move in the direction of the meridian. When a star is to be observed, the screw L D is turned till the plumb-line falls exactly on some point, K, of the graduation, such that the telescope is very nearly directed to the star; and the number of

Method of using the zenith-sector.

---

* It will readily be understood that this description, and the figure belonging to it, are intended to illustrate only the general principle of this instrument, and that most of the details, which can be supplied without difficulty by those conversant with instruments, are wholly omitted. For instance, the screw generally acts in a movable piece which is clamped in any convenient position, so as to diminish very much the range of the screw. The construction represented in the figure is probably the worst form in which the instrument has ever been used.

turns and fractions of a turn (as shown by a scale and divided head, not represented in the figure) are read. When the star enters the field of view, the screw is again turned, till it appears to glide exactly along the wire fixed in the focus of the eye-glass, and the turns and parts of a turn again read. The motion of the screw being thus ascertained, its value in degrees and minutes is to be added to the value of the graduation, K, and thus the apparent zenith-distance of the star is found.

Reversion necessary.

Now, it is evident that this is not the true zenith-distance, except the place of the division 0, be quite correct. It is impossible to insure this; but it is easy to see, that if the instrument be turned half round in azimuth, and the same observation made, the apparent zenith-distance will be just as much greater than the true, as in the former observation it was less. The mean of the two determinations will be the true zenith-distance.

For accuracy it is indispensably necessary, that the telescope F G preserve the same position with regard to the frame in the observations before and after reversion. In the best sectors this has been secured by omitting the bar, A B, entirely, and attaching the limb, C D, to the tube of the telescope. In several, instead of turning the screw, L D, to bring the wire upon the star, the wire is moved by a micrometer-screw within the telescope. And in some, a graduated scale slides in a groove on the arm, C D, and when the instrument has been moved till the star glides along the middle wire, the scale is moved by a micrometer-screw till a division is brought under the plumb-line, and the reading of the micrometer-head is then registered.

Advantages of this instrument.

We request the reader to notice the construction of this instrument, because all the discordances between ancient and modern measures on the same line, appear to be owing to the difference of determinations with the zenith-sector and the repeating-circle. We confess that to us it appears impossible, when the instrument is made with any reasonable care, that the error in its results can be at all serious. The stars observed are in a part of the heavens where the tremor and dancing, which generally affect stars in other positions, are seldom seen; there is no uncertainty about the effects of refraction; the telescope and the whole instrument are not subject to flexure; the variation of temperature produces no sensible effect. We may be excused for reminding the reader, that not only the existence but the magnitude of aberration and nutation were discovered by means of a zenith-sector, and that subsequent observations have added little to the accuracy of the determination.

History of the repeating-circle.

The repeating-circle was invented late in the last century, and was first introduced to the notice of the scientific world by its employment in the French part of the survey for connecting the Observatories of Greenwich and Paris. It was again used in the measure of the arc from Dunkirk to Barcelona, conducted by Delambre and Mechain. From this time, it attained among the French a degree of popularity which can hardly be imagined. The minds of Philosophers, not less than those of Politicians, seem at that period to have been distracted with the idea of obtaining every thing desirable by the application of one sweeping principle. They imagined that the effects of errors of division and errors of observation might be entirely destroyed by repetition, and that no new error would be introduced in their place.[*] And from merely reading the French Works on Astronomy, or almost any other Science, published early in the present century, one might almost imagine that it was impossible to make an Astronomical or Optical observation without a repeating-circle. This instrument, however, was never much used by English observers. This has been remarked by M. Littrow, (in Zach's *Correspondance Astronomique,*) with the commentary, "the English are a practical nation;" which we believe to be the true explanation.

Discor ance of tudes of celona Montjo

One of the first observations which shook the credit of the repeating-circle occurred in the course of the French survey of 1792. In consequence of the breaking out of a war between France and Spain, Mechain, who undertook the survey of the Southern part of the chain, was detained in Spain. He had before observed the latitude of Fort Montjouy, about a mile from Barcelona, and he now wished to repeat the observations; but as he was not allowed to enter the fort, he observed the latitude of Barcelona, and connected it by a small triangulation with Montjouy. The latitude of Montjouy, thus obtained, differed more than 3″ from that found by observation at the place. The chagrin which he felt after attempting in vain to reconcile these observations, undoubtedly contributed to accelerate his death. It was not till the nature of the instrument was better understood that Astronomers had it in their power to explain this apparent inconsistency.

Const error c peatin cles.

It is now universally acknowledged, that all repeating-circles are liable to an error which cannot be removed by any number of repetitions, and which, on that account, is called the constant error: "*constante toutefois jusqu'à un certain point: car il suffit souvent de transporter l'instrument d'un lieu dans un autre, ou de le démonter, pour produire un changement dans le rapport matériel des pièces, et par suite une variation dans la quantité de l'erreur.*" We cite this passage from an interesting Memoir by M. Nicollet on the discordances above mentioned, in the Additions to the *Conn. des Temps*, for 1831. It contains nearly all that is known upon the subject;[†] for the causes of the error are still in obscurity. We beg to refer the reader who wishes to inquire more accurately into the nature of the repeating-circle, to a Paper by Mr. Troughton in the Ist volume of the *Memoirs of the Astronomical Society.*

Prob meth obvia effect

The only mode of observation which appears to be a probable, but not certain, method of removing the error is, if the latitude of a place is the result sought, to observe the zenith-distances of stars passing the meridian at nearly equal distances on both sides of the zenith; the mean of the results will probably be near the truth.

To make this more intelligible we shall give a short

---

[*] It is said to have been the opinion of a celebrated French Mathematician engaged in the survey of 1787, that it was no longer necessary to bestow any care on making the triangles well-conditioned, as all possibility of error in the angles would be removed by the use of the repeating-circle.

[†] In the *Exposé des travaux relatifs à la reconnaissance hydrographique des côtes occidentales de France*, p. 86, M. Daussy thinks, that the constant error in observing horizontal angles is proportional to the angle. In some cases, however, he admits that the observed angles could not be corrected by this hypothesis. The Baron de Zach (*Correspondance*, vol. ii.) mentions a repeating-circle with which the observed angles decreased continually; and facetiously insinuates, that if he had continued the repetition of observations of a right angle for several years he should have reduced it to nothing.

account of the mode of observing with this instrument. Figs. 30 and 31 represent it as used for finding the angular distance of two objects, A and B, in any positions, (the stand, &c., being omitted for clearness.) Both telescopes are movable on the circle, which is graduated on one side only; and the telescope on that side carries one, or (more generally) four verniers. Suppose now in fig. 30, C, the telescope on the graduated side, is directed to the object B, and D, the other telescope, is pointed to A; in this state the vernier or verniers of C are read off. Then the whole circle is turned in its plane till the telescope D (which remains clamped to it) is directed on B; and the telescope C is then released and turned, while the circle remains fixed, till it is pointed to A. It is plain that C has been turned through an angle equal to twice the angle sought. Now the whole circle must be turned again till C points to B, and D must be turned till it points to A. Then the circle must be turned again till D points to B, and C must be turned till it points to A; when C will have been turned through four times the arc; and by a repetition of this process the arc can be multiplied any even number of times. The general rule is, to move the circle only in one direction, and the telescopes only in the opposite direction. Two observers are generally necessary. It is necessary to read the verniers only at the beginning and the end, except it is wished to ascertain whether the angles are generally equal.

For observing zenith-distances of stars, advantage is taken of a spirit-level attached to the telescope D, and the telescope C only is used. The verniers of C are read, and then the whole circle is turned in its plane till C is pointed to the star S; and D is moved on the circle till the bubble of the level E is either in the middle, or is so near it, that by the divisions of the level-scales the error can be accurately estimated. Then the instrument is turned half round on its vertical axis, so that, in fig. 33, the face presented to the reader is the ungraduated face; and (if necessary) the circle is moved till the level-bubble is in the same position as before, or else the error is noted Then leaving the circle and D fixed, C is released and again pointed on the star; after which it is necessary to look to the adjustment of the level. C has now described an angle equal to twice the zenith-distance. This (as before) can be repeated any number of times; the motion of the star in the mean time must be calculated from theory. The correctness of the whole depends on the goodness of the level. If the bubble is kept always at the middle, two observers are necessary, one to look through the telescope, and the other to attend to the level. If the level-scales are read every time, a single observer is sufficient. We prefer this mode, not only as requiring fewer persons, but also as being more accurate.

Stars near the zenith cannot be observed with it.

One circumstance which limits the use of the repeating-circle is this. It is impossible to place the plane of the circle perfectly vertical. The error of verticality in most of the repeating-circles which we have seen* cannot be easily ascertained, (except by observing a star, alternately by direct vision and by reflection from mercury, and marking the time and azimuth.) Suppose, now, in fig. 34, Z is the zenith, S the star, T S the great circle representing the plane in which the circle and its telescope move when the telescope is pointed to S. On reversing the instrument, T′ S is the position of the plane. From Z draw Z T, Z T′, perpendicular to T S, T′ S. T and T′ are the highest points of the circle in the two positions; and, consequently, T′, or rather the point corresponding to it in the circle, is the same as T in the other position. The telescope, therefore, has been moved through S T + T′ S, or 2 S T; and half of this, or S T, is the estimated zenith-distance. To find how much this differs from the true zenith-distance, since $\cos TS = \frac{\cos ZS}{\cos ZT'}$, we have

$$\frac{\cos TS - \cos ZS}{\cos TS + \cos ZS} = \frac{1 - \cos ZT}{1 + \cos ZT},$$

or

$$\tan\frac{TS + ZS}{2} \cdot \tan\frac{ZS - TS}{2} = \tan^2\frac{ZT}{2};$$

or

$$\tan\frac{ZS - TS}{2} = \cot ZS \cdot \tan^2\frac{ZT}{2}$$

nearly. If Z S is small, this expression may become considerable. It is necessary, therefore, to avoid observing stars near the zenith, that is in the part of the heavens most favourable for observation.

The telescopes of the repeating-circle very small.

The smallness of the telescopes attached to the repeating-circles diminishes very much the confidence which we might else be disposed to place in them. The largest that we have seen is only 24 inches long. We apprehend that the long telescopes of the zenith-sectors made before the achromatic object-glass was invented, would give a better image of a star. The telescopes attached to the repeating-circle used by Delambre* would not separate the double star ζ Ursæ Majoris; these two stars are distant 14″ or 15″. With such a telescope, the *minimum visibile* is of course not very small. "However an instrument may be constructed, or in whatever manner it may be used, I have no faith that it can give results nearer the truth than a quantity that is visible in the telescope." This opinion we quote from Mr. Troughton's Paper before cited; and we subscribe to it most heartily.

Magnitude of the constant error.

We know not how far† the flexure of the telescopes and the defects of the level are found to introduce errors in the observations of zenith-distances from which observations of horizontal angles are free; but we

---

[*] In some of Reichenbach's repeating-circles provision is made for the application and reversion of a cross-level.

[*] We copy this statement from the Memoir of M. Nicollet, *Conn. des Temps*, 1831, *Additions*. M. Nicollet has also attempted to prove that the telescope attached to Mechain's circle was unable to separate this star. This circle is now preserved in the Observatory at Milan, where (through the kindness of MM. Cesaris and Carlini) we lately had an opportunity of examining it, and of trying the telescope upon the star in question. It effects the separation perfectly well. We have since found in an anonymous Memoir of great ability inserted in the *Philosophical Magazine* for March 1829, that Mechain himself had with this telescope observed the star to be double, and had published this observation in the *Monatliche Correspondenz* of Zach. This circle (made by Lenoir) appeared to us to be of very inferior workmanship.

[†] It is the practice of the ablest modern observers with the repeating-circle to determine the flexure of the telescope by observing the angular distance (through the zenith) between two opposite marks in the same straight line with the centre of the instrument, or between the wires of two collimating telescopes, which have been adjusted one on the other. The observed distance will be less than 180° by twice the effect of flexure. It is found in general that the flexure produces an error of several seconds.

should expect that such additional errors exist, and that their magnitude is sensible. Now to give an idea of the amount of errors in observations of horizontal angles, we take the first triangle in the *Opèrations Gèodèsiques et Astronomiques en Piémont et Savoie,* of which the angles were observed by a company of Piemontese officers, and by another company of Austrian officers.

Stations.	Number of Series.	Angles found by the Piemontese.	Number of Series.	Angles found by the Austrians.
Trélod	6	81° 51′ 57″.64	2	81° 51′ 52″.13
Granier ...	8	55 26 42 .22	4	55 26 51 .42
Colombier..	6	42 41 22 .70	3	42 41 20 .99

Here between two values of the angle observed on Mont Granier, one of which is the mean of 80 observations, and the other the mean of 48, we find a difference of more than 9″. A serious error, therefore, exists, which repetition has not been able to remove. But the fact is that the repetition was useless; for the results of the different series agree extremely well. The smallest of the Piemontese results is 55° 26′ 40″.0, and the greatest 55° 26′ 44″.5; the smallest of the Austrian is 55° 26′ 50″.0, and the greatest 55° 26′ 52″. What kind of *constant error* existed in these instruments we can hardly imagine, since in the other angles the difference is of the opposite kind. It is true that this is (as far as we have examined) the worst of the triangles; it is true also that these instruments were not repeating-circles of the usual construction, but repeating-theodolites of only eight inches diameter. But the points which we wish to impress on the reader remain, that repeating instruments are subject to an error which cannot be removed by any number of repetitions, and that the amount of this error is such as to make their results unfit to be put in competition with those of a good zenith-sector. Judging from the agreement of the observations with the same instrument in the instance given above, we apprehend that the smallness of the instruments has had no effect on the discordance of the results.

We have treated at length on the relative value of the zenith-sector and the repeating-circle, because in some instances we shall find different amplitudes assigned to the same arc, according as it has been observed with one or other of these instruments, and because some arcs which have been absolutely rejected by writers on the Figure of the Earth will appear, when the nature of the instruments is examined, to be nearly as trustworthy as those which they have retained. It has been so much the fashion for some years (chiefly among French writers) to extol the repeating-circle, that we know no Work in which the relative merits of the two instruments are stated, to which we could refer the reader.

We shall now mention individually some of the principal measures.

Methods pursued in J. Cassini's measure.

In J. Cassini's measure, the bases were measured with wooden rods of 4 toises each. The angles were observed with a quadrant of 39 inches, and an octant of 36 inches radius. For the azimuth, the clock-errors were determined by equal altitudes, and transits of Capella below the Pole were observed. Some of the azimuths, however, were determined by observation of the Sun at rising and setting. The zenith-distances of stars were observed with a sector of much greater arc than that which we have described above. We think it unnecessary to allude further to this measure, as it gave no result which is of any use at the present day.

Mendi Measu

Methods used in Peruvia measur

In the Peruvian arc, the base was measured with greater care than had before been bestowed on that operation, but with less than would now satisfy Astronomers. The standard measure of France was an iron toise preserved in the Châtelet; but it was so rough that a new standard was necessary; and in fact that used in this measure, and called from that circumstance *the toise of Peru* has always been considered as the real standard. Wooden rods were used for the actual measure, and these were compared with the iron toise every day. Two at least were always in their places while the third was moved; they were always kept in a horizontal position. It does not appear that the thermometer was observed during the measure, but the observers compared the temperature by their bodily sensations with that at other seasons, which had been ascertained by the thermometer; and on this rough estimation, the allowance for the expansion was founded. The temperature to which the measure was reduced was 13° of Reaumur, or 61¼° of Fahrenheit.

Expa of sta ascert

The expansion of the iron toise for 1° of temperature was found in the following elegant manner. The toise was mounted on knife edges so as to vibrate like a pendulum, and another bar was similarly mounted so as to be synchronous with it at a given temperature. The air in the place containing the toise was heated, in consequence of which the toise lengthened, and, therefore, vibrated more slowly than the other pendulum; by observing the number of vibrations which elapsed before its vibrations coincided with those of the pendulum, the alteration of time of oscillation, and consequently the alteration of length, was found; it was ·0117 line for 1° of Reaumur. The length of the base was 6274 toises, 3 inches, and 2 lines; this was obtained by two measures which differed only 3 inches, one party beginning at one end, and at the same time another party at the other end. The South end of the base was 126 toises higher than the North; the base, and in fact the whole measure, was corrected so as to refer it to the level of the lowest extremity of the base. The number of principal triangles was 33. The signals were heaps of stones, pyramids of wood, or tents; the angles were observed with quadrants of three feet radius. The triangles were first calculated without any reduction of the observed angles to horizontal angles, and thus the length of the base of verification appeared to be 5260.03 toises; its measured length was 5258.95. The angles were then reduced to horizontal angles; as the apparent elevation of one signal from another was sometimes 6°, this was done not by an approximate formula, but by accurate computation of the spherical triangle. Then the triangles were again calculated, and the positions of the projections of the signals on the level of the lowest end of the base found by the method of parallels and perpendiculars. The azimuths were determined by observations of the Sun near the horizon; there were in all about 20 observations. The general direction of the chain of triangles made an angle of about 14° with the meridian, extending from North-East to South-West. It seems that Bouguer calculated the series considering the meridians through the different points (on account of the proximity to the Equator) as perfectly parallel, while La

Condamine made allowance for the convergence of meridians. La Condamine also thought it proper to diminish the calculated length half as much as the measured length of the second base was less than the calculated length. Finally the distance of parallels of the Observatories erected near the extremities of the arc was found according to Bouguer, 176,940 toises, according to La Condamine 176,950.

Construction of the zenith-sector used in Peru.

The difference of latitudes was determined by observations of α Aquarii and θ Aquilæ, but more particularly of ε Orionis. The sector which they carried out with them was of 12 feet radius, and had an arc of 30°, but they soon found the convenience and accuracy of reducing the extent of arc. The new arc they redivided in a very ingenious manner; and afterwards constructed another sector on the same principle. It was as follows. The zenith-distance of the star used principally at the Southern observatory was about 1° 41′. If the reader will consider the method of observing with the zenith-sector by reversion, as described above, he will find that it is only necessary to have two points on the limb settled with great accuracy (one on each side of the centre) whose distance is nearly 2 × 1° 41′, or 3° 22′. Now the chord of the arc of 3° 22′ 15″ is $\frac{1}{18}$th of the radius. To divide an assumed radius into 18 equal parts is not easy: but it is very easy, assuming the length of the chord, to multiply it 18 times, and thus form the radius. This they accordingly did; then describing an arc of a circle, and taking on it two points at the assumed distance, the graduation was completed. The observation was made by moving the instrument till the plumb-line fell on the point, and a wire in the field of view of the telescope was then moved by a micrometer-screw, till the star was bisected. For the Northern observatory, the zenith-distance of the stars being less, they used in the same manner the arc, whose chord = $\frac{1}{20}$th of the radius.

In the first sector the telescope was connected with the principal bar of the sector by supports of several inches in length. The connection appeared to be not sufficiently firm, and they reduced the length of the supports. After numerous observations it still appeared that the telescope bent or deviated in some manner, and that no confidence could be placed in the instrument. At last Bouguer rivetted all the screws, and wrapped the bar and telescope round and round with iron wire. From this time the results were perfectly consistent.

Another difficulty now presented itself. If the same instrument were used to determine the latitudes of both extremities, as the apparent places of the stars would change between the observations, a perfect acquaintance with their apparent motions was necessary. But the laws and magnitudes of the newly discovered corrections for nutation and aberration were not then sufficiently known to enable them to calculate accurately the apparent places. But having constructed another sector, they determined on observing the same star simultaneously at both extremities. Bouguer accordingly went to Cotchesqui the Northern extremity, and La Condamine to Tarqui the Southern, and at length a satisfactory conclusion was obtained. More than three years, however, had been spent in determining the difference of latitudes. They fixed on 3° 7′ 1″.

One reduction remained. The length of the projection of the arc on the level of the lowest station was found, but it was necessary to find the length of the projection on the level of the sea. To ascertain the height of the lowest station above the sea was difficult, as the mountains between it and the sea were not visible at the coast on account of the constant fogs hanging on the forests below the mountains. At last they found that two of the peaks were visible from an island in the Emerald River; and they finally succeeded in ascertaining the height of the lowest station to be 1226 toises. The length of a degree at the level of the lowest station according to Lacondamine was 56,770 toises, and therefore at the level of the sea 56,749. Bouguer, however, made it 56,746; but he observed that this ought to be increased by seven toises on account of the expansion of the iron toise when compared with the wooden measuring-rods. Delambre recalculated this degree; he found the difference of latitudes to be 3° 7′ 3″; and the length of the degree 56,737 toises.

Value of this measure.

We have the advantage of possessing different accounts of this survey written by persons, each of whom had made nearly enough of independent observations to obtain a result. They had calculated the observations, each in his own way; and their personal friendship was not so ardent as to prevent either of them from pointing out any thing unfair in the proceedings of the other. When to this we add that it was one part of their system to make no important observation, if possible, without witnesses, it will appear that this arc is in all respects worthy of credit.

Methods pursued in the first Swedish measure.

In the Swedish measure conducted by Maupertuis, Clairaut, &c. the signals were commonly cones of barked trees, and the angles were observed with a two feet quadrant. The observed angles were reduced to horizontal angles. The azimuth was determined at Kittis (the Northern station) by observing the Sun's transit over the vertical of the next signal, the clock being regulated by equal altitudes. At Tornea the azimuth was found by observing the Sun near the horizon. The arc was calculated by parallels and perpendiculars, and allowance was made for the difference between a small circle and a great one. The base was then measured on the frozen river; eight rods were made each of four toises in length, and were compared with an iron toise (since called the *toise of the North*, and which had been compared with that used in Peru) at the temperature of 15° of Reaumur or $65\frac{3}{4}$° of Fahrenheit. The rods were laid on the snow; and two troops made independent measures which differed but four inches. The length was 7406 toises 5 feet; whence the distance between the parallels of the observatories was found to be 55,023.4 toises. The sector for determining the difference of latitudes was made by Graham. A detailed description of it may be found in the *Dégrè du Méridien entre Paris et Amiens;* it resembled, in most parts, the sector used by Bradley, now preserved in the Observatory of Greenwich. The telescope tube (which was large and strong, and nine feet in length) was itself the radius of the sector; it carried a limb of small extent, the graduation of which had been carefully verified. The whole was moved by a micrometer-screw acting in opposition to a weight, and care was taken that the screw should always act on the same point. The sector was not reversed, (according to the method of using this instrument described in our general account of it,) and thus the absolute zenith-distances of the stars observed were not determined. But as the same part of the limb was used in the observations of the same star at the two stations, the difference of zenith-distances, and consequently the difference of latitudes, was found, subject only to the error which might arise from disturbance in the relative positions of the telescope and the limb. The firmness of the instrument, (which consisted of but one piece,) the care used in transporting it, and the agreement of the results obtained after two transportations, seem fully to justify the Academicians in this use of the sector. Before the measure of the base δ Draconis was observed at Kittis and Tornea, five times at each; the difference of latitude (neglecting refraction) appeared to be 57′ 26″.93. After the measure of the base α Draconis was observed three times at each place; the difference of latitude was 57′ 30″.42,* the mean is 57′ 28″.7. In this estimation, refraction was not taken into account; it ought therefore to be increased by about 0″.7, which makes the difference of latitude 57′ 29″.4. Consequently the length of a degree is 57,425.5. We have stated in the first section that the later terrestrial measures in the same place, as far as they go, give results that agree perfectly with these. In order to make this measure and that of Svanberg agree in all points, it is necessary to suppose an error of 12″ or more in the French observations of latitude at Kittis.

Reasons for retaining this measure.

From the excellence of the instrument, the reputation of its maker, the care and fidelity of the observers, as shown in the points that have been examined, and the circumstance of their having repeated the observations under the fear that some error had crept into the first set, we have no hesitation in expressing our opinion that this is *impossible*. And we are glad to find that M. Rosenberger, after a careful examination of all the observations, (see the *Astronomische Nachrichten*, No. 121, 122.) has come to the same conclusion. From the difference of the altitudes of α and δ Draconis, compared with their known difference of declination, he has shown that the line of collimation was in the same state before the journey from and after the return to Tornea, as well as before the journey from and after the return to Kittis. And from observations made in France with the same instrument, (see the *Dégré du Méridien entre Paris et Amiens*,) it appears that after repeated voyages the line of collimation was not sensibly changed. The length of the arc which M. Rosenberger is inclined to adopt, is 55,020.16 toises, and the difference of latitude 57′ 30″.44; whence 1° = 57,405.02. The mean latitude is 66° 19′ 37″.

Methods followed in the verification of the arc of J. Cassini.

In the measure which forms the principal subject of the work entitled *La Méridienne Vérifiée*, a base of 6224 toises was measured near Dunkirk, one of 5094 toises near Amiens, one of 5749 toises near Paris, one of 7492 near Bourges, one of 4422 near Rodéz, and one of 7929 toises near Perpignan. The Dunkirk base crossed the entrance of the harbour. This part was not measured, but its length was ascertained by drawing a line perpendicular to the base, and finding by trial the point at which the rays coming from the signal made with this perpendicular an angle of 45°. The base measured near Bourges was one of the sides of a principal triangle. The base near Paris (on the road to Fontainbleau) was measured with four iron rods of 15 feet each; but all the others were measured with fir rods, well painted, and armed at the ends with iron caps. These wooden rods were 18 or 24 feet long, 3 or 4 inches broad, and 2 inches thick; they were compared three times each day with four iron rods of 3 feet each, which had been compared at the temperature of 14° of Reaumur, (63° of Fahrenheit,) with a line of 10 toises traced in the *salle de la Méridienne* of the Observatory at Paris. The mean of the difference was applied as a correction to the length of the wooden rods; it would appear also, (though we have not found any distinct statement,) that a correction was applied for the temperature of the iron rods at the time of comparison. In all cases the rods were applied end to end. The bases were measured at least twice: that near Paris five times. In the bases of Bourges and Rodéz, the angles made by the rods with the horizon were observed, and allowance made for the inclination.

The signals were generally church-towers, windmills, &c.; in a few instances it was found necessary to erect posts or other signals where no conspicuous object could be found.

The angles were measured with a quadrant of two feet radius, and were reduced to the centre of the station. The observed angles were altered to make the calculated lengths of the bases of verification and the calculated azimuth agree with those observed; but in no case did the alteration exceed 5″.

The azimuth of one side of a triangle was determined at each of the principal stations, (Dunkirk, Paris, Bourges, Rodéz, and Perpignan,) by observations of the Sun near the horizon.

South of Bourges, the observed angles were reduced to horizontal angles. The calculation of the terrestrial arc of meridian was made by the method of parallels and perpendiculars.

The sector for celestial observations was of 6 feet radius, and had an arc of 50°, divided by means of its index. The general accuracy of the arc was verified by taking angles all round the horizon, and observing whether their sum amounted to 360°; and the equality of the divisions, by determining the zero point from observations of different stars. The telescope had an internal micrometer. The only stars on which their determinations rest, are α Lyræ, α Cygni, α Persei, Capella, γ Draconis, and η Ursæ Majoris. Each star was observed eight or ten times at each station; and the sector was several times reversed in the course of each series. The final result was, that the length of the arc between Dunkirk and Paris was 125,431 toises, and its amplitude (or the difference of latitudes of the extremities) 2° 11′ 50″.26; between Paris and Bourges, 99,990 and 1° 45′ 7″.33; between Bourges and Rodéz, 155,767 and 2° 43′ 51″.5; between Rodéz and Perpignan, 94,308 and 1° 39′ 11″.2. The latitude of Paris was supposed to be 48° 50′ 10″, or 48° 50′ 12″. Of the excellence of this measure we conceive there can be no doubt.

Method used by Boscov

In the survey conducted by Boscovich, the bases were measured with wooden rods of 27 palms (about 18 French feet) each. These were compared continually (by means of beam-compasses, as described in our general account) with an iron rod of 9 palms, that had been measured by a French iron toise,* furnished by Mairan. Corrections for temperature were applied: the

---

* About 1″ of the difference of these results depended on the inequality of the degrees on the limb, as ascertained in the verification.

* It is stated in a note to the French translation of Boscovich's Work, that this toise was shorter than the *toise of Peru* by $\frac{6}{15}$ of a line, and shorter than the *toise of the North* by $\frac{1}{15}$ of a line. The latter is the same as the toise used in the French arc last described. We know not on what authority the difference between the *toise of Peru* and the *toise of the North* is given: in every other statement that we have seen they are asserted to be equal. See the *Base du Système Métrique*, tom. iii. p. 413; where the comparison of Mairan's toise with the others will be found.

standard temperature was the same, we presume, as that adopted in the Peruvian measure, or 13° of Reaumur's scale. The base near Rimini consisted of two parts, making an angle of 176° 52′ 15″; a part of it crossing a river was measured by a triangle. The rods were supported on trestles; they were not placed in contact, but the distance between their extremities was measured. In uneven ground they were placed in a horizontal position; and the end of one rod was made to touch a plumb-line suspended from the end of the other. Allowance was made for the curvature of the rods when it appeared sensible. The signals were a sort of pyramidal huts, made of large branches of trees. The angles were measured with a quadrant of three feet radius, made by a priest. The triangles were calculated in the same manner as those of Peru. The azimuths were determined by three observations of the setting Sun at Rome, and three at Rimini. The length of the meridian arc was found by parallels and perpendiculars, calculating from the base of Rimini, to be 123,221.3 toises. The sector for celestial observations (made by the same priest) was of nine feet radius; it was similar to that described in our general account, with this difference, that the object-glass as well as the eye-piece of the telescope were attached to the bar, and independent of the intermediate tube; and that the graduations were upon a straight piece, sliding in a groove with a micrometer-screw, forming, in fact, a line of tangents divided into equal parts. The bar, &c. were of iron, and the slider of brass, and an apparatus was made for observing whether the difference of expansion would produce any sensible effect: Boscovich states that he never found it sensible. The stars observed were α Cygni and μ Ursæ Majoris: the number of observations 48. Between the first observations at Rome and the observations at Rimini, the line of collimation had altered its position by more than 2′; and on repeating the observations at Rome, its position was again changed. But as the sector was reversed several times during each series of observations, and the results of the different observations of each series agreed very well, there seems no reason for doubting the accuracy of the ultimate result. The mean amplitude is 2° 9′ 47″, whence 1° = 56,966.8 toises. But as the base near Rome was greater by the measure than by calculation, and some of the sides are lengthened by a different calculation, (Boscovich does not specify what,) and as some of the celestial observations appeared preferable to the rest, Boscovich adopted as the length of 1°, 56,979 toises. As Mairan's toise was shorter by $\frac{1}{29}$ of a line than the toise of Peru, these numbers ought to be diminished by $\frac{1}{25000}$ of the whole. The mean latitude is 42° 59′.

We have given every thing which seems necessary to enable the reader to judge of the value of this measure. Objections have been made to some parts of it by the Baron de Zach. (*Correspondance Astronomique*, vol. vi.) The azimuth observed at Rimini was reobserved by Zach, and the results differ more than 1′. From whatever source it rises, this is of no consequence, as the chain of triangles follows very nearly the direction of the meridian. The same Astronomer has calculated from the observations of Boscovich the latitude of Rimini, and finds that it differs nearly 4″ from that which he has determined by 110 observations of Polaris and α Aquilæ with a repeating-circle. But there is a fallacy in his mode of observation. The advantage of observing, with a repeating-circle, stars on both sides of the zenith, consists in this: that if the declinations of these stars have been determined by an instrument which has no constant error, the constant error of the repeating-circle will be eliminated from the result. But the declination of α Aquilæ used by Zach, was determined by the same repeating-circle, and differs from that commonly used; consequently, his results are affected with the constant error which affects the observations of Polaris. And as the sector of Boscovich was reversed three times during the observations of α Cygni at Rimini, and five times during those of μ Ursæ Majoris, we cannot allow the result to be set aside for any observations made with a repeating-circle.* From the appearance of the observations, and the character of the observer, we consider that great reliance may be placed on the results of this measure.

Methods followed in Lacaille's Measure at the Cape of Good Hope.

The standard used by Lacaille was an iron toise, constructed by the same artist who made the toise of Peru and the toise of the North. From this was made a wooden toise, terminated with brass plates, and exactly of the same length. By means of these, the measuring rods (four fir-rods, each 18 feet long, 3 inches broad, 2 inches thick, and well painted) were verified four times each day. Nothing is mentioned of a correction for temperature; Lacaille merely observes, that the sky was clouded and the South-West wind strong, and that nothing was to be feared on the score of temperature. It would seem that the rods were laid on the ground: Lacaille himself made the contact. Only four triangles were used. The signals were fires, rocks, &c. The angles were measured with a three-feet quadrant; and reduced to the centre of the station and to the horizontal angle. The azimuth was determined by 17 observations of the rising Sun at the Cape Observatory, which was the Southern extremity of the arc. The meridian arc was computed by parallels and perpendiculars. The amplitude was determined from observations made with the same sector which was used in the verification of the French meridian. Sixteen stars were observed at the Northern station (Klipfonteyn) for six days, the sector being three days in one position, and three days in the reversed position. The number of observations at the Cape was more considerable; they are to be found in Lacaille's *Fundamenta Astronomiæ*. The statements of Lacaille respecting the error of collimation (*Astron. Fund.* p. 158.) appear quite satisfactory. The deduced amplitude with Lacaille's last corrections (*Fundamenta*, p. 184.) was 1° 13′ 17″.5; the meridian arc 69,669.1 toises; whence 1° = 57,034.4 toises. The mean latitude 33° 18½′.

It is proper to remark, that Lacaille was so much surprised at this result, that he repeated the measure of the base and all the calculations. The observations of terrestrial angles and celestial zenith-distances did not seem subject to any doubt. Whatever be the consequence, we conceive that this measure must be received as equally certain (excepting, perhaps, some doubt about the trifling correction for the temperature in the measure of the base) with any of the former, and almost any of the subsequent measures.

The localities have since been examined by Captain Everest:† (*Astronomical Transactions*, vol. i.) it ap-

---

* We have just received (through the kindness of the author) Mr. Rumker's observations made at Paramatta. The difference of the latitudes as found by the mean of many repetitions North of the zenith, and the mean of many South of the zenith, is 16″. The instrument is made by Reichenbach.

† We believe that if this distinguished officer had not been pre-

pears that there are large mountain masses to the North-West of the Northern extremity, and to the South-West of the Southern extremity, the effect of which would be to diminish the apparent difference of latitudes.

Methods used by Liesganig.

In Liesganig's arc, the standard was an iron toise, compared, at the temperature 13° of Reaumur, ($61\frac{1}{4}$° Fahrenheit,) with the *toise of Peru*. The measuring rods were each six Vienna fathoms long, spliced like the mast of a ship; they were laid on the ground, and placed in contact. The angles were observed with a quadrant of $2\frac{1}{2}$ feet, that had been carefully verified; they were reduced to horizontal angles. The azimuth was determined by observations of the Sun near the horizon. The meridian arc was calculated by parallels and perpendiculars. The sector of 10 feet radius was similar in all respects to that of Boscovich; its divisions were verified. The stars observed were α and β Aurigæ, α and δ Cygni, γ Draconis, and ι Herculis, (set down as μ Draconis;) each star was observed three or four times in each position of the sector, which was only once reversed. The concluded amplitude was 2° 56′ 45.″5; and the concluded arc of meridian 172,796 Vienna fathoms = 168,149 toises.

We have already stated the reasons for rejecting this measure. If we adopt for the Southern part of the arc the numbers given by the later survey, we ought to increase the meridian arc by 264 toises. But it appears from Zach's statements, (who, however, is no friend to the Jesuits,) that the astronomical observations were falsified. It will be better upon the whole to reject any conclusion derived from this arc of meridian.

Methods pursued in Beccaria's measure.

In the survey made by Beccaria, the base was measured with wooden rods laid on trestles. Two small parts were added by triangulation. The toise (compared at 13° of Reaumur with the toise of Peru) was furnished by Lacondamine: and the correction used for the temperature was Lacondamine's. The signals in general were posts. The angles (observed with a quadrant like that of Boscovich) were reduced to horizontal angles, and these to the angles formed by the chords. The azimuth was observed, and the calculations made, as in the last-described surveys. The sector* was nearly similar in construction to that of Boscovich. The stars observed were α and δ Cygni, and β Aurigæ: the sector was reversed twice or three times at each place. The details of the micrometer readings, &c. are not given. The concluded distance and amplitude were 64,889.6, and 1° 7′ 44″.71, the extreme difference of the results from the three stars amounting only to 2″. It is unnecessary to enter into greater details, as the same line has since been surveyed by MM. Plana and Carlini, whose conclusions (which we shall shortly give) are undoubtedly more accurate than those of Beccaria.

Methods used in North-America arc.

In the measure of the line between Maryland and Pennsylvania, by Mason and Dixon, the whole was measured with two "rectangular levels, or measuring frames." As we do not perfectly understand the description of them given in the *Phil. Trans.* 1768, we shall copy it *verbatim.* "The levels used in this work were each 20 feet in length, and 4 feet in height. They were made of pine, an inch thick, and in form of a rectangle; the breadth of the bottom board was $7\frac{1}{2}$ inches, that of the top 3 inches, of the ends $4\frac{1}{2}$ inches, and the bottom and top were strengthened with boards firmly fixed to them at right angles. The joints were secured with plates of iron, and the ends were plated with brass. The plumb-lines used in setting them level were 3 feet 2 inches in length, and hung in the middle of the levels, being secured in a tube from the wind, in the manner of carpenters' levels; wherefore we called these by the same name." The levels were frequently compared with a brass standard of 5 feet, and the temperature was noted. The allowance for expansion was taken from Smeaton's experiments, and the length was reduced to what it would have been if the brass rod had been used at the temperature 62° of Fahrenheit. By fixing in the ground a stake with a movable piece of iron, which was brought to a certain mark on each level, it was easy to observe whether one level moved when the other was placed in front of it. The line was carried over a few rivers by a triangle, as in the former surveys. For the azimuth, a clock was regulated by equal altitudes, and the clock time of stars' culminations being found, a transit-instrument was directed to them at that instant, and by means of it a meridian mark was fixed; thus the azimuth of a given line could be found, or the direction of a meridian could be fixed. The lines measured were the following. N P, fig. 35 = 78,290.72 feet, in the direction of the meridian: P a = 2,991 miles; this line is in such a direction that if continued to the length of 10′ of a great circle, it would meet the parallel of latitude passing through P: a C = 45.5 feet, in the meridian. C D = 26,608.06 feet, in the direction of the meridian. (These two parts were measured separately from a mistake in fixing the point C, which ought to have been in the parallel of P.) D B = 1491 feet; and the angle C D B = 93° 28′. B A = 434,011.64 feet, making an angle of 3° 43′ 30″ with the meridian. Hence, the distance of the parallels of N and P is 78,290.7 feet; that of P and a, − 14.1; that of a and C, 45.5; that of C and D, 26,608.1; that of D and B, 89.8; that of B and A (computed as described in our

---

vented, by his absence from Europe, from consulting Lacaille's account of the survey, he would have found that some of his objections were without foundation. Lacaille states that the ground was cleared and levelled for the base measure; he states that the instruments were not placed at the centre of the stations, (which was rarely done before the English survey,) and gives the numbers necessary for the reductions. The magnitude of fires visible at the distance of 45 miles need not, perhaps, be so great as to throw any great uncertainty on the terrestrial measure. The instability of the observatory, though always injurious, is of comparatively little consequence, we conceive, in observations with the zenith-sector, and, with reasonable care, its effects can be easily detected.

* Through the politeness of the Members of the Turin Academy we have been allowed to examine this sector, which is now preserved at their apartments. We are at a loss to conceive how such errors can have been committed as those attributed to Beccaria's observations. The tube containing the object-glass appears to be firmly attached to the bar; and the object-glass, though not quite tight in its cell, is tight enough to prevent accidental derangement. This tube is unconnected with the rest of the tube. The eye-piece also appears to be firmly connected with the bar. The object-glass-tube projects about two inches beyond the last of its two supports, and the eye-piece about four inches beyond the last of its supports. Can the weight of the telescope tube (weakly attached to the axis) have twisted the eye-piece? Or are the divisions of the tangent-scale, or the length of the radius, wrongly estimated? No other explanation suggests itself to us. It must be remarked that the wires in the eye-piece, and the plumb-line, are wanting: the pin for the plumb-line suspension is as good as those commonly used. We have no hesitation in saying that we should place more confidence in the observations made by any careful person with this instrument, than in those made with Mechain's circle. The character of the observer, as it appears to us, can alone explain the errors of the observations.

general account) 433,078.8; whence the distance of parallels of N and A is 538,098.8 feet. As the five-feet brass rod, on comparison with the Royal Society's standard, was found to be too short by $\frac{13}{360000}$ of the whole, these numbers ought to be diminished by 19.4; and the distance of the parallels is 538,079.4 feet. By a comparison of the standard just mentioned with the toise of Peru, instituted on this occasion, it was found that the toise = 76,734 inches; whence the distance of the parallels = 84,147.2 toises.

The observations of stars were made with a six feet sector, constructed by Bird, in which the plumb-line was made to bisect a dot at the centre of the instrument. The stars observed were α Lyræ, γ Andromedæ, β Persei, δ Persei, β Aurigæ, Castor; Capella also was observed, but the result disagreeing a few seconds from that given by the others, was rejected. Each star was observed at N and P, three or four times in each position of the sector. The sector was reversed only once at each station. Finally, the difference of latitude = 1° 28′ 44″.99, and the mean latitude 39° 12′; whence 1° = 363,772 feet = 60,628.7 fathoms = 56,888.3 toises. The Royal Society's standard yard has been found by Capt. Kater (*Phil. Trans.* 1821) to be longer than Shuckburgh's by .001365 of an inch; whence the distance of parallels is 538,099.8 feet, and 1° = 363,785 feet = 60,630.9 fathoms, by Shuckburgh's standard.

The only chance of error in this operation consists (we conceive) in the possibility of losing in the measure some whole number of level-lengths. This was provided against with tolerable certainty by previously measuring the whole line with a chain, and fixing posts at certain distances. Of the goodness of the astronomical observations we think there can be no doubt. The results of this measure must, we think, be received as equal in authority to those of any other measure.

The survey of 1787, connecting the meridians of Greenwich and Paris, has sometimes been used in the estimation of the degree deduced from the French measures. The meridian arc, of which the Southern extremity is in France, has sometimes been a little extended by taking Greenwich for its Northern termination. We mention this only to record our protest against such an extension. The chain of triangles connecting the meridians runs East-South-East, and West-North-West, and is of considerable length, and consequently the smallest error in the azimuth (which it is impossible to avoid) will produce a considerable error on the length of the meridian arc.

The bases on which the operations of Delambre and Mechain were founded, (at Melun and Perpignan,) were measured with rods of platinum, 2 toises long, 6 lines broad, and 1 line thick. To each was attached, at one end, a rod of brass; the proportion of the expansions of brass and platinum being known, the expansion of the platinum rod was inferred from the observed difference of expansion of the two rods. This apparatus was enclosed in a wooden box. Four of these compound rods were used: they were placed on trestles, not in contact, the distance being measured by a small slider. The lengths of the bases were expressed in numbers of the length of the toise of Peru, taken at the temperature of 13° of Reaumur, or 61¼° of Fahrenheit.* Allowance was made for the inclination of the bars. The bases consisted each of two parts, making a small angle. The length of the base of Melun was 6075.9 toises· that of Perpignan 6006.25. The length of the latter calculated from the former, through the chain of triangles, differed only 11 inches from the measured length. The angles were observed with repeating-circles. The triangles were calculated as spherical triangles, by Delambre's method. (TRIGONOMETRY, Art. 182.) The azimuths were determined by observations of the Sun near the horizon, and by measures of the angular distance of a signal from the Pole-star. (TRIGONOMETRY, Art. 185.*) The arc of meridian was then calculated by the method which (in our general account of methods) we have described as Delambre's. In the prolongation of this arc to Formentera, the same methods were used, except that the azimuth was ascertained by transits as described in TRIGONOMETRY, Art. 185. The latitudes were found almost entirely by observations of the Pole-star, and β Ursæ Minoris, made with Lenoir's repeating-circle. To give an idea of the extent to which this instrument was used in these determinations, it will be sufficient to state that the latitude of Formentera was fixed by 2500 observations of Polaris, and 1400 of β Ursæ Minoris.

We have already mentioned the discordances in the observations of Mechain at Barcelona and Montjouy, and the doubt thrown by them on the results of observations with the repeating-circle. They have been considered by M. Nicollet in the Memoir before referred to, (*Conn. des Temps.* 1831, *Additions*:) and his conclusions (omitting every thing relating to the inability of the telescope to separate ζ Ursæ Majoris) appear to us perfectly correct. Mechain's observations at these places were not confined to the Pole-star and β Ursæ Minoris, but included several stars passing to the North, and several passing to the South of the zenith. Now M. Nicollet shows that if we use Piazzi's declinations, and find the latitude of each place, first by a mean of the observations of stars passing North of the zenith, and next by a mean of those of stars passing South of the zenith, and take the mean of these results, the difference of latitudes is almost precisely what we should have expected from the known distance of parallels; and thus the difficulty disappears. It has been answered, (*Philosophical Magazine*, March 1829,) that if we compare the observations on the same stars made at the two stations, as with zenith-sector observations, the original difficulty remains. But we think that the author of this answer has not sufficiently considered the nature of the defect attributed to repeating-circles. Of the stars observed at both stations, only one passes South of the zenith. Now if the *constant error* of the circle had undergone any alteration (as is probable after the interval of a year) *all* the stars North of the zenith would give the same error, and with the same sign in the difference of the latitudes. But the stars South of the zenith would give the same error with a contrary sign, and in fact the only South star observed

---

* As there has been a little confusion respecting these reductions for temperature, the reader is referred to the *Phil. Trans.* 1826, p. 568, for an abstract of all the passages in the *Base du Système Métrique* relating to this point, as well as to the comparison of the new standard with the ancient and foreign standards.

* In the Essay on TRIGONOMETRY to which we have referred, it is said that the azimuth is determined by a right-angled spherical triangle. This is only true when the signal is exactly in the horizon; when it is elevated or depressed, it is necessary to calculate the zenith angle of the triangle, whose angles are at the zenith, the Pole, and the signal.

at both places, gives a discordance of an opposite kind. We think, therefore, that M. Nicollet is quite right in fixing the latitude of Montjouy at 41° 21′ 44″.535.

The latitude of Mountjouy is, however, of no essential importance. It is much to be wished that the latitudes of Dunkirk and Formentera were determined with greater certainty. The latter rests on an enormous number of observations, but entirely on stars North of the zenith, and with a circle whose level was attached to the axis; it is probably subject to a much greater error than if it had been fixed by ten observations with Graham's or Ramsden's sector. In the determination of the latitude of Dunkirk, many observations were rejected; and in that of Paris, Mechain rejected observations by thousands, apparently preserving only those whose results presented the greatest agreement. The latitudes of the other intermediate points are still more doubtful. In our present uncertainty we shall adopt from the *Base du Système Métrique* the following numbers: latitude of Dunkirk 51° 2′ 8″.7; latitude of Formentera 38° 39′ 56″.1; distance of parallels 705,189.4 toises; mean length of degree 57,007 toises.

Svanberg's methods.

The base measured by Svanberg was nearly in the same line as that measured by Maupertuis and Clairaut. The measuring rods were iron bars of six mètres each. The observed length was corrected for the flexure of the bars, their horizontal inclination with the direction of the base, &c., but the correction for temperature remains uncertain from a cause which deserves a distinct explanation.

On the manner of using standard measures.

By a toise, or a yard, or a mètre, we mean a certain extent of space in one direction, without any reference to wooden rods or metallic bars. But as it is impossible to measure a line without some material standard, we are compelled to adopt as the practical definition of a toise or a yard, &c. the length of a certain bar of metal, called a standard. If this length be invariable, the measure is fixed without any further condition. But if from change of temperature, or any other change of circumstances, the length of the bar (as compared with the length of others not subjected to the same trial) be found to change, then we must specify the degree of temperature, and the other circumstances under which this certain bar must be placed in order to present the exact length required. If then the length of a base, or the length of a pendulum, has been measured with the standard, at a higher temperature than that specified, and if we know that at this higher temperature the bar was longer than at the specified temperature, it is plain that the length of the bar has not been contained so many times in the line measured as it would have been if used at the specified temperature, and, consequently, the resulting number (which expresses how often the length of the bar is contained in the line) must be increased. Similarly if measured at a lower temperature the number must be diminished.

Reduction for temperature.

It was not till geodetic measures had acquired considerable accuracy, that this refinement was thought of. And when necessity compelled Philosophers to fix on some temperature for the measure of the standard bar, convenience directed them to choose one which could be commanded at all times with little trouble, and which was as likely to occur in ordinary measures as any other. Thus the French toise was the measure of the iron bar called the *toise of Peru* at the temperature of 13° Reaumur, or 61½° Fahrenheit, or 16¼° Centigrade; the English yard was the measure of a brass bar, (or rather some one of several brass bars,[*]) at the temperature of 62° Fahrenheit.

Temperature for the old standards.

But the new French measure was adopted at a time when all other considerations gave way to theory. The mètre is *defined* by 443.296 lines of the toise of Peru, at the temperature 13° of Reaumur. But it is *represented* by the length of a standard platinum bar, at the temperature of freezing water, or 0° of Reaumur's and the Centigrade scale. This change of temperature for the measure of the standard, has introduced no little confusion into the subject of measures generally.[†] In the instance now before us, additional confusion is introduced by the change of the metal used for the construction of the standard.

It is uncertain whether the iron bar used by Svanberg was compared with the platinum standard preserved at Paris, at the temperature of 0°, or 16¼° Centigrade. If the expansions of the two metals, with the same change of temperature, were the same, this would be of no consequence. But their expansions being different, if the two bars had the same length at the temperature 0°, they would not have the same length at the temperature 16¼°. If they were compared at the temperature 0°, it would be right to apply to the measured length of Svanberg's base, the correction corresponding to the expansion of iron between 0° and the observed temperature. If compared at the temperature 16¼°, the length must be corrected for the expansion of iron, between 16¼° and the observed temperature, and for the expansion of platinum between 0° and 16¼°. It is most probable that they were compared at the temperature 0°.

The signals for Svanberg's triangles were so constructed as to allow the light of the sky to be seen through them. The angles were observed with repeating-circles. The azimuths were found by observing the transits of the Pole-star and other stars over the same vertical; from equal altitudes of stars; and from observations of the Sun. The triangles and arc of meridian were calculated by Delambre's method. The latitudes were found by a great number of observations on the Pole-star, made with Lenoir's repeating-circle. The final results are, that the distance between the parallels of Mallorn and Pahtavara is 180,827.68 mètres = 92,777.98 toises, (or 180,794.06 mètres = 92,760.73 toises, if the standards were compared at the temperature 16¼° Centigrade;) the latitude of Mallorn = $72^{g}.8056872$ = 65° 31′ 30″.26; the latitude of Pahtavara = $74^{g}.6079728$ = 67° 8′ 49″.83; whence the difference of latitudes = 1° 37′ 19″.57. This ought to be diminished by 0″.28, because in the calculation of nutation, the true place of the Moon's node has been used instead of the mean place. Hence 1° = 57,198.9 toises.

There is no doubt of the general excellence of this measure. The astronomical determinations, we conceive, are not equal to those in the measure of the French

---

[*] For a comparison of Shuckburgh's, Bird's, Roy's, Ramsden's, and the Royal Society's standard, the reader is referred to a paper by Capt. Kater, in the *Philosophical Transactions*, 1821.

[†] The reader, who may think this explanation unnecessary, is referred for a proof of the confusion on this subject to the *Phil. Trans.* 1818, where Col. Lambton has applied an unnecessary correction to the length of the French arc; to the *Phil. Trans.* 1822, where Mr. Goldingham has applied a correction with the wrong sign to the length of the seconds' pendulum at London; and to Zach's *Correspondance*, vol. viii. p. 150, where Zach has fallen into an error in the comparison of Beccaria's toise with the French mètre.

Academicians in the same Country, but they are as good as could be made with the instrument employed. The anxiety of Svanberg and his companions to omit no reduction, whose value could be sensible, has led them into many refinements that are useless, and some that are erroneous,* but none to such an amount as to hurt the credit of the result.

The rods with which the first base was measured in England were thin glass tubes, 20 feet long, and about an inch in diameter, enclosed in wooden boxes, (except at the ends,) and supported on trestles. Each rod had at one end a small slider driven outwards by a weak spring; and the succeeding rod was pressed against it till the slider was pushed up to a certain point. But the apparatus ultimately adopted was a steel chain of 100 feet in length, consisting of forty links. One chain only was used in the actual measure, but another was carried for the purpose of occasional comparison. The mode of measuring finally employed was this. The chain was supported in several troughs resting on trestles, and extended by a weight of 28 pounds. In any position of the chain, two posts were necessary at each end. One post at the preceding end carried a pully, over which passed the rope sustaining the weight which stretched the chain. To one post at the following end was fixed an apparatus of screws, by which the chain was supported in opposition to the action of the weight, and by which it could be moved slowly. The other post at the following end of the chain carried a scale, to one division of which a mark on the end of the chain was brought by the screw motion; and the other post at the preceding end carried a scale, of which one division was brought by a screw motion to a mark at that end of the chain. When the chain was moved to the next position, the mark on the following end of the chain was brought to that division of the scale with which the mark on the preceding end had coincided. It will easily be seen that the correctness of the operation depends on the immobility of the scale-posts, (which are subject to no strain,) and that in fact three posts at each end were necessary. The expansion of the glass tubes and of the chain were determined by experiments expressly made for the measure. Corrections were applied for the temperature, the inclination, and the height above the sea. The length of the base on Hounslow Heath was 27,404 feet; of that on Salisbury Plain 36,575; and of that on Misterton Carr, (near the Northern extremity of the arc of meridian,) 26,842 feet. Several other bases were measured in different parts of the Kingdom.

The signals were usually flag-staffs, or white lights. The angles were observed with a large theodolite, made by Ramsden, three feet in diameter; an instrument undoubtedly superior to any other that had been used in similar observations. As with this instrument the horizontal angle was immediately observed, no reduction for the height of the signals was necessary. The horizontal angles were reduced to chord angles. The first azimuth was obtained from the meridian mark of the transit-instrument at Greenwich Observatory; afterwards the azimuths were found by observing with the theodolite the Pole-star at its greatest azimuth. The meridian arc was computed by parallels and perpendiculars. The distance of the parallels of Dunnose (in the Isle of Wight) and Arbury Hill (near Daventry) was found to be 586,319.5 feet; that between the parallels of Dunnose and Clifton (near Doncaster) 1,036,337 feet; and that between the parallels of Dunnose and Burleigh Moor 1,442,852.5 feet. The chains were measured with Ramsden's brass yard, which it appears from Captain Kater's comparison (*Phil. Trans.* 1821) exceeded Shuckburgh's, now adopted as the standard, by .002505 parts of an inch, or $\frac{1}{14370}$ of the whole. Thus the meridional distances are found to be 586,360.3, 1,036,409.1, and 1,442,952.9 feet, when measured by Shuckburgh's standard.

Meridian Measures.

The difference of latitudes was determined by observations with a zenith-sector made by Ramsden, apparently the best which has ever been constructed. For a description of this superb instrument we must refer to the *Phil. Trans.* 1803, to the *Account of the Trigonometrical Survey*, vol. ii., or to Pearson's *Practical Astronomy*, vol. ii. It is sufficient here to state that the telescope was eight feet long, and carried the arc; that it was moved by an external micrometer; that the plumb-line bisected a dot at the centre; and that from a very severe examination it does not appear that the error of collimation was sensibly altered during the observations. For the difference of latitude of Dunnose and Burleigh Moor, eight stars were observed; those of the other stations were found by a greater number. In general each star was observed about eight times, the sector being reversed after every day's observation. The amplitudes were thus found to be, between Dunnose and Arbury Hill 1° 36′ 19″.98; between Dunnose and Clifton 2° 50′ 23″.38; between Dunnose and Burleigh Moor 3° 57′ 13″.1. The mean latitude of the last arc is 52° 35′ 45″; the length of 1° = 364,968.3 feet. The middle latitude between Dunnose and Arbury Hill is 51° 25′ 18″; the length of 1° = 365,208.4; the middle latitude between Arbury Hill and Clifton is 52° 50′ 30″; the length of 1°, 364,625.1; the middle latitude between Clifton and Burleigh Moor 54° 0′ 56″; the length of 1°, 365,002.5. By a comparison of the French mètre with Shuckburgh's standard, Captain Kater (*Phil. Trans.* 1818) has found the mètre = 39.37079 inches; and as the mètre = 443.296 lines of the toise of Peru, it follows that the toise = 6.394596 feet. Hence the distance between the parallels of Dunnose and Burleigh Moor = 225,651.9 toises. We believe the results of this measure to be far more exact than those of any of the measures hitherto described.

Methods used in the East-Indian survey.

The methods adopted by Colonel Lambton were in almost all respects the same as those used in the English survey. The base near Madras was measured with a steel chain which was occasionally compared with a standard chain that had been measured by Ramsden's brass standard when the temperature was 50° of Fahrenheit; the length of the base was therefore corrected for the expansion of the steel to this temperature, and

---

* Among these we may reckon Svanberg's method of taking the mean of observations made with the repeating-circle. Instead of taking the difference between the first and last readings, and dividing by the number of multiplications, he takes every possible combination of one, two, three, &c. multiples, and gives to each a vote proportional to its number. But it seems plain that every observation of a double angle is perfectly independent, (as the telescopes are pointed anew for every observation,) and, therefore, we have no right to take two or three double angles together, as we should have if it were possible to observe at once four or six times the angle. Every observation being independent, and therefore all being à *priori* equal in accuracy, the probably best determination is the mean of all, that is the difference of the first and last readings divided by the number of multiplications. In the instance that he has mentioned, (p. 33.) the difference of determinations, by Svanberg's, and by the common method, is 1″.4.

for the contraction of the brass to the temperature 62°. The expansion of the chain was determined by independent experiments. Corrections were applied for the inclination, the height above the sea, &c. The same course was pursued in the measure of the base near Bangalore, of that in the Coimbetoor, of that near Palamcottah, of that near Gooty, and of that near Daumergidda: their lengths were respectively 40,006, 39,794, 32,301, 30,507, 32,609, and 30,806 feet. On comparing the chains previous to the measure of the base near Gooty, there appeared to be some reason for supposing that the standard chain had altered its length; and it was then compared by means of beam-compasses with a brass bar.

The signals were flag-staffs and white lights. The angles were observed with a large theodolite. The observed horizontal angles were reduced to chord-angles, and the triangles calculated as plane triangles. The azimuths were determined by observations of Polaris at his greatest azimuth, made with the theodolite. The meridian arc was calculated by parallels and perpendiculars; but the principal stations were so nearly in the same meridian that no allowance was made for the difference between the perpendicular and the small circle passing through a station. Two different meridians were, in fact, measured; in the first of these (near the Coromandel coast) the meridional distance between Trivandeporum and Paudree was found = 574,328 feet; and in the second, the distance from Punnæ (near Cape Comorin) to Putchapolliam = 1,029,101; that from Putchapolliam to Namthabad = 1,489,131; and that from Namthabad to Daumergidda = 1,073,428 feet. To reduce these to Shuckburgh's standard, it must be observed (*Phil. Trans.* 1823) that the triangles extending over the shorter meridian arc, and the Southern part and 105,996 feet of the middle part of the longer arc, were calculated from the measure by Ramsden's chain; and those on the rest of the middle part and the Northern part from the measure made with the brass bar. The former is too long by .00250 inch, and the latter too short by .00064 inch in every yard. The lengths thus corrected are 574,368, 1,029,173, 1,489,198, and 1,073,409 feet.

The latitudes were found by observations with a zenith-sector of five feet radius, constructed by Ramsden, and similar to that used in the English survey. It appears that its error of collimation changed by a very small quantity during the operations, but was steady enough at each station. For the determination of some of the amplitudes, seventeen stars were used, each of which had been observed eight or ten times, the sector being reversed after every day's observation. The absolute latitudes depended on a smaller number of principal stars. The final results were as follows: latitude of Trivandeporum 11° 44′ 52″.6; of Paudree 13° 19′ 49″.0; latitude of Punnæ 8° 9′ 38″.4; of Putchapolliam 10° 59′ 48″.9; of Namthabad 15° 6′ 0″.2; and of Daumergidda 18° 3′ 23″.5. The latitudes of some intermediate points were observed, and in one of them it appeared that the disturbance of local attraction was sensible. The length of 1° is, in the arc from Trivandeporum to Paudree 362,988 feet, in the Southern part of the long arc 362,864, in the middle part 362,941, and in the Northern part 363,071 feet.

Considering the extent of this arc,* as well as the exactness of every part of the operations, we do not hesitate to state our opinion that it is superior to every other that we have described.

Metho used in remeas ment o Beccar arc.

Some triangles observed by the Baron de Zach, for the estimation of the accuracy of Beccaria's measure, were founded on a base of little more than 600 yards in length. An erroneous reduction was applied for temperature, and the base was measured but once; MM. Plana and Carlini, therefore, measured a new base of nearly the same length, and in nearly the same situation. The measuring rods were of wood, 12 mètres in length, in the form of hollow parallelopipeds. To the preceding end of each was attached a metallic frame in the form of a hollow parallelogram and in the same plane as one side of the parallelopiped. A fine thread was stretched across this frame, so that when the rod was horizontal the thread was vertical. In measuring, every rod was placed horizontal upon trestles; the second rod was not made to touch the first, but was so placed that a fine dot near its following end was bisected by the thread carried by the frame on the preceding end of the first rod. By this simple contrivance the use of the plumb-line was entirely avoided, and there was no fear of disturbing one rod by the contact of another. The rods were compared after each of the two measures with a standard mètre, by means of a microscopic apparatus. Some triangles, observed with the repeating-circle, connected this with one of Beccaria's principal sides; and the rest of the triangles were observed by the surveyors of the French Government. A chain of triangles had also been observed, connecting Beccaria's with a base measured near the Ticino; and others connecting it with the triangles crossing the Alps, and ultimately with the bases measured in France. The results from the different bases agreed very nearly. The azimuth was determined at the Observatory of Turin, from the meridian mark of the transit-instrument. The parts of meridian were calculated by Delambre's formulæ. The length of Beccaria's arc, deduced from the base on the Ticino, was 126,385.25 mètres, or 64,845 toises.

The latitudes were determined by observations made with a repeating-circle. At each extremity, Polaris, and two stars South of the zenith, as well as the Sun, were observed; several series of observations were made on each; the mean of the latitudes given by Polaris was taken as one determination, subject to the constant error of the circle, and the mean of the latitudes given by the other stars and the Sun, as another determination, subject to the constant error with the contrary sign. The mean of these was free from the constant error. Thus the latitude of Beccaria's station at Mondovi was found to be 44° 23′ 44″.37; that of Andrate 45° 31′ 15″.44, the amplitude 1° 7′ 31″.07, less by 13″ than that given by Beccaria.

The whole of this measure, and in particular the determination of the latitudes, seem to have been made with so much care, that we must allow its excellence. It is, in fact, almost the only one in which proper caution has been used in the determination of the latitudes with the repeating-circle.

Meth used Hano meas

The apparatus used in the Hanoverian* base-measure is described in a pamphlet, entitled *Schreiben an den Herrn Olbers von H. C. Schumacher, enthaltend eine Nachricht über den Apparat, dessen er sich zur Messung*

---

* This arc has been extended by Captain Everest to latitude 24° 7′. The details are not yet published.

* We had not received the account of this and the following measure when the first section of this Treatise was sent to press.

der Basis bei Braack im Jahre 1820 bedient hat. Three bars of hammered iron were used, each 12 French feet in length, and 1$\frac{1}{4}$ inch broad and deep; the ends were armed with steel plates, at one end flat, and at the other spherical. They were carried in wooden boxes completely closed, the ends only projecting; to prevent flexure they were supported by counterpoises applied at different parts. The boxes were placed on trestles of variable heights; the rods were placed horizontal, and at the same height, as long as the nature of the ground allowed. A small interval was left between the flat end of one rod and the spherical end of the next, and this was measured by dropping between them a glass wedge whose depth was forty-eight times the thickness of its back. When it became necessary to alter the height of the bars, a cylinder of bell-metal was employed, which by means of a level was placed very exactly vertical, and the same glass wedge was used to measure the distance between the top of the cylinder and the upper bar, as well as between the bottom of the cylinder and the lower bar. Of the length of the base, and the details of the survey, we find no mention; and we believe that no further account has been published.

The difference of latitudes of the observatories at Göttingen and Altona, was ascertained by observations made with Ramsden's zenith-sector, (the same which was used in the English survey.) Forty-two stars were observed at both places; each about six times in each position of the sector. In general, the sector was reversed after each night's observation. The details will be found in the *Bestimmung des Breitenunterscheides zwischen den Sternwärten von Göttingen und Altona, &c. von* C. F. Gauss. The results were, latitude of the observatory at Göttingen, 51° 31′ 47″.85; of the observatory at Altona, 53° 32′ 45″.27; amplitude of the arc, 2° 0′ 57″.42. The last is, undoubtedly, one of the most accurate determinations ever made.

It is stated by M. Gauss that the observatory of Altona is 115,163.7 toises North, and 7.2 toises West, of that at Göttingen. This estimation is founded on the base mentioned above; the measuring bars have not been definitely compared with the French toise, but M. Gauss states, that it is impossible that there can be any serious error in the estimation. The resulting length of one degree is 57,127.2 toises.

The arc measured by M. Struve, and extending from Jacobstadt, on the Düna, to the island Hochland, in the Gulf of Finland, depends on a base of 2315 toises. This line was but once measured with iron bars of two toises in length, each of which carried at one end a lever of great sensibility, (*Fühlhebel,**) by which the contact with the next was made. By means of a microscopic apparatus, they were compared with a standard made by Fortin. To detect any error in the base measure, it was divided into two parts, and these were connected by a triangulation. The signals were poles supported by wooden pyramids. The angles were measured with Reichenbach's universal instrument, (a sort of theodolite,) in which the horizontal circle was 14 inches in diameter. For the azimuths, the Pole star was observed with the same instrument, at Jacobstadt, Dorpat, and Hochland; at Dorpat, also, another determination was obtained from the meridian-mark of the transit-instrument. The triangles were calculated by Legendre's theorem, and the distance of parallels by a method explained by Bessel in the *Astronomische Nachrichten*, No. 3. It consists in supposing arcs of great circles, A D, A F, &c., drawn from the station at one extremity A of the chain, fig. 36, to each of the other stations, and calculating each of the triangles A B D, A D F, &c., either as spherical triangles, or with the assistance of Legendre's theorem as plane triangles. Thus knowing A B, B D, and the angle A B D, the side A D and the angles B A D, B D A are found. Subtracting B D A from the sum of B D C, C D E, E D F, the angle A D F is found; and A D, D F, are known: hence A F, F A D, A F D, are found. This process is continued to the last station, as F; then all the angles at A being known, and the azimuth of A B being known, that of A F is known; also the length of A F is known; and then the distance of the parallels can easily be found by either of the methods already explained. The amplitude was found from observations of γ, ζ, and η, Ursæ Majoris, with an eight-feet transit-instrument adjusted to move in the prime vertical. It was carefully levelled, and was reversed after each night's observation. The clock (upon the goodness of which the exactness of this operation entirely depends) was made by Repsold. The latitudes were also determined by observations of Polaris and β Ursæ Minoris, with 18-inch circles made by Reichenbach: allowance was made for the flexure of the telescopes. By a mean, the latitude of Jacobstadt was found to be 56° 30′ 4″.7; that of Dorpat, 58° 22′ 47″.4; that of Hochland, 60° 5′ 9″.9. The terrestrial distances of the parallels were, from Jacobstadt to Dorpat, 107,281.6 toises; from Dorpat to Hochland, 97,538.5 toises. The lengths of 1° given by these parts are 57,108.8, and 57,165.5 toises. M. Struve remarks that the general flatness of the country, and the apparent absence of disturbing causes, would not have led him to expect so great a difference. An abstract of these operations will be found in the *Astronomische Nachrichten*, No. 164.

Meridian Measures.

Bessel's method of calculating the distance of parallels.

The method of determining the latitude by transits (upon which it appears that M. Struve principally relied) has been so little used that we are unable to form a decided opinion on its merits. But the well-known character of the observer, and the caution evidently employed in every part of the operation, leaves no doubt of the general accuracy of these results.

Continuation of the Indian arc.

Since the last sheet was sent to press, the account of the continuation of the Indian arc by Captain Everest, mentioned in the note to p. 212, has been published. The new bases at Takal Khera (near Ellichpoor) and near Kulliampoor, (in the vicinity of Seronj,) were measured with the same chain and referred to the same brass bar which Colonel Lambton had used. Their lengths were 37,913 and 38,412 feet. Night-signals were generally preferred, as it was found that in the healthy season of the year the nights were very favourable, and the magnitude of terrestrial refraction at night such as to make stations visible which were not visible in the day. The large theodolite with which the greater part of the triangulation was performed had sustained much injury from an accidental blow while used by Colonel Lambton for the purposes of general geography, and the limb was completely distorted. Colonel Lambton, however, by the use of wedges,

---

* We are not acquainted with the construction of this instrument.

screws, pullies, and wooden hammers, restored the circle so nearly to its original shape, that the difference between the readings on any point of the limb, and on the point 90° from it, did not exceed 26″. By altering the zero point nine times for each observed angle it was presumed that the effect of this distortion was almost annihilated. Great skill is shown in the apportionment of the errors of observation. In the computation of the triangles, Legendre's method was used; as it appeared to be more exact than the method of referring to the chord triangles (used generally by the English geodists.) The azimuths were determined by observations of Polaris, β Ursæ Minoris, and β Cephei, at their greatest digressions. The meridian arc was calculated by computing separately the intervals between the points where the sides of the triangles (produced if necessary) cut the meridian of Takal Khera. The meridional distance from Daumergidda to Takal Khera, as deduced from the Beder base, was 1,105,618 feet: that deduced from the Takal Khera base 1,105,381. The difference is not explained; Captain Everest has adopted the mean, or 1,105,499 feet. The distance from Takal Khera to Kulliampoor is 1,097,320 feet; and the results from the two bases at its extremities agree almost exactly. The amplitude was found by numerous observations of 24 stars with the zenith-sector used by Colonel Lambton. The extent of the Indian arc has now become so great that it is impossible to observe the same stars at both extremities with the sector, and therefore the absolute latitudes must be calculated from the catalogued places of the stars. Colonel Lambton's observations were therefore recomputed with the improved catalogue, and the united results are: latitude of Punnæ, 8° 9′ 31″.685; of Daumergidda, 18° 3′ 16″.075; of Takal Khera, 21° 5′ 51″.940; and of Kulliampoor, 24° 7′ 11″.851. For details we must refer to Captain Everest's interesting *Account of the Measurement of an Arc of the Meridian between the Parallels of* 18° 3′ *and* 24° 7′

Section 5.—*Measures of Arcs of Parallel.*

Method used in the measure of the arc of parallel across the mouth of the Rhone.

In the verification of the French meridian by Cassini de Thury and Lacaille, the arc of parallel extending from Mont St. Victoire, near Aix, to the meridian of a station near Cette was thus measured. In fig. 37, let P be the pole of the Earth; V, Mont St. Victoire; S, the station near Cette; V*s*, an arc of parallel; C K, H *u*, perpendiculars on P H, P V. By a triangulation founded on a base measured near Arles, and by observation of the azimuth of H at V, with the usual calculations by parallels and perpendiculars, H *u* = 24,710.7 toises, *u* V = 10,422.7; whence the distance of the parallels of H and V = 10,328.3, which, considering 1° = 57,048, corresponds to a difference of latitudes 10′ 52″. The latitude of V being found = 43° 31′ 50″, that of H is found. And the length of H *u* will not sensibly differ from the length of the arc of parallel passing through H; increasing this in the proportion of cos lat. H : cos lat. V, V *k* is found = 24,785.2. Now investigating the convergence of meridians, and applying it to the angle P V H, V H *k* is found; and V H C having been determined by the triangulation, C H *k* and C H P are found. From this angle, and the length of C H, c *k* is found in the same manner as V *k*: it is 33,149.5. By a similar process *c s* = 20,728.9. The sum or V *s* = 78,663.6.

Mea of Ar Paral

It has been explained in Section 3, that the difference of longitude of two places can be found if we have any means of comparing clocks regulated to the solar or sidereal time at those places. The most convenient method is, to observe from both places some instantaneous signal, and to note the time indicated by both clocks at the time of observation. In the present instance, the difference of longitudes was determined by observing from V and S the explosion of ten pounds of gunpowder at a point between them. The duration of the flash was estimated at less than half a second. The clocks were regulated by equal altitudes of the Sun and stars. By a mean of four explosions, on December 14 and 15, 1739, and January 4 and 5, 1740, the difference of longitudes was found to be $7^m\ 33^s\frac{1}{4}$ of time, or 1° 53′ 19″ of arc; whence 1° of parallel in latitude 43° 31′ 50″ = 41,618.

Of the observations for determining the clock errors, (upon which the difference of the longitude wholly depends,) no details are given. The extreme difference of the four determinations, which are quite independent, is 1½ second of time. The result, we imagine, is not subject to any great error, though the omission abovementioned makes it difficult to assert this positively.

Metho used i meas the E arc o rallel.

In the course of the English survey, several arcs of parallel have been measured. The only one which, from its length, appears worthy of confidence, is that between Beachy Head and Dunnose. The difference of longitudes was thus ascertained *geometrically*. Proceeding from the bases measured on Hounslow Heath and Salisbury Plain, by the method of parallels and perpendiculars, and considering the latitude of Greenwich = 51° 28′ 40″, and the length of 1° = 60,851 fathoms, the latitude of Beachy Head was found = 50° 44′ 23″.71. Similarly the latitude of Dunnose was found = 50° 37′ 7″.31. At Beachy Head the azimuth of the signal on Dunnose was found, by observing the angle between it and a staff at a convenient distance, and by observing with the great theodolite, the difference of azimuth of this staff, and the Pole-star at its greatest azimuthal digression. By nine observations the angle between Dunnose and the North meridian was found to be 96° 55′ 58″. Similarly, by seven observations at Dunnose, the angle between Beachy Head and the North meridian was found to be 81° 56′ 53″. The problem now to be solved is this: Given the astronomical latitudes of two stations on a surface (not necessarily spheroidal) differing little from a sphere, and their reciprocal azimuths, to find the difference of longitude, or the inclination of their meridian planes. The following beautiful solution is given by Dalby, and is the foundation of the method used in the English and Indian surveys; the considerations connected with it are almost sufficient for a complete theory of spheroidal triangles.

Diff of lo may foun reci obs of a

In fig. 38, let B and O be two stations sufficiently elevated to be reciprocally visible; O B the straight line described by the rays of light; B R, O S normals, drawn in the direction of gravity; let P R S be that line parallel to the Earth's axis of rotation which cuts both these normals. (There is but one such line, as will easily be seen by supposing the whole figure projected on an equatorial plane; and whether it coincides or not with the axis of rotation is of no consequence.) The azimuth of O as seen at B is the inclination of the planes O B R, P B R; similarly, the azimuth of B as seen from O is the inclination of B O S, P O S. With radius C *p* = 1 construct a sphere, and take two points b, o, whose astronomical latitudes are the same as those of B and O, and whose meridian planes coincide with their meridian planes; that is, let C b and C o be parallel to R B and S O. Now we are to find the relation between the azimuths of o seen from b, and b seen from o, and those of O seen from B, and B seen from O.

From R draw R G parallel to S O, or C o; and from S draw S Q parallel to R B, or C b. Then each of the planes G B R, O Q S, is parallel to $o\,b$ C; and P B R, $p\,b$ C, are the same plane; also P O S, $p\,o$ C, are in the same plane. Consequently, the inclination of the planes P O S, Q O S, is equal to the angle o; and the inclination of P B R, G B R, is equal to the angle at b. Hence the azimuthal angle at O is *less* than that at o by the inclination of the planes B O S, Q O S; and the azimuthal angle at B is *greater* than that at b by the inclination of the planes O B R, G B R. If then the inclination of B O S, Q O S, be equal to the inclination of O B R, G B R, the *sum* of the azimuthal angles at B and O will be equal to the *sum* of those at b and o. We must now discover in what cases those inclinations are equal.

First, they are equal when R coincides with S, as both inclinations then vanish. This happens when the figure is spherical, with any latitudes, or with equal latitudes when the figure is any solid of revolution.

Secondly, from B draw B H perpendicular on O S, and B L perpendicular on the plane Q O S; and from O draw O K perpendicular on B R, and O M perpendicular on the plane G B R. Then the tangent of the inclination of O B R, G B R, is $\frac{\text{O M}}{\text{K M}}$; and the tangent of the inclination of B O S, Q O S, is $\frac{\text{B L}}{\text{H L}}$. The numerators are equal, (as they are the perpendicular distances of two parallel planes at different points;) are the denominators also equal? To discover this, project the figure on the plane G B R, (fig. 39,) then the lines K M, H L will be equal, if O N, B N are equal. This will happen when B O N = O B N, which holds when the reciprocal depressions are equal. Further than this we cannot proceed; but it will easily be seen that O N, B N are very nearly equal in all cases where O and B are equally elevated above a surface whose curvature does not alter very rapidly. If unequally elevated, the error in the assertion (that the inclinations of O B R, G B R, and of B O S, Q O S, are equal) arises only from this circumstance, that a perpendicular to the horizon at O does not appear perpendicular when seen from B; the effect of which, as we mentioned before, is quite insensible. We may therefore assert, that, for all practical purposes, these inclinations are equal; and, consequently, that the sum of the azimuthal angles at B and O is equal to the sum of those at b and o.

The first conclusion that we shall derive from this theorem is, that the spherical excess in a spheroidal triangle is the same as in a spherical triangle, whose vertices have the same astronomical latitudes and the same difference of longitude. In fig. 40, let B O C be a spheroidal triangle, and $b\,o\,c$ the corresponding spherical triangle. Adding the equations

$$\text{POB}+\text{PBO}=pob+pbo,$$

$$\text{PCB}+\text{PBC}=pcb+pbc,$$

Measures of Arcs of Parallel.

we have

$$\text{POB}+\text{PCB}+\text{OBC}=pob+pcb+obc.$$

Subtracting

$$\text{POC}+\text{PCO}\qquad=poc+pco,$$

there remains

$$\text{COB}+\text{OCB}+\text{OBC}=cob+ocb+obo,$$

and, consequently,

$$\text{COB}+\text{OCB}+\text{OBC}-180^\circ=cob+ocb+obc-180^\circ.$$

Theorem for finding the difference of longitude.

We shall next observe, (and this, in fact, is the application for which the theorem was invented,) that any equation relating to the spherical triangle $p\,o\,b$, fig. 38, in which only $p\,o$, $p\,b$, $o\,p\,b$, and $o+b$ are concerned, is equally true if we substitute for them colat. of O, colat. of B, difference of longitudes of O and B, and sum of azimuthal angles at O and B, (these being respectively equal to the former.) Now (Trigonometry, Art. 117.) $\tan\frac{op\,b}{2}=\frac{\cos\frac{p\,b-p\,o}{2}}{\cos\frac{p\,b+p\,o}{2}}\cdot\cot\frac{b+o}{2}$, and therefore $\tan\frac{1}{2}\,\text{diff. longitudes}=\frac{\cos\frac{1}{2}\,\text{diff. latitudes}}{\sin\frac{1}{2}\,\text{sum of latitudes}}\times\cot\frac{1}{2}$ sum of azimuthal angles. This is the theorem to be used for finding the difference of longitudes. An examination of it by the method given in Trigonometry, Art. 161, will make it evident that, in general, a small error in the latitudes produces no sensible error in the determination, while an error in the azimuths is of great importance; but that when the latitudes are small, the errors receive large multipliers in the ultimate result. This method ought not, therefore, to be used for stations near the Equator; and we shall therefore take no notice of the arc of parallel measured by Col. Lambton in India.

Ought not to be used in low latitudes.

From the data given above, the difference of longitude of Beachy Head and Dunnose is found to be 1° 26′ 47″.87; which will not be sensibly altered by the minute alterations since made in the latitudes.

The terrestrial arc of parallel was found by a method equivalent to the following. In fig. 41 let B L, D E be two parallels through B and D; B W and D R perpendiculars to the meridians P B, P D. In the triangles W B D, R B D, the necessary angles being known, and the chord of B D being found by triangulation = 339,397.6 feet, the arc B W was found = 336,119.1, and D R = 336,983.5. Now the latitudes of B and W differ so little that we may suppose their normals to intersect the axis in the same point T, fig. 42; construct a sphere, with centre T, passing through B; then W and L will be nearly in its surface. Then it is easily seen that tan W T B = cos lat. B × tan diff. long.; and $\text{B W}=\text{T B}\times\text{W T B}=\text{T B}\times\frac{\text{W T B}}{\tan\text{W T B}}\times\cos\text{lat. B}$ $\times\tan\text{diff. long.}$ Also the arc of small circle B L = T B × cos lat. B × diff. long.; consequently $\text{B L}=\text{B W}\times\frac{\text{diff. long.}}{\tan\text{diff. long.}}\times\frac{\tan\text{W T B}}{\text{W T B}}$. Now diff. long. = 1° 26′ 47″.87, and W T B = 54′ 56″.21; whence B L is found = 336,076.2. Similarly, D E is found = 336,940.5. These are arcs of parallel corresponding to a difference of longitude of 1° 26′ 47″.87, in latitudes 50° 44′ 23″.7 and 50° 37′ 7″.3; the corresponding lengths of one degree are 232,316.5 and 232,914.0.

It is stated by Captain Kater, (*Phil. Trans.* 1828,) that the theodolite used for determining the azimuth angles at Beachy Head and Dunnose (upon the accuracy of which the value of the result wholly depends) did not admit of adjustment sufficiently exact to give these angles with the necessary precision. Be this as it may, it appears certain (from the description of the mode of observation) that every care was taken to insure all the accuracy that it was possible to obtain. The result of these observations was intended to fix a scale of longitude for the great Map of England; and the observers knowing fully the importance of the determination, appear to have been well satisfied with its accuracy. Whether the error of collimation was corrected does not appear; but in the description of the instrument it is expressly remarked, that the telescope admitted of being reversed for this purpose. The result, however it may disagree with that which we shall next present, must, we imagine, be considered as equally valuable in proportion to the extent of the arc.

Correction of the difference of longitude of Dover and Falmouth by transportation of chronometers.

From the value of an arc of longitude nearly coinciding with those which we have given, (the lengths of 1° of parallel given in the *Trigonometrical Survey* are 38,718 and 38,818 fathoms,) the difference of longitude between Dover and Falmouth was calculated to be $6° 20' 52''.5$, or $25^m 23^s.5$ of time. To determine this independently, Dr. Tiarks was sent by sea with twenty-four chronometers to compare the apparent times at Dover and Falmouth. Three trips were made; the apparent time was determined by equal altitudes; this was compared with the time shown by the chronometers; and thus, the error of the chronometers with regard to each of these apparent times being found, the difference of the Dover and Falmouth time at the same instant was found. The result was that the difference of longitude is $25^m 28^s.4$; and this probably cannot be subject to any great error. This amounts to the same as saying, that an arc in the parallel of Beachy Head (lat. $50° 44' 23''.7$) whose length is 1,474,672 feet, embraces a difference of longitude of $25^m 28^s.4$ of time, or $6° 22' 6''$; or that 1° of parallel = 231,563 feet.

Measure of the arc of parallel from Padua to Marennes.

In the determination of the difference of longitude of two places at a very great distance from each other, and where the transportation of chronometers easily and rapidly cannot be accomplished, the following methods may be used. The difference of longitude may be ascertained by astronomical observations carried on simultaneously at the two extremities; as observations of the Moon's right ascension at the time of her transit; observations of eclipses of Jupiter's satellites, (which are a sort of signals seen at both places at the same absolute time;) and observations of occultations of stars by the Moon, or of solar eclipses, (which differ from the last only in this respect, that the absolute time of the phenomenon is not exactly the same at both places, but that the difference admits of calculation.) The last is the most accurate of all known methods. Or the difference of longitude may be found by dividing the arc into several partial arcs, such that a point comprised in each may be visible at both its extremities, and establishing at each of those extremities a temporary observatory, and then determining the difference of longitude of these extremities by observation of artificial signals as in the French arc; and thus making the whole determination the sum of the several partial and independent determinations. Or instead of making all the determinations independent of each other, and dependent on the correctness of the apparent time used at each of the temporary observatories, the signals may be made at the signal posts, and observed at the temporary observatories, along the whole line in the same evening: then if there be any error in the assumed apparent time at one of the intermediate observatories, it will have the effect of increasing the determined extent in longitude of the arc on one side, and diminishing it for that on the other side, so that their sum will be unaltered. It is only necessary that the rates of the clocks be known pretty accurately. (See Mr. Herschel's Paper, *Phil. Trans.* 1826.) It is found in practice extremely difficult to establish the system of cooperation necessary for this method. In the arc which we are now considering, the second method was generally used, but the principle of the last was introduced in one part of it.

Differe of long of Padu and Mi

In August 1824, signals were made by the explosion of gunpowder on four evenings on the summit of Monte Baldo, a mountain on the East bank of the Lago di Garda. Ten signals were made each evening; the quantity of powder used for each signal was three-quarters of a Viennese pound. They were observed by several astronomers at the observatories of Padua and Milan, (as well as at Bologna, Modena, and Verona.) Their difference of longitude was found to be $10^m 43^s.27$ in time. All the observations are given in the Milan *Ephemeris* for 1826: they appear to have been made with all possible care, and the extreme discordance of the results is little more than a second of time. The difference of longitude of the church of Santa Giustina at Padua, and the cathedral at Milan, was inferred to be $10^m 45^s.38$.

Differe of long of Mil and M Cenis.

In September 1821, ten signals were given on each of three evenings, on the mountain Roche Melon. They were observed at the observatory of Milan, and at a temporary observatory on the plain of Mont Cenis. The error of a chronometer (by Earnshaw) on mean solar time was found from observations with a transit-instrument erected near the hospice, and the chronometer was then carried to the place at which Roche Melon is visible. The difference of longitude was found $= 9^m 0^s.20$; whence the difference of longitude of the cathedral at Milan and the hospice at Mont Cenis $= 9^m 0^s.81$. The details are given in the *Opérations Géodésiques, &c.* It is easily seen that the difficulty of fixing firmly the instruments and other causes render this determination less certain than the last; but it appears to be satisfactory.

Differ of lon of Mo Cenis Genev

In September 1822, observations were made for the purpose of finding the difference of longitude of Mont Cenis and Mont Colombier, a hill on the right bank of the Rhone below Geneva. At Mont Cenis it was found necessary to carry Earnshaw's chronometer to a point 2000 feet above the observatory. The chronometer was compared, before going and after returning, with the transit clock; it was also compared when at the place of observation by secondary signals seen there and at the observatory. The results were different: the mean was generally taken. The tempestuous state of the weather made the determination of the absolute time at Mont Colombier very uncertain, and the following arrangement was therefore made. On some of the evenings on which signals made on Mont Tabor were observed at Mont Cenis and the observatory on Mont Colombier, signals were also made on another part of Mont Colombier, and observed at the observatory of Mont Colombier and that of Geneva. Consequently (as we have already explained) the difference of longitude between Mont Cenis and Geneva was found, unaffected by any error in the absolute time at Mont Colombier. The mean of the results from twelve signals (six on September 5, and six on September 7) was $3^m\ 8^s.76$. As this is affected by the errors attending four observations of signals, and as the number of signals is small, this determination cannot be considered equal to the last.

In precisely the same manner, and at the same time, the difference of longitude of Geneva and Solignat was found. Signals made on Pierre-sur-autre were observed at Solignat and Colombier, and signals on another part of Colombier were observed on Colombier and at Geneva. The time at Solignat was determined by absolute zenith distances of stars observed with repeating-circles. The mean of the results of twelve signals on September 6 and 7, was $11^m\ 53^s.97$. See *Conn. des Temps*, 1828. This is liable to the same objections as the last; but if combined with the last, the result will be almost free from any error in the absolute time at Geneva. The difference of longitude of Geneva and the station on the Puy d'Isson (near Solignat) was inferred to be $11^m\ 57^s.82$.

If the signals on September 7 were thought sufficiently numerous, there would be no necessity for using the observations made at Geneva. On that evening the difference of longitude of Mont Cenis and Colombier was found to be $4^m\ 44^s.28$, and that of Colombier and Solignat $10^m\ 18^s.81$, whence that of Mont Cenis and Solignat $= 15^m\ 3^s.09$, and that of Mont Cenis and Puy d'Isson $15^m\ 6^s.94$, unaffected by the error of absolute time on Colombier.

In August 1823, the difference of longitude of Solignat and La Jonchère was determined by twenty signals on the Mont d'Or. The mean was $6^m\ 49^s.99$; from which the difference of longitude of the Puy d'Isson and Sauvagnac (near La Jonchère) $= 6^m\ 51^s.39$. Signals were, in fact, made on three evenings; but the results given by the first evening's observations differ steadily two seconds from those of the other evenings. No explanation of this anomaly could be given, and the results of the first evening's observations were rejected. This circumstance seems to throw some doubt upon the conclusion adopted. The absolute times were determined from zenith distances of stars.

In September 1823, the difference of longitude of La Jonchere and St. Preuil, was found in the same way from ten signals on September 20, given on Puy-Cogneux. Though signals were given on eight evenings it was only possible (from some atmospheric cause) to see them on one. M. Nicollet considers, however, that the favourable circumstances under which these observations were made leave no doubt of the accuracy of the result. The difference of longitude of La Jonchère and St. Preuil appeared to be $6^m\ 28^s.34$; that of Sauvagnac and St. Preuil, $6^m\ 23^s.09$.

In October 1823, similar observations were made at St. Preuil and Marennes. The mean of forty-six signals gave for the difference of longitude $3^m\ 49^s.01$; and between St. Preuil and the steeple of Marennes, $3^m\ 48^s.99$.

Determination of Figure of Earth from Geodetic Measures.

Adding together these differences, we find for the difference of longitude between the steeple of St. Giuslina at Padua, and the steeple of Marennes, $51^m\ 56^s.25$, or 12° 59′ 3″.75. The terrestrial length of the corresponding arc of parallel in latitude 45° 43′ 12″, as found from the French and Piedmontese survey, (we know not by what method of calculation,) is 1,010,996 mètres.

Value of this determination.

It is difficult to estimate the value of this determination. We are not, ourselves, inclined to rate it very high. Of the accuracy of the determinations on the Italian side of the Alps there can be little doubt. The credit of the Mont Cenis observations rests entirely on the steadiness of rate of a single chronometer, which was every day carried on a mountain path to a considerable elevation. Of the French determinations it seems probable that one (if not two) is liable to considerable errors. Those who know practically the difficulty of determining the time at a fixed observatory, and with the best instruments, to an accuracy of one-tenth of a second, will probably allow that there may have been at any of the temporary stations an error of a quarter of a second of time in the correction of the clock. When to this are added the errors of chronometers, and of observations of signals, and the doubt which is thrown on some parts by large and unexplained discrepancies, and when it is considered that the determinations of the six partial arcs are absolutely independent; we cannot flatter ourselves that the difference of longitude of the extreme points is determined within one second of time. And the principal observers were themselves so sensible of this uncertainty that they had (we believe) concerted a plan for the immediate determination of the difference of longitude of Marennes and Padua, by occultations or other astronomical phenomena observed at both places. The respective governments (as we are informed) refused to defray the expenses, on the ground that the arc might in a short time be extended further to the East. It is much to be regretted that the accurate determination of the extensive arc already surveyed should in the mean time be withheld from the scientific world.

Section 6.—Determination of the Figure of the Earth, from the Geodetic Measures.

Abstract of elements of all the arcs.

The following Table contains an abstract of the elements of the arcs above described. The foreign measures are reduced by supposing the toise = 6.394596 English feet,* (according to Shuckburgh's standard,) and the mètre = 3.280899 English feet.

---

* This number is deduced from Captain Kater's measure of the mètre, (*Phil. Trans.* 1818,) supposing the mètre = 443,296 lines of the toise of Peru. The comparison mentioned in the *Phil. Trans.* 1768, allowing for the difference between the Royal Society's standard and Shuckburgh's standard as determined by Captain Kater, (*Phil. Trans.* 1821,) gives for the length of the toise 6.394743 feet of Shuckburgh's standard. Boscovich's arc has been corrected for the quantity (.03413 line) by which Mairan's toise was found to be shorter than the toise of Peru. (*Base du Système Métrique*, tom. iii. p. 414.) The English arcs of parallel, as well as the other English arcs, are reduced to Shuckburgh's standard.

Arcs of Meridian.

No.	Description.	Latitude of Middle Point.	Amplitude.	Length in English feet.	Remarks.
1	Peruvian arc as calculated by Delambre	−1°31′ 0″	3° 7′ 3″.1	1131057	Mountainous country. The amplitude probably well determined.
2	Maupertuis's Swedish arc.	66 19 37	0 57 30.4	351832	Mountainous country. A very little doubt about the amplitude.
3	French arc by Lacaille and Cassini de Thury......	46 52 2	8 20 0.3	3040605	Apparently very good.
4	Roman arc by Boscovich .	42 59	2 9 47	787919	Mountains in the middle of the arc, and sea at both extremities. The determination appears a good one.
5	Lacaille's arc near the Cape of Good Hope	−33 18 30	1 13 17.5	445506	Mountains in the neighbourhood. The determination appears good.
6	American arc by Mason and Dixon	39 12	1 28 45.0	538100	The country favourable; and apparently no doubt about the result.
7	French arc from Formentera to Dunkirk.......	44 51 2	12 22 12.6	4509402	The latitudes depend on inadequate observations with repeating-circles.
8	Svanberg's Swedish arc....	66 20 10	1 37 19.3	593278	Mountainous country. The latitudes doubtful, as in the last arc.
9	English arc from Dunnose to Burleigh Moor......	52 35 45	3 57 13.1	1442953	Excellent.
10	Lambton's first Indian arc.	12 32 21	1 34 56.4	574368	Excellent.
11	Lambton's second Indian arc, as extended by Everest................	16 8 22	15 57 40.2	5794599	Excellent.
12	Piedmontese arc by Plana and Carlini...........	44 57 30	1 7 31.1	414657	The determination excellent. Mountains at both extremities.
13	Hanoverian arc by Gauss .	52 32 17	2 0 57.4	736426	Excellent, subject only to a small doubt about the standard.
14	Russian arc by Struve	58 17 37	3 35 5.2	1309742	Excellent.

Arcs of Parallel.

No.	Description.	Latitude.	Extent in Longitude.	Length in English feet.	Remarks.
15	Arc across the mouth of the Rhone, by Lacaille and Cassini de Thury	43°31′50″	1°53′19″	503022	Pretty good.
16	Roy's arc between Beachy Head and Dunnose	50 44 24	1 26 47.9	336099	Apparently very good.
17	Arc from Dover to Falmouth...............	50 44 24	6 22 6	1474775	Apparently good.
18	Arc from Padua to Marennes	45 43 12	12 59 3.8	3316976	Subject to the accumulated errors of six independent determinations in difficult circumstances.

Equations of the arcs.

Forming for each of the meridional arcs the equation of p. 194, line 22, and for each of the arcs of parallel the expression of p. 193, line 42, we obtain the following Table.

No.	Equations.
1	$b \times .0544111 - be \times .05426 = 1131057$
2	$b \times .0167280 + be \times .02536 = 851832$
3	$b \times .1454455 + be \times .08688 = 3040605$
4	$b \times .0377524 + be \times .01489 = 787919$
5	$b \times .0213197 - be \times .00203 = 445506$
6	$b \times .0258163 + be \times .00512 = 538100$
7	$b \times .2159001 + be \times .10627 = 4509402$
8	$b \times .0283097 + be \times .04293 = 593278$
9	$b \times .0690040 + be \times .06160 = 1442953$
10	$b \times .0276169 - be \times .02371 = 574368$
11	$b \times .2785749 - be \times .20944 = 5794599$
12	$b \times .0196403 + be \times .00978 = 414657$
13	$b \times .0351849 + be \times .03132 = 736426$
14	$b \times .0625662 + be \times .07326 = 1309742$
15	$b \times .0238980 + be \times .03523 = 503022$
16	$b \times .0159783 + be \times .02556 = 336099$
17	$b \times .0703392 + be \times .11251 = 1474775$
18	$b \times .1582185 + be \times .23931 = 3316976$

We shall now proceed to discuss these equations.

1. Comparing the longest arcs, Nos. 7 and 11, we find $b = 20852460$, $e = .003818$.

2. Comparing No. 7 and No. 2, $b = 20816330$, and $e = .006850$.

3. Comparing No. 7 and No. 8, $b = 20851450$, and $e = .003418$.

4. As there is some doubt about both the Swedish arcs, (Nos. 2 and 8,) take the sum of the equations corresponding to them, and compare this with the equation of No. 7. Thus we find $b = 20838100$, and $e = .004722$.

5. The comparison of No. 1 and No. 3 gives $b = 20861200$, and $e = .008558$. The comparison of No. 1 and No. 7, gives $b = 20853720$, and $e = .003196$. This is nearly the same comparison as that from which the French determined the length of their mètre.

6. As the Roman and Piedmontese arcs (Nos. 4 and 12) are in circumstances of locality opposite in character, we may perhaps take the sum of their equations to represent nearly the equation which would be given by an arc in circumstances unaffected by these

peculiarities. Comparing this sum with No. 11 we have $b = 20897940$, $e = .006180$.

7. Comparing No. 11 with the sum of Nos. 9, 13, and 14, we find $b = 20853650$, $e = .003367$.

8. The comparison of the two American arcs (No. 1 and No. 6) gives $b = 20834100$, $e = .002283$.

9. The comparison of Nos. 5 and 11 gives $b = 20910300$, $e = .006961$.

The discordance of these results, especially in the values which they give for the ellipticity, seems to show that several of the measures are affected with some considerable cause of error. This supposition at least is necessary if we suppose the Earth's Figure (at the level of the sea) to be one of revolution, and the generating curve to be at all similar to an ellipse. The most probable disturbing cause is the attraction of mountains; and it will be seen above, that the greatest discordances exist in those comparisons in which Nos. 2, 4, 5, and 12 are used; all of which are in mountainous Countries. Let us then exclude all which are in that predicament, namely, Nos. 1, 2, 4, 5, 8, and 12, and with the others endeavour to ascertain the Earth's dimensions.

10. Comparing the sum* of Nos. 3, 6, 7, 9, 13, 14 with the sum of Nos. 10, 11, we find $b = 20854270$, $e = .0033808$.

11. If we confine ourselves to the modern arcs, we may compare the sum of Nos. 7, 9, 13, 14 with the sum of Nos. 10, 11, and we get $b = 20853355$, $e = .0033232$.

The mean of the two last may, perhaps, be considered a good determination. (This amounts to the same as giving the modern arcs double the credit, *cæteris paribus*, of the ancient arcs.) Thus we find $b = 20853810$ feet, $e = .0033520$.

Substituting these values in each of the equations of meridian arcs, we get the following apparent errors. These may be produced by errors in the geodetic measures, or by errors in the astronomical determination of amplitude.

No.	Latitude of Middle Point.			Calculated Length.	Measured Length.	Error in Measure.	Correspond-ing Error in Amplitude.
1	−1°	31′	0″	1130886	1131057	+171	−1″.7
2	66	19	37	350615	351832	+1217	−12.0
3	46	52	2	3039166	3040605	+1439	−14.2
4	42	59		788322	787919	−403	+4.0
5	−33	18	30	444456	445506	+1051	−10.4
6	39	12		538726	538100	−626	+6.2
7	44	51	2	4509768	4509402	−366	+3.6
8	66	20	10	593366	593278	−88	+0.9
9	52	35	45	1443302	1442953	−349	+3.4
10	12	32	21	574260	574368	+108	−1.1
11	16	8	22	5794708	5794599	−109	+1.1
12	44	57	30	410259	414657	+4398	−43.4
13	52	32	17	735929	736426	+497	−4.9
14	58	17	37	1309865	1309742	−123	+1.2

The reader is now able to judge whether the dimensions which we have used, or any others, are likely to represent with tolerable accuracy the measured lengths of meridian arcs on the Earth's surface. We have sometimes thought that the measured arcs appeared too small, or the amplitudes too great, in middle latitudes; or that the comparison of equatorial arcs with those in middle latitudes gave a smaller ellipticity than that of arcs in middle latitudes with Northern arcs. These indications would show (see Section 3) that the Earth's Figure is protuberant at middle latitudes above the elliptic spheroid. But after careful examination we believe that there is no unequivocal appearance of this And we do not perceive, that the difference between the calculated and the measured arcs would be materially diminished (at least for the best arcs) by adopting a different value for the ellipticity. And observing that Nos. 1 and 6 are nearly in the same longitude, that Nos. 2, 3, 4, 5, 7, 8, 9, 12, 13, 14, are nearly in the same longitude 90° from the former, and that Nos. 10 and 11 are in a third longitude 60° from the last, we think ourselves entitled to conclude that there is no important difference between the different meridians of the Earth.

Determination of Figure of Earth from Geodetic Measures.

On the whole we are inclined to think, that as far as meridian measures go, the Earth's form may be very well represented by that of an ellipsoid of revolution with the dimensions that we have assigned. The greatest differences are at the places and in the directions that we should *à priori* have expected. No. 12 is measured across the great basin of Piedmont and absolutely abuts on the feet of very lofty mountains at both extremities; No. 3 is terminated by the Pyrenees;* No. 5 is in circumstances partly similar to those of No. 12; and No. 2 is in a mountainous country. The other differences are not greater than such as might be produced by a small lump of unequal density below the Earth's surface, or (as Captain Everest has shown in his *Account of the Measurement, &c.*) by a mountain range at a considerable distance.

The assumed dimensions satisfy the arcs of meridian.

We shall now proceed to consider the arcs of parallel.

Discussion of arcs of parallel.

12. Comparing No. 17 with No. 9, $b = 20841200$, $e = .003763$. These then are the dimensions of the ellipsoid that corresponds most exactly to the curvature of England.

13. Comparing No. 18 with No. 11, $b = 20855220$, $e = .003466$.

14. Comparing No. 18 with No. 7, $b = 20848880$, $e = .003667$.

Here we may observe that upon comparing an arc of parallel nearly in latitude 45°, with two arcs of meridian of which one is in a low latitude, and the other

---

* In determining elements from a number of observations or measures, the method of *minimum squares* has frequently been used. We have rejected the use of this method, for the following reason. It is perfectly certain, that the elements determined by this method, if substituted in the equations of condition, will generally give the greatest apparent errors of linear measure in the smallest arcs, and *vice versâ*. A consequence so directly opposed to common sense cannot, we think, be supported by any symbolical reasoning. The doctrine of chances (from which this method is deduced) is more liable than any other to errors of omission in the preliminary considerations for the solution of any problem; and we prefer resting in the belief that there is some such error in the proof of this method, to receiving the consequence abovementioned. We have, therefore, thought best to use the method commonly employed in Astronomy, *viz.* to take the sum of groups of the equations of condition, and to consider each sum as one equation: the groups being selected so as to make the coefficient of e large and positive in one sum, and large and negative in the other.

* A part of this error is undoubtedly to be attributed to the errors of bases, &c. mentioned by Delambre, *Base du Système Métrique*, tom. iii. p. 163. Perhaps a small part of his differences is to be assigned to the later measure.

nearly in latitude 45°, the first comparison gives a smaller ellipticity than the second. This, as we have mentioned in page 197, would indicate that the Earth's Figure projected at middle latitudes above the spheroidal form. But we place little reliance on this conclusion, because the determination of the extent in longitude of the arc of parallel does not appear to us sufficiently certain.

Comparison of calculated and measured arcs of parallel.

If we substitute the values $b = 20853810$, $e =$ 0033520, in the equations of arcs of parallel, we get the following apparent errors.

No.	Latitude.	Calculated Length.	Measured Length.	Error in Measure.	Error in Amplitude.		Lateral Deviation of Plumb-line.
					In Space.	In Time.	
15	43°31′50″	500827	503022	+2195	−30″.0	−2ˢ.00	21″.7
16	50 44 24	334995	336099	+1104	−17.2	−1.15	10.9
17	50 44 24	1474705	1474775	+70	−1.1	−0.07	0.7
18	45 43 12	3316187	3316976	+789	−11.1	−0.74	7.8

The assumed dimensions satisfy the arcs of parallel.

The magnitude of these errors, and the fact of their all having the same sign, appear at first sight rather alarming. It must, however, be remarked, that the two first arcs are measured across low land or sea, and terminated at both extremities by hills, and the effect of the attraction of the hills would be to make the amplitude smaller than if no such inequality existed. The extremities of the third and fourth arcs are more favourably situated; and in these the errors are within the limits of errors of observation. On the whole we are pretty well satisfied with the agreement between the computed and measured arcs.

Conclusion deduced from the measures of arcs.

The following are our conclusions from the discussion of the measures.

1. The measured arcs may be represented nearly enough *on the whole* by supposing the Earth's surface (at the level of the sea, or at the level at which water communicating freely with the sea would stand) to be an ellipsoid of revolution, whose polar semiaxis is 20,853,810 English feet, or 3949.585 miles, and whose equatorial radius is 20,923,713 feet, or 3962.824 miles. The ratio of the axes is 298.33 : 299.33; and the ellipticity (measured by the quotient of the difference of the axes by the smaller) is $\frac{1}{298.33}$, or .003352. The meridional quadrant is 32,811,980 feet.

2. In order, however, to conciliate the various measures with this assumed form, it is necessary to suppose that in some observations, made apparently with the greatest care and with competent instruments, the latitude is erroneous to the amount of at least 22 seconds. But these errors occur almost without exception in the localities where we should have expected them (on the principle of universal gravitation) from the disturbance of the adjacent mountains.

3. It is necessary also to suppose that in some cases the direction of gravity is altered to the East or West of that which it would have, were the Earth's Figure perfectly regular. These instances also occur in localities where (as above) we might *à priori* have expected them.

4. In consequence of these discordancies, the dimensions above given are liable to some uncertainty. We are, however, inclined to think that e cannot be so small as .00325, nor so great as .00345.

Obser tions Pendul

5. It appears (see Section 2, Art. 12 and 33) that if the whole attraction were directed to the Earth's centre, the ellipticity would be $\frac{1}{580}$; if the Earth were homogeneous, and the particles mutually attracted each other, the ellipticity would be $\frac{1}{230}$. The ellipticity given by the measures is between these. We are entitled then to suppose that the state of the Earth is intermediate to these two states: that is, to suppose that the interior of the Earth is more dense than the surface, but that the mutual attraction of the parts near the surface is sensible when compared with the attraction exerted by the parts near the centre.

Section 7.—Observations of Pendulums, for the purpose of measuring the Force of Gravity.

Neces for usi pendul

The necessity of using the pendulum for measuring the force of gravity, will easily be seen if we consider the impossibility of ascertaining the magnitude of that force by any experiments on *single* descents of free masses. The quantity to be measured is the velocity which gravity creates in any freely descending body by its action continued during one second (or any other given duration) of time. This will be known, if we determine the space through which gravity draws the body in that time. But with all the contrivances that we can use for retarding the motion in a known proportion so as to make it measurable to our senses, it is impossible to make the measure of the space sufficiently accurate. Any one who has seen experiments with Atwood's or Smeaton's apparatus will allow that we cannot expect to measure the space described within a hundredth part of the whole. With the pendulum we can ascertain the same thing (in the opinion of some philosophers) within a four-hundred-thousandth part of the whole. This accuracy arises partly from the circumstance that the experiments with the pendulum may be continued for a very long time, with the certainty that there is no interruption between the end of one vibration and the beginning of the next, and partly from the very remarkable fact that the friction and other disturbing causes which ultimately put a stop to the experiment, (and which in the case of a descending body in Atwood's and other apparatus, would completely alter the results even if we had the power of observing them accurately,) do not injure its accuracy as long as it lasts.* We shall now proceed to describe the general principle, and the most approved methods of deducing the magnitude of gravity from observations of the pendulum.

Gen prin the the dulu

In our Treatise on Mechanics, § XV. it is shown that the time of vibration (expressed in seconds) of a simple pendulum whose length is l, in double the circular arc whose versed sine to that radius is b, will be nearly expressed by $\pi\sqrt{\frac{l}{2g}} \times \left(1 + \frac{b}{8l}\right)$, where g equals the space through which a body would fall freely in a second of time; the arc being supposed small. If the arc be extremely small the time will not differ

---

* For a demonstration of this we must beg to refer to the *Cambridge Transactions*, vol. iii. p. 111, &c.

much from $\pi\sqrt{\frac{l}{2g}}$. Suppose such a length to be given to the pendulum that the time of vibration may be one second. Then $\pi\sqrt{\frac{l}{2g}} = 1$, or $g = \frac{\pi^2 l}{2}$. The space g then will be found by multiplying the length of the pendulum by $\frac{\pi^2}{2}$. And if gravity is not the same on different parts of the Earth, the length proper for making the time of vibration equal to one second will not be the same in all. But when the lengths at the different places are determined, the proportion of the forces of gravity at those places (measuring the forces by the spaces through which bodies would fall freely in one second) will be the same as the proportion of these lengths.

Different places the seconds' pendulum has different lengths.

Found by observing the time of vibration of a given pendulum.

But it is seldom in our power to make a pendulum which shall vibrate exactly in one second. Instead of this we observe the time in which a pendulum of known length vibrates. Now, it is easily seen from the expression $t = \pi\sqrt{\frac{l}{2g}}$, or $l = \frac{2g \, . \, t^2}{\pi^2}$, where t is the time of vibration, that the length of the pendulum at the same place is proportional to the square of its time of vibration. The length of the seconds' pendulum then bears to the known length the same ratio as unity to the square of the number of seconds in the observed time of vibration.

Compound pendulum may be used as well as simple pendulum.

All this, however, supposes the pendulum to be a material point suspended by a string without weight; a construction which evidently is imaginary. But it is shown in **Mechanics**, § XX., that if a compound pendulum be given, we may calculate the length of a simple pendulum which would vibrate in the same time, whatever be the magnitude of gravity. A pendulum, therefore, such as may be made in practice, may be used in all respects for the same purposes as the imaginary simple pendulum.

Method of transporting an invariable pendulum to different places.

The method which we have described, is in fact that which has been adopted in many of the most important experiments. The absolute length of the seconds' pendulum is thus determined afresh at every station of observation. But a method has also been used of finding the proportion between the force of gravity at each place, and the force of gravity at some place (London for instance, or Paris) where its absolute magnitude has been well ascertained. This is done by transporting the same pendulum, after having observed it at the place of reference, to all the different stations, and observing the time of vibration at all. Then, since $g = \frac{\pi^2 l}{2 t^2}$, and l is the same at all the observations, (the pendulum being invariable,) g is inversely proportional to t^2. Consequently, the force of gravity at any new station, is to the force of gravity at the place of reference, inversely, as the square of the time of vibration at the new station to the square of the time of the same pendulum's vibration at the place of reference; or directly, as the square of the number of vibrations per day at the new station to the number of vibrations per day at the place of reference. The lengths of the seconds' pendulums are in the same ratio; consequently, that at the place of reference being known, that at the new station is found.

Observations of Pendulums.

We shall now mention some additional considerations which must in all operations of great accuracy be taken into account.

Correction for the length of the arc of vibration.

First, we have supposed the arcs of vibration to be indefinitely small. When the arc is supposed small, but not so small that the term depending on it can be wholly neglected, the time of vibration is nearly $\pi\sqrt{\frac{l}{2g}} \, . \left(1 + \frac{b}{8l}\right)$. If the arc of vibration be n degrees on each side of the vertical, then

$$b = l \, . \, \text{versin.} \, n^\circ = 2l \, . \sin^2 \frac{n^\circ}{2} = l \, . \, \frac{n^2 \sin^2 1^\circ}{2},$$

(nearly,) and the time of vibration is nearly

$$\pi\sqrt{\frac{l}{2g}} \, . \left(1 + n^2 . \frac{\sin^2 1^\circ}{16}\right).$$

This is the time observed; and if the observations continue for so short a time that n does not sensibly alter, the observed time of vibration ought to be divided by $1 + n^2 . \frac{\sin^2 1^\circ}{16}$, or the number of vibrations per day ought to be multiplied by the same quantity, in order to represent the time or number of vibrations in indefinitely small arcs, (to which alone all our reasoning above will apply.) But if the observations continue for a long time it is necessary to know what is the law of decrease of the arc. The laws of friction and resistance of the air for small velocities being little known, it is best to recur to direct experiment. It was found by Borda (and we have found the same by our own observations) that the decreasing arcs form very nearly a geometrical series.* Putting m for the number of vibrations observed, (m being a large number,) p for the proportion of each arc to the preceding arc, (where $1 - p$ is extremely small,) n' for the number of degrees in the last arc $= n \, . \, p^{m-1}$, the degrees of the successive arcs are n, $n p$, $n p^2$, &c. ... $n p^{m-1}$, and the sum of all the times of vibration

$$\pi\sqrt{\frac{l}{2g}} \times \left\{m + \frac{n^2 . \sin^2 1^\circ}{16}\left(1 + p^2 + p^4 + \&c. . + p^{2m-2}\right)\right\}.$$

The sum of the geometrical series is

$$\frac{1 - p^{2m}}{1 - p^2} = \frac{1 - p^{2m-2}}{1 - p^2} \text{ very nearly;}$$

hence the sum of all the times

$$= \pi\sqrt{\frac{l}{2g}} \times \left\{m + \frac{n^2 - n'^2}{1 - p^2} \, . \, \frac{\sin^2 1^\circ}{16}\right\}.$$

But $p^{m-1} = \frac{n'}{n}$, therefore $p^2 = \left(\frac{n'}{n}\right)^{\frac{2}{m-1}} = \left(\frac{n'}{n}\right)^{\frac{2}{m}}$ very nearly, therefore $\log p^2 = \frac{2}{m} (\log n' - \log n)$. But $\log p^2 = \text{modulus} \times \overline{p^2 - 1}$ nearly (as $p^2 - 1$ is very small;) hence $1 - p^2 = \frac{2}{\text{modulus} \times m} \, . \, (\log n - \log n')$; consequently the sum of all the times

---

* In our experiments the decrease of the arc at first was a very little more rapid than according to the geometric law, and at last a very little slower.

$$= \pi\sqrt{\frac{l}{2g}} \times \left\{m + m \cdot \frac{\text{modulus} \times (n^2 - n'^2)}{\log n - \log n'} \cdot \frac{\sin^2 1^\circ}{32}\right\};$$

and the mean of the observed times

$$= \pi\sqrt{\frac{l}{2g}} \times \left\{1 + \frac{\text{modulus} \times (n^2 - n'^2)}{\log n - \log n'} \cdot \frac{\sin^2 1^\circ}{32}\right\}.$$

The quantity within the brackets is that by which the observed mean time of vibration ought to be divided, or the number of vibrations per day ought to be multiplied, in order to reduce the vibrations to vibrations in indefinitely small arcs.

Correction for the temperature.

Secondly, we have supposed the length of the pendulum to continue invariable. But a metallic wire or metallic bar undergoes considerable changes in its length from changes in temperature, and it is necessary, therefore, to reduce the number of vibrations to the number which would have been made if the pendulum had been at some standard temperature. Suppose by heat the pendulum's length is increased above that at the standard temperature in the ratio of $1 : 1 + y$ (y being very small:) then the time of vibration is increased in the ratio of $1 : \sqrt{1 + y}$, or $1 : 1 + \frac{y}{2}$ nearly, and the number of vibrations per day is diminished in that ratio. Consequently, the observed number of vibrations ought to be increased in that ratio in order to find the number which would have been made if the pendulum had been at the standard temperature. If the temperature during the observation be lower than the standard temperature, the observed number of vibrations ought to be diminished.

Correction for the weight of the air.

Thirdly, the vibrations have generally been observed in air. But the state of the air being variable, it is desirable to calculate the number of oscillations which would have been made in vacuum, all other circumstances being the same. For this we have only to observe that the effect of the air (like that of any other fluid upon a body immersed in it) is to diminish the weight of the pendulum by a quantity equal to the weight of the air displaced, or to diminish the apparent force of gravity in the same proportion.* If this diminution be in the ratio of $1 : 1 - z$, then the time of vibration (as will appear by changing g into $g(1 - z)$ in the expressions above) will be increased in the ratio of $1 : \frac{1}{\sqrt{1 - z}}$, and consequently, the number of vibrations per day diminished in the ratio of $1 : \sqrt{1 - z}$, or $1 : 1 - \frac{z}{2}$ nearly. These are the vibrations observed; and therefore to get the number of vibrations in vacuum we must increase the observed number in the ratio of $1 : 1 + \frac{z}{2}$. As the weight of the air is nearly proportional to the height of the barometer, it is necessary for the calculation of this correction to observe the barometer.

We shall now describe some of the practical methods of observing the vibrations of the pendulum.

In a few instances the pendulum of a clock has itself been used as an invariable pendulum to be transported from one station to another. This is the simplest of all methods, as the clock may be used as a transit clock, and its rate immediately determined by transits of the fixed stars: at all events comparison with another clock is all that is necessary. And though the accuracy is undoubtedly not so great as with the apparatus that we shall presently describe, yet very valuable results may be obtained in this manner. If the escapement is so constructed that the pendulum receives the impulse of the wheels when it is at the middle of its vibration, (which is nearly the case in the dead-beat construction,) the time of vibration is not altered by the maintaining power. The suspension of the pendulum is a matter of some difficulty. If it be suspended by a spring in the usual way, the time of vibration is not the same and does not vary in the same manner as the time of vibration in a circular arc, and the elasticity of the spring varies with variations of temperature. If it be suspended on knife-edges, (this is the term commonly used for a prismatic bar of very hard steel, on one edge of which, having an angle of from 20° to 90°, the pendulum turns during its vibration,) there is, perhaps, some fear of the edge slipping on its supports when it receives the pressure of the wheel-work. Satisfactory results have, however, been obtained with this construction.

Methoc
Bougu
Lacond
mine,
gentil,

The method commonly used in the beginning of the last century was to suspend a small weight (commonly in the shape of two frustra of cones with their bases in contact) by a fibre of *pite*, (a preparation, we believe, of the leaf of a species of aloe,) and placing it before a clock to observe the number of vibrations which it made, not by counting them, but by observing when it had gained or lost two vibrations upon the clock pendulum. The clock was thus used to count the great number of vibrations; the observer counted only those which the detached pendulum gained or lost upon it. The number of vibrations which it would have gained or lost in a day being found by proportion, and the number of vibrations per day of the clock pendulum being ascertained by observations of the stars, the number of vibrations of the detached pendulum per day is found. From this, by the application of the corrections above-mentioned, the number of vibrations per day in indefinitely small arcs and in vacuum is found. The length of the pendulum was found by measuring the distance between the lower edge of the forceps that held the thread and the upper surface of the weight; or between the lower edge of the forceps and a plane on which the bottom of the weight would just rest. It is to be remarked, that the length of the seconds' pendulum thus found is always too great, as the curvature of the thread does not begin close to the suspending forceps.

Bord
m th

The method which was first used by the French, nearly at the time of measuring the arc between Dunkirk and Barcelona, was the following. A spherical ball of platinum, and a brass cap covering about one-fifth of its surface (represented in fig. 43) were ground together so as to fit accurately in every position of the ball. When this is the case, if the cap be suspended the ball will adhere to it provided a very small quantity of grease be interposed. The peculiar advantage sought in this construction was to destroy the effects of unequal Specific Gravity in different parts of the ball

---

* We shall speak hereafter of an alteration which it has been found necessary to make in this proportion.

ure of Earth.

by altering its position with regard to the direction of gravity. A fine metallic wire was attached to the cap and fastened at the top to a small apparatus connected with a knife-edge. (See fig. 44.) The upper part of this was a stalk cut with a screw-thread on which a small weight could be adjusted. The time of vibration of the pendulum being known very nearly before the observations were begun, the weight was adjusted so that the small apparatus of fig. 44, without the wire, would vibrate on the knife-edge in that time. Consequently, when the wire, cap, and ball were attached to it, the suspending apparatus might be wholly neglected in the calculation of the length of the equivalent simple pendulum. The knife-edge rested upon a steel plate. The number of vibrations per day was ascertained in the same way as in the first method: a shade with a vertical edge being placed so that when the pendulum was at rest, the vertical edge, as viewed in a small telescope, coincided with the pendulum wire. A cross was made on the bob of the clock pendulum, and the observation consisted in noting when the wire and cross disappeared at the same time behind the edge. All the corrections were applied which we have described. The length was measured by screwing up from below a horizontal plate of steel till it just touched the ball; then the pendulum being removed, a bar of known length with a T head (to the lower surface of which the end of the bar had been accurately fitted) was placed in such a manner that the lower surface of the T head rested on the upper steel plate, and a graduated slider on the bar was then made to touch the lower steel-plate. The ball was placed on the steel-plate and the same slider was used to determine its diameter; the wire and cap were weighed; then to determine the length of the isochronous simple pendulum, a formula was used founded on that given in MECHANICS, § XX. At every station of observation it was necessary to repeat the whole of this process.

The process used by Captain Kater for determining the length of the seconds' pendulum at London (for fixing the standard of English measures) was the following. The pendulum consisted of a bar A B of plate brass, (fig. 45,) about $1\frac{1}{2}$ inch broad, and $\frac{1}{8}$ inch thick. At A was a knife-edge of the hardest steel, its back bearing firmly against solid knees of brass; and at B a similar knife-edge. When the pendulum was in use, these edges rested on horizontal plates of agate. At C was a large flat bob, and at D and E two small slips or tails, the use of which we shall mention hereafter. At F was an adjustible weight, and at G a smaller weight, which by means of a screw could be adjusted with very great nicety. The principle of the operation was to observe the number of vibrations per day made by the pendulum when suspended on the knife-edge A, and again when suspended on B. If these were not equal, the sliding weights F and G were moved till they became equal. Then as A and B were at different distances from the centre of gravity, it was certain (see MECHANICS, § XX.) that B was the centre of oscillation corresponding to the centre of suspension A, and therefore, that the distance between A and B was the length of the simple pendulum vibrating in the same time. The distance between the knife-edges was compared with the distance of two divisions on the standard scale by a microscopic apparatus furnished with internal micrometers.

Observations of Pendulums.

The number of vibrations per day was determined by observing in the following manner the difference between the vibrations of the detached pendulum, and the vibrations of a clock pendulum. Suppose the pendulum suspended on the edge A. On the bob of the clock pendulum, which had been blackened, was placed a circle or lenticular figure of white paper, whose breadth was nearly equal to the breadth of the tail D. Between the two pendulums, or (which was the original construction) in the field bar of the telescope with which they were viewed, was placed an adjustible diaphragm, consisting of two perpendicular cheeks, which were placed at such a distance that they appeared to touch the edges of the tail D when the pendulum was at rest. Now suppose both pendulums to vibrate, the detached pendulum vibrating more slowly than the clock pendulum. The tail D is seen to cross the opening of the diaphragm, and is followed by the white patch on the clock pendulum. At every succeeding vibration the patch follows more closely, and at last is completely covered by the tail while it passes. This is called a *disappearance*. After a few vibrations it appears again, preceding the tail. This is called a *reappearance*. The time of disappearance was generally considered as the time of coincidence of vibrations, though in strictness the mean of the times of disappearance and reappearance ought to be taken, but the error produced by this mistake is seldom sensible. This is very far the most accurate way of comparing the vibrations of two pendulums. It is immaterial whether the detached pendulum vibrate in a greater or less time than the clock pendulum, but it is essential to the operation that it vibrate in a smaller arc; a condition which there is no doubt of securing in these experiments.

The English observations for ascertaining the length of the seconds' pendulum at different places have generally been made by transporting an invariable pendulum whose vibrations were observed before going and after returning at London or Greenwich. The construction was similar to that of fig. 40, supposing it deprived of the knife-edge B, the tail E, and the sliding weights F and G.

Bessel's method.

A method, proposed we believe in the last century, has lately been put in practice by M. Bessel for ascertaining the length of the seconds' pendulum at Königsberg. The pendulum consists of a heavy ball suspended by a fine wire, which is made to vibrate first with one length of wire and then with a different length. The advantage proposed in this construction was the following. It is easy to measure accurately the vertical distance between two points of suspension on which the pendulum successively vibrates, and therefore (as the ball in both experiments is depressed to the same place) the difference of length of the two pendulums is easily found. This distance too is not necessarily a fractional part of the standard, and in M. Bessel's experiments was, in fact, exactly one toise. And as the small corrections depending on the diameter of the ball, &c. are easily calculated from an approximate knowledge of the length of the pendulum, the difference between these corrections is easily found. Thus the difference of length of the simple pendulums isochronous to the pendulums observed is found with great accuracy. The times of vibration being also observed (which are proportional to the square roots of these lengths) we deduce from them the proportion of the lengths. From these two data the lengths are found. Now it was supposed that this measure could be made more accurately than those necessary to Borda's method, where the diameter of the ball must be ascertained, or than those of Kater's method, where the distance between two edges is to be measured. The sort of suspension used by M. Bessel was different from the others, consisting in unwrapping the wire from a horizontal cylinder round which the upper extremity was folded. And in the observation of coincidences, instead of placing the pendulum within a few inches of the clock pendulum, it was placed at a considerable distance, and the image of the clock pendulum formed by an interposed lens was thrown upon the detached pendulum: so that all disturbance of one pendulum by the other was effectually prevented.

Carlini's method.

In some observations by M. Carlini, the upper end of the wire was attached to a small apparatus represented in fig. 46. In the upper part of this is a wheel with a sharp edge, turning like the rowel of a spur; the edge serves as a knife-edge for suspension, and by turning the wheel the suspension is changed. The piece upon which it rests is represented in fig. 47; it is supposed to project from a wall. A microscope is placed in such a manner as to view the lower edge of the wheel directly, and likewise to view its image formed by reflection in the curved surface of fig. 47; the place where they appear to meet is very accurately the place of suspension. By means of a microscope placed at the bottom, the upper and lower surfaces of the ball were viewed even during the vibration. The vibrations were observed as by M. Bessel; a plane mirror, as well as a lens, being necessary for the formation of the image of the clock pendulum.

We shall now proceed to mention, individually, some of the principal pendulum observations.

Richer's observations.

In the Ancient *Mémoires de l'Académie*, vol. vii. is Richer's account of his observations at Cayenne; which we cite as a matter of curiosity* only, it being, we believe, the first of the kind, and that which seems to have attracted Newton's attention. The vibrations of his pendulum were very small and were sensible during 52 minutes of time; they were compared with those of an excellent clock; the observation was repeated several times every week for ten months; the result was that at Cayenne the seconds' pendulum was 1½ lines shorter than at Paris. The latter he considered to be 3 feet 8⅗ lines. This is the whole of his account.

Those of Deshayes.

In the *Mémoires* for 1701, is an abstract of the results obtained by Deshayes. At Cayenne, latitude 4° 56′, he found the length of the seconds' pendulum rather less than 3 feet 6½ lines; at Grenada, latitude 12° 6′, at Martinique, latitude 14° 44′, the same; at St. Christopher, latitude 17° 19′, and several places in St. Domingo between latitude 18° 19′ and 19° 58′, 3 feet 6¾ lines; at another point in St. Domingo, latitude 19° 48′, 3 feet 7 lines. These results (about which no further account is given) are evidently worth little.

Observations by M. de la Croyère at Archangel.

In the *Petersburgh Transactions* for 1735, are recorded the observations made at Archangel by M. de la Croyère. The pendulum was a brass ball 14½ lines in diameter supported by a thread of *pite* the top of which was held by a sort of forceps. An iron measure, copied from the standard in the Paris observatory, was used for making a pendulum of the length of the seconds' pendulum at Paris, (estimated at 3 feet 8½ lines;) this length, however, was measured to the centre of the ball, and the error thence resulting was calculated. The vibrations were compared with those of a clock. The result was that the seconds' pendulum at Archangel was longer than that at Paris by $\frac{3}{20}$ of a line. Not a word is said of the temperature of the standard; and this leaves a small uncertainty as to the correct length.

By Cam bell at J maica.

In the *Philosophical Transactions* for 1734, is an account by Bradley, of the transportation of a clock with an invariable pendulum (made by Graham) from London to Black-River in Jamaica, latitude 18°. The construction of the pendulum is not described. The observations in London, which lasted 10 days, were made by Graham, and those in Jamaica, for 26 days, by Mr. Colin Campbell. At London the clock gained $1^s.2$ daily on sidereal time; and at Black-River it lost daily $2^m\ 5^s.5$. The rates were found by transit observations. A spirit thermometer was observed; and the effect of the temperature was calculated on the rough observation that clocks of this construction did not generally alter their rate at London between summer and winter above 25^s or 30^s per day. The allowance made was $8^s.7$; and thus the difference of rate depending on the alteration of gravity was $1^m\ 58^s$. This may be considered a good determination, as the greatest uncertainty from the rough estimation of the effects of temperature could not amount to more than two or three seconds per day.

By Mai at Pari

In the *Mémoires* for 1735 is Mairan's account of his observations of the length of the seconds' pendulum at Paris. A horizontal plane, movable by screws, was placed exactly 1 toise from the lower surface of his forceps. The thread was of *pite;* it was fixed in the leaden ball (6 lines in diameter) by making a small hole and burnishing the edge upon the end of the thread. The distance between the lower surface of the ball and the horizontal plane was found by trying which of several pieces of glass would just fit under it; and measuring by a scale, with the assistance of a lens, the thickness of the glass. The diameter of the ball was measured in the same way by means of a parallel ruler. The ball was left to hang on the thread one day before the experiments were begun. At first Mairan tried to count the vibrations; but was obliged at last to resort to the method of coincidences with clock pendulum. For this purpose he was obliged to use a pendulum of little more than 3 feet in length; and the distance was now measured by placing the toise on one side, and screwing up the plane till it touched the sphere. Some observations were, however, made with pendulums of 6 and 9 feet; balls of brass, ivory, &c. were also used. The mean of twelve experiments gave for the length of the seconds' pendulum 3 feet $8\frac{17}{30}$ lines. There appears to be no correction for the weight of the air nor for temperature; the mean height of the thermometer was about 13° of Fahrenheit, which is so near the temperature commonly used in the application of the French toise, that the difference may be neglected. This appears to be an excellent determination, subject only to the error of Mairan's toise, and that common to the kind of suspension that he used. But, as an isolated experiment,

---

* See also the *Recueil d'Observations faites en plusieurs voyages, &c.* The length of the seconds' pendulum at Paris had been measured by Picard for the purpose of fixing a standard; and incidental observations had been made by Feuillée at Portobello and Martinique, by Halley at St. Helena, &c. They are worth very little.

it is nearly useless in the investigation of the Figure of the Earth.

The same volume contains two determinations by Godin of the Paris pendulum, one with a machine by Graham, (which is not described,) the other with a simple pendulum whose bob was the frustra of two cones united by their bases. The latter determination agrees very nearly with Mairan's: the former gives a measure shorter by $\frac{1}{6}$th of a line. At Petit Goave in St. Domingo, latitude 18° 27′, with a brass ball an inch in diameter, suspended by a line of pite which was attached with sticking-plaster, he counted 7684 vibrations and compared them with a clock, and thus found for the length of the seconds' pendulum, 3 feet 7$\frac{1}{3}$ lines. After this he used a double frustrum of a cone with a longer thread, and measured the distance to the upper surface by a sort of sliding rule. By counting 2012 vibrations he found for the length 3 feet 7$\frac{8}{15}$ lines. Bouguer (see the same volume) found 3 feet 7$\frac{1}{3}$ lines. Lacondamine used a 12-feet pendulum; but finding some difficulty in the measure, he adopted a pendulum of little more than 3 feet, which was attached to the slider of his beam-compasses; he found 3 feet 7$\frac{11}{60}$ lines.

At Porto-bello, latitude 9° 33′, Godin and Bouguer found 3 feet 7$\frac{7}{90}$ lines for the length of the seconds' pendulum; at Panama, latitude 8° 35′, they found 3 feet 7$\frac{1}{5}$ lines; at Punta-Palmar, 2′ South latitude, Lacondamine found 3 feet 6.96 lines; at Riojama 9′ South, Bouguer found 3 feet 6.82 lines, and Lacondamine 3 feet 6.93 lines; at Quito, 25′ South, they found 3 feet 6.83 lines. The elevation of the last-mentioned place makes it almost unsafe to use such a measure in conjunction with those taken near the level of the sea. We copy these numbers from the table near the end of the IVth volume of the *Œuvres de* Maupertuis. The numbers given by Bouguer himself in his *Figure de la Terre*, for the length of the seconds' pendulum in vacuum, are: at the Equator, at an elevation of 2434 toises, 36 inches 6.69 lines; at an elevation of 1466 toises, 36 inches 6.88 lines; at the level of the sea, 36 inches 7.21 lines; at Porto-bello, 36 inches 7.30 lines; at Petit Goave, 36 inches 7.47 lines; at Paris, 36 inches 8.67 lines.

Maupertuis observed the rate of an invariable pendulum attached to a clock, at Paris and at Pello, latitude 66° 48′. This instrument was made by Graham: the pendulum was of brass, suspended by a knife-edge of steel which rested on steel planes. The temperature of the places of experiment at Paris and at Pello was the same, and the extent of the arcs of vibration the same. At Pello it gained $59^s.1$ per day on its Paris rate. At London it appeared from Graham's observations that it gained $7^s.7$ per day on its Paris rate. The observations at Pello lasted four days. As they feared that in a country full of iron and magnetic stones there might be some magnetic influence, they tried in another clock bobs of different metals, but the difference at Pello and Paris was the same in all. Great confidence may be placed in this kind of observation, where one of the principal difficulties (that of measuring the pendulum) is entirely avoided.

In 1752, (see *Mémoires* for 1751,) Lacaille observed the length of the seconds' pendulum at the Cape of Good Hope and the Isle of France, and on his return, at Paris. The length at the Cape, given in the *Mémoires*, is 3 feet 8.07 lines. In Delambre's *Histoire de l'Astronomie au XVIIIme. Siècle*, p. 478, M. Mathieu has given the results of a recalculation of all Lacaille's observations: they are as follows. Length of seconds' pendulum at the Isle of France, latitude 20° 10′ South, 3 feet 7.785 lines; at the Cape of Good Hope, 33° 55′ South, 3 feet 8.139 lines; at Paris, 48° 51′ North, 3 feet 8.79 lines. These results are comparable among themselves, but are not strictly comparable with others, because some corrections are introduced by M. Mathieu which were not introduced by observers of that age.

Observations of Pendulums.

By Legentil.

In the *Voyage dans les Mers de l'Inde* of Legentil, published 1779, are contained observations of the pendulum at Pondicherry, latitude 11° 56′ North; at Manilla, latitude 14° 34′ North; and at Foul-point in Madagascar, latitude 17° 40′ South. They have been recalculated by M. Mathieu, (*Astronomie au XVIIIme. Siècle*, p. 698.) who observing that the standard was the same as Bouguer's, and therefore that Bouguer's and Lacaille's observation at Paris might be considered as comparable with these if the same reductions were made in all, has applied to all the same reductions, and thus found the following comparable lengths: Paris, 3 feet 8.582 lines; Pondicherry, 3 feet 7.345 lines; Manilla, 3 feet 7.517 lines; Foul-point, 3 feet 7.441 lines.

By Phipps, at Spitzbergen

In the account of Phipps's voyage towards the North Pole (made 1773) are some observations with an invariable clock pendulum made by Graham. The ball was a brass sphere 4 inches in diameter; the rod a steel wire $\frac{1}{10}$th of an inch thick; it turned upon knife-edges, which were not left quite sharp, the edge being rounded to a cylinder of $\frac{1}{400}$ inch radius. These knife-edges turned in notches made in two pieces of hardened steel; the notches were angular and rounded at the bottom. The rod was not fixed firmly to the knife-edges, but attached to a pin whose direction was parallel to the plane of vibration, in order that an equal bearing on both extremities might be ensured. The escapement was not absolutely a dead-beat, but slightly recoiling; as it is well known to artists that a pendulum on a knife-edge suspension may be thus made to vibrate in equal times under the action of very different weights. At London the clock went exactly mean solar time. On a small rocky island* near Spitzbergen, latitude 79° 50′ North, an equatorial was mounted as an altitude and azimuth instrument, and at about five in the afternoon the transit of the Sun's limb over the vertical wire was observed: this observation was repeated the next day. Besides this, the clock was compared with a chronometer, whose rate was well known. A correction was applied for the temperature. The conclusion was that the rate was accelerated $72^s.28$ per day. Again, in latitude 79° 44′ North, the clock was kept going for about three days, and compared with the chronometer, whose rate was determined by many altitudes of the Sun immediately before and after the observations. The acceleration, thus determined, was $73^s.06$ per day. On returning from the voyage, the clock was found to go true time at London. These results appear to be perfectly trustworthy.

By Borda, at Paris.

We have already described at great length the manner in which Borda's observations were made at Paris. We shall merely add that the pendulum was about 12 feet long, so that every vibration corresponded nearly to every second vibration of a clock. The whole apparatus was enclosed in a box, to prevent currents of air

---

* This is very near to the place where Captain Sabine afterwards observed the pendulum, but it does not appear to be the identical spot.

from affecting it. All the corrections which we have mentioned were applied, except that for elevation above the sea. The mean result from twenty experiments of four or five hours each, was 3 feet 8.5593 lines. See the *Base du Système Métrique*, tom. iii.

By Biot, on the French meridian.

The same methods were followed (see tom. iv. of the same Work) by Biot (except that he used a pendulum of about 3 feet in length) at Formentera, latitude 38° 40′; at Paris, latitude 48° 50′; at Bordeaux, latitude 44° 50′; at Figeac, latitude 44° 37′; at Clermont, latitude 45° 47′; at Dunkirk, latitude 51° 2′; at Leith Fort, latitude 55° 59′; and at Unst, in the Shetland Islands, latitude 60° 45′. The lengths were reduced to those which would have been observed at the level of the sea by increasing them in the duplicate ratio of the actual distance from the Earth's centre to the distance of the level of the sea from the Earth's centre; this amounts to the same as neglecting the attraction of the elevation on which they were placed. The results are respectively, (in mètres,) 0.7412520, 0.7419175, 0.74160863, 0.741612279, 0.7417052, 0.7420761, 0.994531014, and 0.742723136. All of these, it must be observed, are lengths of the decimal pendulum (making 100,000 oscillations in a mean solar day) except the last but one, which is the length of the sexagesimal seconds' pendulum. All these determinations must be considered as most valuable. Two invariable pendulums also were observed at Greenwich and at Paris; they appeared to show a retardation at Paris of 10^s.79 daily; but it is expressly remarked, that the circumstances were very unfavourable to accuracy.

By Malaspina.

In the Additions to the *Connaissance des Temps* for 1816, is M. Mathieu's account of the observations made in an expedition under the command of Malaspina, undertaken by order of the Spanish Government, from 1789 to 1794. Their pendulum had a wooden rod; it was enclosed in a glass box; the vibrations were counted by two persons, who relieved each other at the end of every sixty; a third person stood at the clock. The following are their results for the length of the seconds' pendulum (taking for unit the length of the simple pendulum equivalent to their pendulum.)

Place.	Latitude.				Length.
Mulgrave........	59	34	20	N.	1.0082893

These results cannot be compared with any others, as scarcely any other observation (except Legentil's) has been made at any of these places for the determination of the absolute length of the pendulum.

In the *Phil. Trans.* for 1818, are contained Captain Kater's observations for determining the length of the seconds' pendulum at Portland Place, London. The principle we have already described: the result was corrected for extent of vibration by observing the arc at each coincidence and using the mean between two adjacent arcs for the vibrations between them; for temperature, by allowing 0.423 vibration for each degree of Fahrenheit; and for the weight of the air and elevation above the sea in the manner that we have described. They gave for the length in latitude 51° 31′ 8″, 39.13860 inches. But in the *Phil. Trans.* for 1819, Dr. Young remarked that the correction usually applied for the elevation above the sea was too great, as it neglected the attraction of the elevated mass. If we stood on a sphere of the same density as the Earth's mean density, the reduction would be but ¾ of that which is usually made; on a hemisphere, still less; on table land of mean density, the reduction would be ¼ of that usually made; on table land of density = ⅔ mean density, it would be ½; on table land whose density $= \frac{2.5}{5.5} \times$ mean density (which would probably represent pretty nearly the density of most rocks at the Earth's surface) the reduction would be $1 - \frac{3}{4} \quad \frac{2.5}{5.5}$, or $\frac{66}{100} \times$ usual reduction. The last result thus reduced, and with other corrections, is 39.13929 inches. This is the number used in all the subsequent comparisons.

Dr. Y corre for el tion.

The same Volume (for 1819) contains Captain Kater's determinations (by the transportation of an invariable pendulum) at Shanklin in the Isle of Wight, latitude 50° 37′; at Arbury Hill, latitude 52° 13′; at Clifton, latitude 53° 28′; at Leith Fort, latitude 55° 58′; at Portsoy, latitude 57° 41′; and at Unst, latitude 60° 45′. The results were 39.13614, 39.14250, 39.14600, 39.15554, (obtained under unfavourable circumstances,) 39.16159, and 39.17146 inches.

Obse tions Kate Engl meri

In the history of Captain Ross's voyage to Baffin's Bay (made in 1818) is an account of the going of a clock (with invariable pendulum vibrating on a knife-edge, which rested on hollow cylinders of agate) as determined by 7 days' observation at London, 3 days at Brassa in the Shetland Islands, latitude 60° 1′, and 4 days at Hare Island, latitude 70° 26′. And in Parry's first voyage are observations on the going of two similar clocks at London, before and after the voyage, and at Melville Island, latitude 74° 47′, during 38 days. The result* (see *Phil. Trans.* 1821) is, that at Brassa the length of the seconds' pendulum is 39.16929; at Hare Island 39.1984; and at Melville Island, 39.2070 inches.

Obse tion Ross Par voy

In the *Phil. Trans.* for 1823, are detailed accounts of observations made by Captain Basil Hall and Mr. Foster with an invariable detached pendulum at London; at Abingdon Island, one of the Galapagos, latitude 0° 32′; at San Blas de California, latitude 21° 30′; and at Rio de Janeiro, latitude 22° 55′ South. In this, as in

---

* In the *Connaissance des Temps*, 1827, *Additions*, M. Arago has given his opinion that these observations would be rejected without scruple if they opposed any received theory, and that, therefore, they are useless when they favour it. With the greatest possible respect for the opinion of this illustrious philosopher, we must in this instance withhold our assent to it. The conclusion is not so accurate as if deduced from the use of invariable detached pendulums, but it is probably much superior to that which would be obtained in difficult circumstances by the French method. From our own experimental acquaintance with these clocks, we know them to be excellent.

other instances, we cannot enter into the details, and can only state that the operations appear quite satisfactory. The resulting lengths of the seconds' pendulum are 39.01717, 39.03829, (by a mean;) and 39.04375.

In the same Volume is an account of observations made by Sir Thomas Brisbane, Mr. Rumker, and Mr. Dunlop, with an invariable detached pendulum at London and Paramatta in New South Wales, latitude 33° 49′ South. The length of the seconds' pendulum at the latter is 39.07696.

Captain Sabine's *Account of Experiments to determine the Figure of the Earth*, &c. published in 1825, contains a very valuable* series of observations made with two detached invariable pendulums. The principal novelties in the manner of conducting the observations was, that for coincidences the mean of disappearances and reappearances was taken; and that the correction for temperature was determined from experiments made at London in different temperatures; the effect of an alteration equal to 1° of Fahrenheit was found to be 0.421 vibrations per day. Two clocks with invariable attached pendulums (the same which were used on Captain Parry's voyage) were also observed. The results, as finally corrected in the *Phil. Trans.* for 1828, will be given in our general table.

In 1809 experiments† were made at Madras observatory by Captain Warren, with a leaden ball 1⅛ inch diameter, suspended by a fibre formed from the wild plantain tree. Its vibrations were counted, and the time of an astronomical clock noted by an assistant. For the measure, plates of glass were fixed to the wall, and paper attached to them, and upon these a scale was transferred from Colonel Lambton's scale. The beam compasses were applied to the lower surface of the support, and the lower surface of the ball, and were then taken to the scale. The diameter of the ball was inferred from its weight. From 10 days' observations the length of the seconds' pendulum was found to be 39.026273 inches (in air, and measured by Lambton's scale.) This determination is certainly inferior to one that we shall presently give.

In 1821 an expedition under the direction of Mr. Goldingham, made observations at Pulo Gaunsah Lout (a small island in latitude 1′ 49″ North) with an invariable pendulum, which had been observed at London. The deduced length of the seconds' pendulum is 39.021260 inches. Every care appears to have been taken to make this accurate.

The *Phil. Trans.* for 1822 contain Mr. Goldingham's determination, with the same pendulum, of the length of the seconds' pendulum at Madras, latitude 13° 4′: it is found to be 39.026302, and appears to be very accurately determined. In this, and in the last, the reduction for temperature is applied in a very confusing manner; but we have satisfied ourselves that it is correct.

In the *Phil. Trans.* for 1826 is Lieutenant Foster's account of a very careful series of observations at Port Bowen, latitude 73° 14′, with an invariable pendulum which had been observed at Greenwich. The conclusion was that the length of the seconds' pendulum = 39.203472 inches. This, however, is founded on the supposition that 39.13911 is the length of the seconds' pendulum at Greenwich, reduced to the level of the sea. It is, however, nearly the length at Portland Place, London. We shall soon mention the difference between these lengths.

By Freycinet in various latitudes

The French expedition sent out in 1817—1820, under Captain Freycinet, made observations at Paris; at Rio de Janeiro, latitude 22° 55′ South; at the Cape of Good Hope, latitude 33° 55′ South; at the Isle of France, latitude 20° 10′ South; at Rawak, near New Guinea, latitude 0° 2′ South; at Guam, the capital of the Marian Islands, latitude 13° 28′; at Mowi, one of the Sandwich Islands, latitude 20° 52′; at Port Jackson, latitude 33° 52′ South; and in the Isles Malouines, latitude 51° 35′ South. Three invariable brass pendulums were used, and one wooden one. When observed, they were enclosed in glass boxes, and a small clock placed near them had its pendulum adjusted, till it vibrated exactly in the same time. This clock (used only as a counter) was compared with a chronometer every half hour; for determining the rate, the mean of five chronometers was used. The proportionate lengths of the seconds' pendulum are 1.00002271, 0.99783528, 0.99871582, 0.99794[illegible], 0.99709575, 0.99759331, 0.99792816, 0.99877424, 1.00022319. These determinations are probably pretty good. See the *Voyage autour du Monde, &c. par* Freycinet.

By Duperrey in the Pacific.

In a similar expedition made in 1822—1825 under Captain Duperrey, two of the same pendulums were employed. The method appears to have been the same as in the operations last described. The following are given as representing the lengths of the seconds' pendulum. At Paris, 1; at Toulon, latitude 43° 7′, 0.99950585; at the Malouines, 1.00025995; at Port Jackson, 0.99871430; at the Isle of France 0.99789022; at Ascension, latitude 7° 56′ South, 0.99729881. We extract these numbers from the *Additions* to the *Conn. des Temps*, 1830.

By Sabine at Paris.

The *Phil. Trans.* for 1828 contain Captain Sabine's observations on an invariable pendulum at London and at Paris. From an extensive series it appears that a pendulum which at London makes 85,940 vibrations per day, is retarded at Paris to the amount of 12.03 vibrations. As the length of the seconds' pendulum at London, uncorrected for elevation, is 39.13908 inches, the length at Paris is 39.12813. This is a very valuable determination, as it makes a great number of determinations comparable, which without it could not safely be brought together.

By Sabine at Greenwich.

In the *Phil. Trans.* for 1829 is a series of observations by the same gentleman for determining the difference of gravity at Portland Place, London, and the Royal Observatory, Greenwich. It appears that at Greenwich, no correction being applied for elevation, the pendulum is accelerated about 0.48 of a vibration per day, and therefore, the length of the seconds' pendulum at Greenwich is greater than at Portland Place by .000435. If the correction for elevation be applied, according to Dr. Young's rule, the difference is 0.60 of a vibration, or .000544 inch in the length. We do not ourselves believe that the pendulum, as commonly constructed, can be relied on to this degree of accuracy.

The same Volume contains experiments leading to a very remarkable result with regard to the correction for the weight of the air. They are, in fact, a repetition of

---

* The publicity of some discussions respecting these observations compels us to give our own opinion. We shall decline entering into any inquiry respecting the original observations, and shall merely state that we have the most perfect confidence in the results.

† The accounts of this and the next set of experiments were presented by the East India Company to the Astronomical Society of London, by favour of whom we have been allowed to inspect them.

experiments announced by Bessel in the *Astronomische Nachrichten*, No. 128, and published in the *Berlin Transactions* for 1826. It would seem that a quantity of air moves with the pendulum, and adds to its inertia, and therefore that besides a retardation arising from the diminished weight of the pendulum, there is another retardation arising from the increased mass of matter to be put in motion. A pendulum was made to vibrate in air, in vacuum, and in hydrogen gas, of elasticity equal to the elasticity of the atmosphere. It appears that the reduction to vacuum, as commonly made, ought to be increased in the ratio of 1 : 1.655. With a spherical bob, the reduction ought to be doubled. As, however, all the comparative observations have been made with little difference in the height of the barometer, the error in the reduction has very little effect on their results. It is remarkable that the correction for hydrogen gas appears to be double of what it would be if we supposed the amended corrections proportional to the Specific Gravities of the fluids. Bessel determined the atmospheric correction by observing the length of the seconds' pendulum in air, first with a bob of brass, and secondly, with a bob of ivory. The correction, being greater for the latter than for the former, in the proportion of the Specific Gravities, was determined with great accuracy from the difference of the observed lengths.

Experiments by Bessel and Sabine to determine the effect of the air on the vibrations of a pendulum.

Observations by Biot in the Mediterranean and Italy.

The *Mémoires de l'Institut*, vol. viii. contain a paper by M. Biot, from which we extract the following determinations by himself of the length of the seconds' pendulum at Milan, latitude 45° 28′; at Padua, latitude 45° 24′; at Fiume, latitude 45° 19′; at Barcelona, latitude 41° 23′; at Formentera, latitude 38° 40′; and at Lipari, latitude 38° 29′. Expressed in millimètres they are 993.547642. 993.607294, 993.584075, 993.2321312, 993.0696597, 993.0791638. The former determination at Formentera, it appears, was not satisfactory. The details of these experiments are not given.

By Rumker in New South Wales.

The IIId Volume of the *Transactions of the Astronomical Society* contains a series of observations in Borda's method, made by Mr. Rumker at Paramatta. It appears that the length of the pendulum was measured by screwing up the steel plate, first till it touched the ball, then till it touched the measuring bar. The diameter of the ball was measured by winding a thread eleven times round it. The result in millimètres is 992.412801. Many details of the calculation are omitted.

By Fallows at the Cape of Good Hope.

In the *Phil. Trans.* for 1830 is a determination by Mr. Fallows, of the proportion of Gravity at London and at the Cape of Good Hope with an invariable pendulum. The number of vibrations per day at London was 86164.97, and at the Cape 86097.86. With the length 39.13929 inches for the seconds' pendulum at London, we find for the Cape 39.07836.

By transportation of an invariable pendulum, (from London, we believe,) Svanberg ascertained the length of the seconds' pendulum at Stockholm, latitude 59° 21′, to be 39.165414 inches. We are unable to refer to the original account of this experiment.

The length of the pendulum at Königsberg, latitude 54° 42′, reduced to the level of the sea, has been found by Bessel (by his method described above) to be 440.8179 lines. The two pendulums whose difference he measured, vibrated in 1″.7127 and 1″.0020. Observations of invariable pendulums transported from Paris gave a greater length. See the *Berlin Transactions* for 1826, or the *Quarterly Journal*, March, 1829.

The difference of Gravity at London and Altona has, we believe, been ascertained by Captain Sabine with an invariable pendulum. The results, so far as we know, have not yet been published.

Deduct
from P
dulum
servatio

Observations have been made in London by Mr. F. Baily with a pendulum with two knife-edges. The pendulum consists of a massy brass bar without any bob. This construction appears to be attended with the following source of inaccuracy; if the suspension planes are not very well levelled, the pendulum will not vibrate in a vertical plane, and the time of vibration will be too great. In Captain Kater's construction this was provided against by making the bar so thin that it would bend into the proper position. Mr. Baily's results differ sensibly from those of Captain Kater.* See the *Philosophical Magazine*, February, 1829.

Section 8.—Deduction of the Figure of the Earth from Pendulum Observations.

Length
second
pendul
at Paris

The first element which it is important to settle is, the length of the pendulum at Paris. In these reductions we shall suppose the French foot = 1.065766 × English foot; and the mètre = 39.37079 English inches.

	Eng. Inches.
Now Borda's experiments give 440.5593 lines =	39.12776
Biot's (uncorrected for elevation) give for the decimal pendulum $0^m.7419012$, or for the sexagesimal	39.12848
Sabine's	39.12813

The mean is 39.12812, and this is probably very accurate. If corrected for elevation by Dr. Young's rule it gives at the level of the sea 39.12877.

Mann
calcu
all th
length

From this length, and the length at London, (39.12908, or corrected by Dr. Young's rule for elevation 39.12929,) we have deduced the length at all the places where an invariable pendulum was observed. The absolute lengths measured by the French in the present century we have reduced to English measures. The absolute lengths measured in the last century we have compared with the Paris length given by the same observer, and have applied the difference to *our* value of the Paris length. Legentil's are compared as we have mentioned.

The observations may now be very well divided into first-rate and second-rate. We have reduced all of the first class to the level of the sea by Dr. Young's rule, using the multiplier .6. In the second class we have not attempted any alteration, except in Warren's, which we have corrected for the error of the standard, and reduced to vacuum.

Len
sum
corr
witl
theo
form

Now in Section 2, Art. 65, it appears that theory would lead us to expect that gravity at the latitude λ, or the length of the seconds' pendulum which is proportional to it, may be represented by $E\,(1 + F \sin^2 \lambda)$. Making this assumption for each of the lengths, and arranging them in the order of latitude, we have the following Table. Where two observers are mentioned, we have taken the mean of the lengths deduced in the way that we have described.

---

[*] Mr. Baily remarks that Shuckburgh's scale seems to have sustained some injury. It appears, however, that the same divisions were used for the measure of the pendulum as for the comparison with the mètre, and nearly the same as for the comparison with other English standards; and thus the error in the result of measures which are only comparative is probably insensible.

---

* The whole of these (except Bessel's) are erroneous to the amount of the error in the correction for the density of the air. The magnitude of this error is nearly the same for all, and is about .0018.

Constants in the formula determined.

To determine E and F from the first-rate observations, the most favourable groups will be formed by taking for one the sum of the first 24 equations and the 49th, and for the other the sum of the 24 remaining equations. Thus we get

$$E \times \{25 + F \times 16.9070\} = 978.80528$$

$$E \times \{24 + F \times 3.8983\} = 937.16322.$$

The solution of these equations gives E = 39.01677, F[*] = .005133. These values give for the length of the Equatorial pendulum 39.01677, for the Polar pendulum 39.21704, and for the pendulum at latitude λ $39.01677 + .20027 \times \sin^2\lambda$.

Substituting these values of E and F in each of the equations, we get the following apparent errors in measurement of the pendulum, or in the number of vibrations per day.

Comparison of calculated and measured lengths.

In order to compare the lengths determined from Malaspina's observations with the others, we have calculated from the formula $39.01677 + .20027 \times \sin^2\lambda$ the length at each of his stations. We have divided the sum of all these by the sum of his numbers; and have used the quotient as a common multiplier by which we have multiplied each of his numbers. The length thus produced we have called the *observed length*, and we have compared it with our *calculated length* as in the other cases.

From an examination of these apparent errors, the following conclusions may be deduced.

1. The observations that we have called second-rate, and the Spanish observations, are perfectly useless for the investigation of the Earth's form.

2. Upon scrutinizing the errors of the first-rate observations, it would seem that, *cæteris paribus*, gravity is greater on islands than on continents. This is a conclusion, however, that cannot be adopted till the correction for elevation is ascertained with greater certainty. The stations of observation on continents, or large islands, are frequently more elevated than those on small islands; and, therefore, if our correction (the usual correction multiplied by 0.6) is too small, as it is additive, it will make the pendulum's length, reduced to the level of the sea, much too small at the continental stations and not much too small on islands. Yet we think our correction (adopted from Dr. Young) a good one, as it removes some apparent anomalies. At Clermont, for instance, an elevated station, with the usual

---

[*] It is remarkable that when Newton found the decrease of gravity at the Equator to be greater than in a homogeneous spheroid, he supposed the ellipticity to be greater than for a homogeneous spheroid. We shall draw an inference exactly contrary to this.

correction, gravity appears too great; with ours there is no remarkable inequality. These considerations will show what caution must be used in adopting any theory* which rests upon very delicate differences of gravity.

3. But it is impossible to avoid remarking, that in the high North latitudes the greater number of errors have the sign +, and that about the latitude 45° they have the sign −; those about the Equator being nearly balanced. No alteration of our numbers is sufficient to correct this. If we increased the multiplier of $\sin^2\lambda$, we might make the errors at high latitudes as nearly balanced as those at the Equator: but then those about latitude 45° would be still greater than at present. To destroy these without altering the others we may add a term $- A . \sin^2\lambda . \cos^2\lambda$. We have seen in Section 2. Art. 71. that such a term ought to exist, though we could only offer a conjecture as to its magnitude. From the table of errors it would seem that the length of the seconds' pendulum would be better expressed by $39.01677 + .20277 \times \sin^2\lambda - .00880 \times \sin^2\lambda . \cos^2\lambda$. The last term is ten times as great as our imperfect theory would lead us to expect. Still, as an empirical formula, this is the best that we can offer.

4. There does not seem to be any reason for thinking that gravity is different at different longitudes; as the irregularities on different meridians do not appear greater than those at places near one another. Nor does it appear that there is any difference between the Northern and Southern hemispheres.

Now to determine the Earth's ellipticity we must refer to the formula of Section 2. Art. 65. It appears that gravity, or the length of the seconds' pendulum, being expressed by $E\,(1 + F \sin^2\lambda)$, F will $= \frac{5m}{2} - e$, and consequently $e = \frac{5m}{2} - F$; where m is the ratio of the centrifugal force at the Equator to the force of gravity there. To determine m, we have, Equatorial seconds' pendulum $= 39.01677$; hence the space through which the Equatorial gravity would make a body fall in 1^s is $\frac{\pi^2}{2} \times 39.01677$, and the velocity which it would generate in 1^s is $\pi^2 \times 39.01677$. Also (MECHANICS, § XIV.) the velocity which would be generated in 1^s by the uncounteracted centrifugal force produced by describing in T seconds a circle whose radius is R, is $\frac{4\pi^2 . R}{T^2}$; or at the Earth's Equator $\pi^2 \times \frac{4 \times 251084556}{(86164.1)^2}$.

Consequently $m = \frac{4 \times 251084556}{39.01677 \times (86164.1)^2} = .0034672$;

and $= e\,.0086679 - F$.

The question now is, what value shall we choose for F? Shall we represent the length of the seconds' pendulum by $39.01677 + .20027 \sin^2\lambda$, or by $39.01677 + .20277 \sin^2\lambda - .00880 \sin^2\lambda \cos^2\lambda$? The former gives $F = .005183$; the latter gives $F = .005197$. We are now in a case where our theory partly fails, and where it is impossible to say which of the empirical forms is more likely to be correct. If we adopt the former value of F we find $e = .003535$; if the latter, $e = .003471$. Either of these values of e is considerably greater than that which we found from the discussion of the geodetic measures (.003352).

Physical Theory of Precession and Nutation, &c.

Greater than that given by measures of arcs.

We cannot offer any conjecture as to the cause of this difference. If the regions of the Earth in middle latitudes were composed of lighter materials than the other parts, it might possibly happen that the gravity at middle latitudes (from the resulting projection of the Earth at these parts) would be diminished, while at the Poles and Equator it would be increased. The same alteration of figure would cause the ellipticity, deduced principally from measures near the Equator and in middle latitudes, to appear less than it ought. The only way of verifying such an idea would be, to measure an extensive arc of meridian near the Pole, (for we consider the Swedish arcs to be almost useless,) a thing which is not likely to be ever effected. But is such an idea worth verifying? We cannot say that it is: and we have uttered it only in the effort to produce some conjectural explanation of an apparent anomaly.

No explanation of the difference.

We can find, however, another conclusion which it is more pleasing to dwell upon. If the form of the Earth's meridian were traced on paper the nicest eye would be unable to distinguish it from a circle. The ellipticity is so small that the closest inspection without measure could not judge which was intended for the greater and which for the smaller axis. The whole quantity in dispute is less than one-sixteenth of this ellipticity. Instead of being surprised that such a difference exists, we may well be astonished at the accuracy of modern measures of all kinds which make so small a quantity a subject of controversy.

Section 9.—Physical Theory of Precession and Nutation, and Deductions of the Earth's Ellipticity from their observed Magnitudes.

Difficulty in the fundamental explanation of precession.

To point out the peculiar difficulty which at first sight appears to exist in the explanation of these phenomena, we will consider the Earth in the situation which it has at the summer solstice. In fig. 48 let S be the Sun, B the pole of the Earth whose centre is A. If now the Earth were a sphere, the attraction of the Sun upon it would not tend to disturb its motion of rotation. But from the preceding discussions it appears, that the Earth is an oblate spheroid, and that, consequently, at K and L its form is protuberant above the spherical form. The attraction of the Sun upon K is more powerful than that on the principal mass of the Earth; the attraction on L is less powerful. Considering the effect of these forces in producing motion relative to A, the effect of the former is the same as if K were drawn towards S, that of the latter the same as if L were pushed away. The effect of both of these forces seems, to twist the spheroid so as to remove B further from S. But in point of fact the effect is, to lift up the pole B from the paper, while A remains in it; B preserving the same distance from S. This is the difficulty to be explained.

Precession explained by the composition of rotatory motions.

The explanation is to be sought in the composition of rotatory motions given in the Treatise on MECHANICS, Art. 143, &c. The Earth is revolving round the axis A B. The tendency of the forces that we have described is to twist the Earth round an axis which would be represented by sticking a pin perpendicular to the paper at A. The consequence is, that at the end of a short time the Earth is revolving about an axis lying

---

* Captain Sabine has observed, (we think correctly,) that in many instances the inequalities in the force of gravity appear to depend on the geological character of the stratum. On basaltic rocks, for instance, the number of vibrations is greater, and on alluvial soil less, than we should have inferred from the latitude of the station.

in the plane which passes through the pin and A B, but shifted from A B towards the pin. (We say towards the pin and not the other way, because the direction of the shifting is determined by observing on which side of the old axis the motion impressed by the extraneous forces is opposed to the motion due to the original rotation; as it is plain that the position of the new axis must be in that part where the two motions destroy each other.)

From this it appears, that the actual axis of rotation does in fact wander within certain small limits through the Earth. Since it continues to rise upwards from the paper at the extremity B while the Earth is revolving, it is easily seen that the pole describes on the Earth's surface a very small circle whose circumference = daily motion of the pole. The pole of the terrestrial ellipsoid then, whose form is determined by the rotation, will be in the centre of this small circle. And the motion will be the same as if the Earth revolved round one invariable axis, namely the axis of the ellipsoid, and this axis were lifted up from the paper.

Suppose the extraneous forces would impress in 1ˢ an angular velocity a round the axis represented by the pin; and suppose ω to be the angular velocity round the original axis. As the velocity a is not impressed at once, but by degrees, suppose the 1ˢ divided into n equal parts. At the end of the first part, the original velocity ω round A B is compounded with the velocity $\frac{a}{n}$ round the pin. The new axis (by the theorems referred to) is in a position dividing the angle between A B and the pin (a right angle) into two parts whose sines are in the proportion of ω and $\frac{a}{n}$; that is the angle which it makes with A B has for tangent $\frac{a}{n\,\omega}$. And the velocity of rotation round the new axis (see MECHANICS) is to that round the old one, as the sine of 90° to the sine of the complement of the last-mentioned angle; and consequently it $= \omega\sqrt{1 + \frac{a^2}{n^2\,\omega^2}} = \sqrt{\omega^2 + \frac{a^2}{n^2}}$. In the same manner, after the second portion of time, the angular velocity will be $\sqrt{\omega^2 + \frac{2\,a^2}{n^2}}$, &c.; and after 1ˢ or n portions of time, it will be $\sqrt{\omega^2 + \frac{n\,a^2}{n^2}} = \sqrt{\omega^2 + \frac{a^2}{n}}$. Now let the communication of the motion be gradual, that is, let n be indefinitely great, and this becomes ω. That is, the velocity of rotation is not altered. Taking up the investigation again, it will appear that in every n^{th} part of 1ˢ the axis is shifted through the angle whose tangent is $\frac{a}{n\,\omega}$: and, therefore, in 1ˢ the axis is shifted through $n \times$ angle whose tangent is $\frac{a}{n\,\omega}$, that is, making n indefinitely great, through the angle $\frac{a}{\omega}$ (as measured on the circumference of a circle whose radius = 1.)

The velocity of rotation is not altered.

Measure of the motion of the Earth's axis produced by an extraneous force.

We must begin then with calculating the value of a. Now to find the momentum of the impressed forces in producing rotation round A, we shall take the difference of the forces acting on each point P and on A (this amounts to the same as impressing on all the particles a force equal to that on A, which evidently would not alter the rotation.) The Sun's force on P $= \frac{S}{SP^2}$ (putting S for the acceleration produced by the Sun's action at distance 1): the resolved parts in the directions P N and N A are $\frac{S\,.\,PN}{SP^3}$ and $\frac{S\,.\,SN}{SP^3}$; or subtracting $\frac{S}{SA^2}$ the force on A, they are $\frac{S\,.\,PN}{SP^3}$ and $S\left(\frac{1}{SN^2} - \frac{1}{SA^2}\right)$, as S P is very nearly equal to S N. The values of these, supposing S A very great, are nearly $\frac{S}{SA^3}\,PN$ and $\frac{-2\,S}{SA^3} \times AN$. The momenta of these forces acting on a particle δm are $\frac{S}{SA^3}\,PN \times AN \times \delta m$ and $\frac{-2\,S}{SA^3}\,AN \times -PN \times \delta m$; their sum is $\frac{3\,S}{SA^3}\,AN\,.\,PN\,.\,\delta m$. Let A M parallel to the equator $= x$; M P parallel to the axis $= y$; B A S $= \theta$; then A N $= x \sin\theta - y \cos\theta$; N P $= x \cos\theta + y \sin\theta$; and the momenta of the forces is $\frac{3\,S}{SA^3} \times \{(x^2 - y^2)\sin\theta\,.\,\cos\theta + x\,y\,(\sin^2\theta - \cos^2\theta)\}\,\delta m$.

Calculation of the momentum of the Sun's attraction.

Consequently the momenta of forces upon the whole spheroid is the sum of the quantities $\frac{3\,S}{SA^3}\sin\theta\,.\,\cos\theta \int x^2\,\delta m$, $-\frac{3\,S}{SA^3}\sin\theta\,.\,\cos\theta\,.\int y^2\,\delta m$, $\frac{3\,S}{SA^3}(\sin^2\theta - \cos^2\theta)\int x\,y\,\delta m$. But since for every value of x we can find pairs of particles, whose values of y are equal, and have different signs, $\int x\,y\,\delta m$ will be 0. Also, putting a and b for the major and minor semiaxes, and ρ for the density of the spheroid, it is easily seen that $\int x^2\,\delta m$ must be proportional to $a^2 \times$ mass of spheroid, or proportional to $a^2 \times a^2\,b\,.\,\rho$, or equal to $C\,.\,a^4\,b\,.\,\rho$; and that $\int y^2\,\delta m$ must be in the same proportion to $b^2 \times a^2\,b\,.\,\rho$, or equal to $C\,a^2\,b^3\,.\,\rho$: and therefore the whole momentum of forces $= \frac{3\,S}{SA^3}\sin\theta\,.\,\cos\theta\,.\,C\,.\,a^2\,b\,(a^2 - b^2)\,\rho$. If $a = b\,(1 + e)$ where e is small, this $= \frac{6\,S}{SA^3}\,.\,\sin\theta\,.\,\cos\theta\,.\,C\,b^5\,e\,.\,\rho$.

Calculation of the momentum of inertia.

If, as in Section 2. Art. 44. we suppose the spheroid to consist of a series of spheroidal shells of different densities, the momentum of forces will be $\frac{6\,S}{S\,A^3} . \sin\theta . \cos\theta . C \int \rho . \frac{d\,(b^5\,e)}{d\,b} . d\,b$, or $\frac{6\,S}{S\,A^3} \sin\theta . \cos\theta . C . \psi\,(b)$.

Now to find a (Mechanics, § XIX.) we must divide this by the moment of inertia, or $\int (x^2 + y^2)\,\delta m$: which for a homogeneous spheroid $= C\,a^2\,b\,(a^2 + b^2)\,\rho = 2\,C . b^5 . \rho$ nearly; and for a heterogeneous spheroid $= 2\,C \int \rho . \frac{d\,(b^5)}{d\,b}\,d\,b$. Call the general integral $v\,(b)$, and the value which it has at the surface v (b), and we have for the moment of inertia $2\,C\,v\,(b)$.

Calculation of the motion of the Earth's axis produced by the Sun.

Dividing by this the moment of the forces, we have $a = \frac{3\,S}{S\,A^3} \frac{\psi\,(b)}{v\,(b)} \sin\theta . \cos\theta$: and consequently the motion of the Earth's axis in $1^s = \frac{3\,S}{S\,A^3 . \omega} . \frac{\psi\,(b)}{v\,(b)} \sin\theta . \cos\theta$; which for convenience we may call $D . \sin\theta . \cos\theta$.

Direction of this motion.

Now this motion is perpendicular to the plane passing through the Sun and the Earth's axis. In fig. 49, let B represent the place of the Pole, and ○ the place of the Sun as seen from the Earth's centre; let ♈ ♋ be the ecliptic, P the pole of the ecliptic, B b perpendicular to B ☉. Then the Earth's pole is moving with the velocity D . sin B ☉ . cos B ☉ in the direction B b. This produces an alteration in the distance of B from P, and an alteration in the place of ♋. We shall investigate these separately.

Change in the inclination of the Earth's axis to the ecliptic produced by the Sun.

First, the resolved part of the velocity of B in the direction B P is D . sin B ☉ . cos B ☉ . sin ☉ B ♋ = D cos B ☉ . sin ☉ ♋ = D cos B ♋ . cos ☉ ♋ . sin ☉ ♋. Let P B = I: then cos B ♋ = sin I. Also let the Sun be supposed to go (apparently) through the ecliptic in a year or T seconds, with a uniform motion, (the effect of the inequality of motion is not sensible,) and let t be the time since the Sun was at ♈. Then ♈ ☉ $= \frac{2\pi}{T}\,t$, and cos ☉ ♋ . sin ☉ ♋ $= \sin\frac{2\pi}{T}\,t . \cos\frac{2\pi}{T}\,t = \frac{1}{2}\sin\frac{4\pi}{T}\,t$; and the resolved velocity in the direction B P is $\frac{D}{2} \sin I . \sin\frac{4\pi}{T}\,t$. Integrating this with respect to t we find the motion in the direction B P $= -\frac{D . T}{8\pi} . \cos\frac{4\pi}{T}\,t = -\frac{D . T}{8\pi} . \cos 2$ ♈ ☉. And the inclination is changed to I $+ \frac{D . T}{8\pi} \cos 2$ ♈ ☉. It is plain that the last term is periodical: and, therefore, though the inclination is changed in the course of a year, it is the same in all successive years. The variable term is called Solar Nutation.

Precession of equinoxes produced by the Sun.

Secondly, the resolved part of the velocity of B perpendicular to B ♋ is D . sin B ☉ . cos B ☉ . cos ☉ B ♋. Now cos ☉ B ♋ = sin B ☉ ♋ . cos ☉ ♋: the expression becomes then D . × (sin B ☉ . sin B ☉ ♋) × (cos B ☉) × cos ☉ ♋ = D × (sin B ♋) × (cos B ♋ . cos ☉ ♋) × cos ☉ ♋ = D . sin I . cos I. sin² ♈ ☉ $= \frac{D}{2} \sin I . \cos I \left(1 - \cos\frac{4\pi}{T}\,t\right)$. Integrating with respect to t we have for the motion of B perpendicular to P B, $\frac{D}{2} . \sin I . \cos I . t - \frac{D . T}{8\pi} \sin I . \cos I \sin\frac{4\pi}{T}\,t$. The motion of ♋ is found by dividing this by sin I, and it is, therefore, $\frac{D}{2} . \cos I . t - \frac{D . T}{8\pi} \cos I . \sin 2$ ♈ ☉. The last term is periodic: it is considered a part of solar nutation. The first increases uniformly; it shows that ♋ is continually travelling towards ♈, or backwards: the regression in one year is $\frac{D}{2}$ cos I . T. This is called Solar Precession.

General explanatoin of lunar precession and lunar nutation.

The last investigations apply as well to the Moon as to the Sun. The only difference is that the Moon revolves in so short a time round the Earth that the periodic terms analogous to solar nutation are hardly sensible. So that putting M for the mass of the Moon, M A for her distance from the Earth's centre, $\frac{3\,M}{M\,A^3 . \omega} \times \frac{\psi\,(b)}{v\,(b)} = E$, I′ the angular distance between the pole of the earth and the pole of the Moon's orbit, T′ her periodic time; the motion of the Earth's pole during one revolution of the Moon is $\frac{E}{2} \sin I' \cos I' . T'$ in a direction perpendicular to the great circle joining the pole of the Earth, and the pole of the Moon's orbit. Now the pole of the Moon's orbit describes (nearly) a circle in 18½ years round the pole of the ecliptic. And this change of place, altering the direction and magnitude of the motion of the Earth's pole, produces the inequality called Lunar Nutation.

In fig. 50, let p be the pole of the Moon's orbit. Then the motion of the Earth's pole in 1^s will be $\frac{E}{2} \sin B\,p . \cos B\,p$ in the direction B b. The resolved part of this velocity which increases the distance of B and P is $\frac{E}{2} \times (\cos B\,p) \times (\sin B\,p . \sin P\,B\,p) = \frac{E}{2} \times (\cos B\,P . \cos P\,p + \sin B\,P . \sin P\,p . \cos P) \times (\sin P\,p . \sin P)$. Let $P\,p = I''$, and let the periodic time of p round p in a retrograde direction be T'': and let t be the

Change in the inclination of the Earth's axis to the ecliptic produced by the Moon.

time since p passed the arc P B. Then the velocity above $= \frac{E}{2} \times \left\{ \cos I . \sin I'' . \cos I'' . \sin \frac{2\pi t}{T'} + \frac{1}{2} \sin I . \sin^2 I'' \sin \frac{4\pi t}{T'} \right\}$. Integrating this with respect to t, we have for the increase of P B, $\frac{E . T'}{4\pi} \times \left\{ - \cos I . \sin I'' . \cos I'' . \cos \frac{2\pi t}{T'} - \frac{1}{4} \sin I . \sin^2 I'' . \cos \frac{4\pi t}{T''} \right\}$. These terms are one part of lunar nutation. They are evidently periodical; and, therefore, the inclination of the Earth's axis to the axis of the ecliptic is not permanently altered.

Precession of the equinoxes produced by the Moon.

Again, the resolved velocity perpendicular to P B is $\frac{E}{2} \sin Bp . \cos Bp . \cos PBp . = \frac{E}{2} \sin Bp . \cos Bp . \frac{\cos Pp - \cos BP . \cos Bp}{\sin BP . \sin Bp} = \frac{E}{2} . \cos Bp . \frac{\cos Pp - \cos BP . \cos Bp}{\sin BP} = \frac{E}{2} (\cos I . \cos I'' + \sin I . \sin I'' . \cos P) . \frac{\sin^2 I . \cos I'' - \sin I . \cos I . \sin I'' . \cos P}{\sin I} = \frac{E}{2} \{ \sin I . \cos I . \cos^2 I'' - (\cos^2 I - \sin^2 I) \sin I'' . \cos I'' . \cos P - \sin I \cos I . \sin^2 I'' . \cos^2 P \}$. Putting $\frac{2\pi t}{T'}$ for P, and integrating with respect to t, we find for the motion perpendicular to P B, $\frac{E}{2} \left\{ \sin I . \cos I . (\cos^2 I'' - \frac{1}{2} \sin^2 I'') . t - \frac{T'}{2\pi} (\cos^2 I - \sin^2 I) \sin I'' . \cos I'' . \sin \frac{2\pi t}{T'} - \frac{T''}{8\pi} . \sin I \cos I \sin^2 I'' . \sin \frac{4\pi t}{T''} \right\}$. The two last terms are evidently periodical: they are the remaining part of lunar nutation. The retrograde motion of ♋ will be found by dividing the motion of the Pole by sin I; it is, therefore, $\frac{E}{2} \left\{ \cos I . (\cos^2 I' - \frac{1}{2} \sin^2 I') t - \frac{T''}{2\pi} . \frac{\cos 2I}{\sin I} . \sin I'' . \cos I'' . \sin \frac{2\pi t}{T'} - \frac{T'}{8\pi} . \cos I . \sin^2 I'' . \sin \frac{4\pi t}{T''} \right\}$. The two last terms, which are periodical, constitute the equation of the equinoxes in longitude. The first term increases uniformly: it is called lunar precession.

Sum of solar and lunar precession.

The lunar precession in one year is found by putting T for t: it is therefore $\frac{E . T}{2} . \cos I . (\cos^2 I'' - \frac{1}{2} \sin^2 I'')$. The whole annual soli-lunar precession is, therefore, $\{ D + E (\cos^2 I'' - \frac{1}{2} \sin^2 I'') \} \frac{T}{2} \cos I$. Putting for D and E their values, this becomes $\left\{ \frac{S}{SA^3} + \frac{M}{MA^3} (\cos^2 I'' - \frac{1}{2} \sin^2 I'') \right\} . \frac{3 T \cos I}{2\omega} . \frac{\psi (b)}{v (b)}$.

To reduce this to numerical calculation, we must remark that (Mechanics, Art. 65. where u corresponds to our S, and a to our S A,) $T^2 = \frac{4\pi^2 . SA^3}{S}$, therefore $\frac{S}{SA^3} = \frac{4\pi^2}{T^2}$. Also, by the same formula, as the Moon revolves round the Earth as a centre, $\frac{\text{Earth's mass}}{MA^3} = \frac{4\pi^2}{T'^2}$: and consequently, if the Moon $= \frac{1}{n}^{th}$ of the Earth, $\frac{M}{MA^3} = \frac{4\pi^2}{nT'^2}$.* This makes the expression $\{ 1 + \frac{T^2}{nT'^2} (\cos^2 I'' - \frac{1}{2} \sin^2 I'') \} \frac{6\pi^2 \cos I}{T\omega} . \frac{\psi (b)}{v (b)}$. But since ω is the angular velocity of the Earth, T ω is evidently the angle through which the Earth revolves in a year $= 366.26 \times 2\pi$. Thus the annual precession becomes $\{ 1 + \frac{T^2}{nT'^2} (\cos^2 I'' - \frac{1}{2} \sin^2 I'') \} . \frac{3\pi . \cos I}{366.26} . \frac{\psi (b)}{v (b)}$. This is measured by an arc of a circle whose radius is 1. If we express it in seconds of a degree, it must be multiplied by $\frac{360 \times 60 \times 60}{2\pi}$: this gives for the annual precession in seconds, $\{ 1 + \frac{T^2}{nT'^2} (\cos^2 I'' - \frac{1}{2} \sin^2 I'') \} . \frac{540 \times 60 \times 60}{366.26} \cos I \frac{\psi (b)}{v (b)}$. If we knew accurately the value of n, we might compare this expression with the observed value of annual precession (which is known very accurately) and might thence infer the value of $\frac{\psi (b)}{v (b)}$. This, it is plain, would give us considerable assistance in determining the form and constitution of the Earth.

Soli-lunar precession in a form for calculation.

But as n is not very certainly known, it will be better to use also another observable quantity depending on n. The most easily observable is the first term of lunar nutation in the increase of P B. This coefficient we have found to be $\frac{E . T'}{4\pi} . \cos I . \sin I'' . \cos I''$, or $\frac{M}{MA^3} . \frac{3 T'}{4\pi . \omega} \cos I . \sin I'' . \cos I'' \frac{\psi (b)}{v (b)}$, or $\frac{3\pi T'}{nT'^2 . \omega}$

---

* Instead of n we ought in strictness to have put $n + 1$. See Physical Astronomy, p. 653. The effect of this error is insensible.

$\cos I . \sin I'' . \cos I'' . \frac{\psi(b)}{v(b)} = \frac{3\pi}{n} . \frac{T''}{T} . \frac{T^2}{T'^2 . 366.26 . 2\pi} . \cos I . \sin I'' . \cos I'' . \frac{\psi(b)}{v(b)}$, which in seconds (as in the former case) $= \frac{1}{n} . \frac{T''}{T} . \frac{T^2}{T'^2} . \frac{270 \times 60 \times 60}{366.26 . \pi} . \cos I . \sin I'' . \cos I'' . \frac{\psi(b)}{v(b)}$.

Lunar nutation in a form for calculation.

Now suppose $I = 23° 28'$; $I'' = 5° 8' 38''$; $\frac{T''}{T} = 18.6$; $\frac{T}{T'} = \frac{366.26}{27.32}$; also call the whole annual precession a, and the term just mentioned b. Then on performing the calculations, we shall have these equations,

$$a = \left(4869 + \frac{864490}{n}\right) . \frac{\psi(b)}{v(b)}$$

$$b = \frac{231460}{n} . \frac{\psi(b)}{v(b)}.$$

Solving them,

$$n = 47.54 \times \frac{a}{b} - 177.56$$

$$\frac{\psi(b)}{v(b)} = .0002054 \times a - .0007671 \times b.$$

Function depending on the Earth's form deduced from observed values of precession and nutation.

The last value is the only one for which we have occasion at present.

Now a is very nearly 50.3; the value of b given by Bradley is 9.0; by Mayer 9.65; by Maskelyne 9.55; by Laplace 9.40; by Lindenau 8.99; by Brinkley 9.25. Then we get for $\frac{\psi(b)}{v(b)}$ the following values:

According to Bradley, $\frac{\psi(b)}{v(b)} = .003428$
Mayer $= .002930$
Maskelyne $= .003006$
Laplace $= .003121$
Lindenau $= .003436$
Brinkley $= .003236$.

The last value is perhaps the most probable; (it has been adopted as such by Mr. Baily in the construction of the Astronomical Society's Tables, and we think properly.) Now it must be observed that we cannot from this deduce the Earth's ellipticity without assuming some law for the density of the strata, and solving approximately a troublesome equation. For though $\psi(b) = \frac{5}{3}\left(e - \frac{m}{2}\right) b^3 . \phi(b)$, (Section 2. Art. 63.) and, therefore, $\frac{\psi(b)}{v(b)} = \frac{5}{3}\left(e - \frac{m}{2}\right) . \frac{b^3 \phi(b)}{v(b)}$, where $\phi(b)$ and $v(b)$ do not depend on e; yet the values both of e and of $\phi(b)$ and $v(b)$ will depend on the value of the constants in the law (whatever it may be;) and, therefore, when e is determined on the assumed law in terms of the constants by the formula of Section 2. and $\phi(b)$ and $v(b)$ are expressed in terms of them, there will, upon making $\frac{5}{3}\left(e - \frac{m}{2}\right)\frac{b^3 . \phi(b)}{v(b)}$ equal to one of the values above, be a complicated equation to solve. If, for instance, we assume the law mentioned in Section 2. Art. 68. and take Brinkley's value of nutation, we shall have this equation to solve

This function will not give the Earth's ellipticity without a knowledge of the law of density.

$$.003236 = \left\{\frac{5m}{2} . \frac{\frac{3f}{q^2 b^2} - 1}{\frac{q^2 b^2}{f} + f - 3} - \frac{m}{2}\right\} . \frac{f}{2 + f - \frac{6f}{q^2 b^2}},$$

Calculation with Brinkley's nutation.

where $f = 1 - \frac{qb}{\tan qb}$. Solving this by approximation, with the value $m = .0034672$, we find $q\,b = 143° 53'$; and substituting this in the expression

$$e = \frac{5m}{2} . \frac{\frac{3f}{q^2 b^2} - 1}{\frac{q^2 b^2}{f} + f - 3}, \text{ we find } e = .3323.$$

The smaller values of $\frac{\psi(b)}{v(b)}$ give smaller values for e.

We may remark that the mass of the Earth is $= \frac{4\pi}{3} \int \rho \frac{d . b^3}{db} db$ nearly, and its volume $= \frac{4\pi}{3} b^3$ nearly, therefore the mean density $= \frac{3 \int \rho . b^2 db}{b^3}$ nearly. With the law above mentioned, and the value

Figure of the Earth.

Earth's mean density compared with density at surface.

of q b just found, we find for the mean density $\frac{3\,\mathrm{A}}{q^2\,\mathrm{b}^3}$. sin q b . f, that at the surface being $\frac{\mathrm{A} \,.\, \sin q\,\mathrm{b}}{\mathrm{b}}$. The proportion of these is $\frac{3\,f}{q^2\,\mathrm{b}^2}$, or 2.20; a proportion that agrees pretty well with the results of experiments hereafter to be mentioned.

Section 10.—*Deduction of the Earth's Ellipticity from the observed Inequalities of the Moon's Motion.*

In Section 2. Art. 67. we have found for the inequality in the Moon's latitude depending on the Earth's non-sphericity, $-\left(\mathrm{e}-\frac{m}{2}\right)\times\frac{4\,.\,\overline{60}|^3}{\pi}\,\mathrm{M}\,.\left(\frac{\text{Earth's period}}{\text{Moon's period}}\right)\left(\frac{\text{Earth's radius}}{\text{Moon's distance}}\right)^2.\ \sin\mathrm{I}\,.\,\cos\mathrm{I}\,.\,\sin\theta$. This expression is, in fact, the same as Laplace's, (*Mécanique Céleste,* livre 7, No. 29.) observing that g is very nearly $= 1 + \frac{3}{4}\,m^2$ (in Laplace's notation.) If $\mathrm{I} = 23°\,28'$, and $\frac{\text{Earth's radius}}{\text{Moon's distance}} = \sin 57'$, and $\frac{\text{Earth's period}}{\text{Moon's period}} = \frac{365.25}{27.25}$, and $\mathrm{M} = \frac{70}{71}$, this is equal to $-\ 4891'' \times\left(\mathrm{e}-\frac{m}{2}\right)\times\sin\theta$. Now this inequality has been found to exist, (it has the effect of increasing the apparent inclination of the Moon's orbit in one position of her nodes, and of diminishing it as much in the opposite position,) and its magnitude has been inferred from observation. The multiplier of sin θ in Bürg's Tables is $-\ 8''.0$; in Burckhardt's it is the same. This value gives $\mathrm{e}-\frac{m}{2}=\frac{8}{4891}=.001636$; and considering m (as before) $= .003467$, we have $\mathrm{e} = .001636 + .001734 = .003370$.

Ellipticity calculated from inequality in the Moon's latitude.

From inequality in the Moon's longitude.

We have mentioned in the same place, that there is an inequality in the Moon's longitude depending on the non-sphericity of the Earth. Laplace's expression (which our limits do not allow us to investigate) is equivalent to C . sin longitude of the ascending node of the Moon's orbit, where $\mathrm{C} = \frac{19}{2}$. tan mean inclination of Moon's orbit × the coefficient of the last inequality. Making mean inclination $= 5°\,8'\,38''$, C is found $= 4183'' \times\left(\mathrm{e}-\frac{m}{2}\right)$. In Bürg's Tables C is $6''.8$; in Burckhardt's it is $7''.0$ The first gives $\mathrm{e}-\frac{m}{2} = .001626$, $\mathrm{e} = .003360$; the second gives $\mathrm{e}-\frac{m}{2}$ $.001673$, $\mathrm{e} = .003407$. Any of these values agrees nearly enough with that deduced from the geodetic measures.

Inequal of th Moon Motic

Doubts the cert of these clusion

In estimating the reliance to be placed on these values, it must be observed that they are deduced from observations which are insufficient if they do not extend over a period of nearly 20 years. The same remark applies to the deductions of the last section. This always throws a very little doubt on the accuracy of such a determination, as in all probability the observations which are compared have been made by different persons and in different manners. The small lunar inequalities, besides, are involved among a mass of terms much greater than themselves; but an error in their determination has less influence on the value of e than an equal error in the determination of nutation. We mention these things merely to show that these deductions could not be put in competition with those derived from geodetic measures, or pendulum observations, if the discordancies among the latter were not so great as to make every confirmation of their results desirable. The coincidence of the results is however satisfactory, as it gives us a strong confidence that the result deduced from the measures is not far from the truth, and that our theory is in the main correct.

Section 11.—*Observations which show that the Attraction of Masses comparatively small is sensible; and Determinations of the Earth's mean Density.*

Anom in co ing di parts same merid

Among these we may place the discrepancies which have been observed in comparing different parts of the same arc. Of these it must be confessed, that in some instances no distinct explanation can be given. At Arbury Hill, for instance, one of the stations nearly bisecting the English arc of meridian, the latitude was observed, and was found to differ about 5″ from any that could be admitted, on any supposition of the Earth's form; at Dodagoontah, on the great Indian arc, an unexplained disturbance to nearly the same amount was observed; at Takal Khera the same thing was observed; but Captain Everest appears to have accounted perfectly for this by the attraction of a range of mountains at the distance of 15 miles, (the range running Eastward from the termination of the Western Ghauts.) The magnitude of these disturbances, it must be observed, is much greater than any error that could possibly happen in the use of the astronomical instruments or in the geodetic measures, without the most unreasonable neglect. And in inferring the latitude of one place from the observed latitude of another not on the same meridian, through the medium of a geodetic measure, results have frequently been obtained which differ much from the observed latitudes. Thus (*Conn. des Temps,* 1827, *Additions*) the latitude of Turin deduced from that of Milan differs from the observed latitude by 8″.9; that of Venice by 9″.5; that of Rimini by 27″.4. We regret that in the statement which we have copied, there is no mention of the dimensions of the Earth which have been used in deducing the difference of latitudes from the geodetic measure.

In ing tud pla sm tan

In ar sa gr

Another class of observations leading to the same conclusion is the difference between the values of degrees given by different arcs passing over nearly the same ground. We have seen that in the Swedish arcs it is necessary to suppose one disturbance to the amount of 12″, or two disturbances whose sum = 12″. In the arc of parallel between Beachy Head and Dunnose, as compared with that between Dover and Falmouth, there is evidence (though less perfect) of disturbance nearly as great.

I n a

In the Piedmontese arc, if we wish to reconcile it in any degree with the arcs in greater and smaller latitudes, we must suppose that the effect of the disturbances is more than 40″. But no one who considers the situation of the alluvial basin of Piedmont, with the re of Earth.

highest part of the chain of the Alps to the North, and the Apennines (of no inconsiderable height) to the South, will doubt that this is perfectly explained by their attractions.

These observations, though they render the application of our complete theory doubtful, yet serve to give the strongest confirmation of its fundamental principle. We must not reject* them because they disagree with our theory; we must endeavour to ascertain whether they are consistent with the principle of universal gravitation, and if we find them to be consistent, we must examine what alteration must be made in the other suppositions of our theory to make it represent the facts of observation.

[illegible] for [illegible]

Now all that is necessary is, to imagine that, after the Earth had assumed a form of equilibrium and become solidified, parts of the external crust were elevated by some internal force. And if successive coatings were deposited from a fluid covering the whole, we must suppose irregularities of deposition, in many cases connected with the former, to have taken place. These inequalities, on the principle of gravitation, might account for disturbances in the Earth's form, or rather in the form of the sea, great in themselves, but small in comparison with the magnitude of the Earth. The circumstance, however, of islands being found scattered over every part of the Ocean seems to justify us in the belief that the Earth was originally fluid, and that its form has not been much altered by posterior convulsions.

The disturbances alluded to have shown the expediency, and suggested the possibility, of determining by observation the attraction of mountains; and the desire of throwing some new light on the constitution of the Earth has prompted several experiments for ascertaining the mean density of the Earth. In the last century, too, it was doubtful whether the Earth's ellipticity was less than $\frac{1}{230}$, (the value assigned by Newton,) and the determination of the Earth's mean density might (assuming the principle of gravitation) assist in settling that point. For, as has been seen, if the principal attractive mass of the Earth were at its centre, the ellipticity would be not much greater than $\frac{1}{580}$; and therefore if the central part of the Earth were more dense than the parts near the surface, the ellipticity might be expected to be less than $\frac{1}{230}$. the value which it would have if the Earth were homogeneous. The first experiment of this sort was that of Bouguer, mentioned in our first Section; of which we take no further notice, as the person who made it did not think its results worthy of any confidence.

know- of the 's den- will in ermining them.

Determination of the Earth's mean Density.

The second was that of Dr. Maskelyne on the attraction of Schehallien. The history of this is given in our first Section; the astronomical observations are in the volume of the *Phil. Trans.* for 1775. The sector was made by Sisson, with the plumb-line passing over a dot at the centre of the instrument; it was divided by taking an arc (7° 9′ 59″.917) whose chord = ⅛th of the radius, and continually bisecting this arc: it was used with a micrometer-screw as we have described in Section 3. At each of the stations it was reversed but once. The error of collimation, as determined by a mean of the observations on the different stars, appears to have changed only a fraction of a second between making the observations on the North and on the South sides of the mountain. On the South side 76 observations were made, face East, and 93, face West; and on the North side 68 observations, face West, and 100, face East: the whole number of stars observed was 43. The situation of the observatory on each side was about half way up the hill. The difference of astronomical latitude was found to be 54″.6. The distance in feet between the parallels passing through the two observatories was found to be 4364.4 feet. This was determined by a survey of the mountain founded on two bases, one of 3012 feet and another of 5897 feet, measured with deal rods that were compared with the Royal Society's brass standard. From the extremities of these bases two cairns on the ridge of the mountain were observed, and the distance between them found. These cairns were not visible at the observatories, but signals were fixed at distant points where a cairn and an observatory appeared in the same vertical; then the angle between these signals, as seen from the observatory, was the same as that between the cairns. The same signals were observed at the cairns, instead of the observatories. The distance 4364.4 feet, at the rate of 101.64 feet to one second, (according to Bouguer's table,) gave for the difference of geodetic latitude 42″.94. The difference between this and the observed difference, or 11″.6, is to be attributed to the attraction of the mountain.

Attraction of Schehallien found by astronomical observations.

For determining the figure and dimensions of the mountain, stations were chosen all round it; then poles were fixed in the hill-side in vertical planes, as determined by observations with a theodolite in one station, and the azimuth and altitude of each was observed at another station. A few, however, were placed in horizontal planes; and some in different manners. The calculation of the attraction was made by Dr. Charles Hutton. (*Phil. Trans.* 1778.) An accurate map being made, concentric circles were described with one observatory for the centre, and with radii in arithmetical progression, their common difference being 666⅔ feet. Each of the rings between these was divided into 48 parts, according to the following law: a line being drawn in the direction of the meridian, radii were drawn making angles with it whose sines were successively $\frac{1}{12}$, $\frac{2}{12}$, $\frac{3}{12}$, &c. Then it is easily seen that the attraction (in the direction of the meridian) of each of the prisms thus formed is a constant multiplied by the sine of the angular altitude of its top. This was determined by an easy practical method, for which, with many other details, we must refer to the original Memoir. Indeed the various contrivances* of calculation in this

Survey of the mountain and calculation of its attraction.

---

* In the *Phil. Trans.* 1812, is a paper by Don. J. Rodriguez, (we believe one of the gentlemen who assisted Delambre in his survey,) in which observed latitudes are compared with assumed dimensions of the Earth, and the difference is at once set down as an error of observation. The reader, who has taken the trouble to examine our Section on Meridian Measures, and its results, will judge how uncertain the dimensions of the Earth still are, and how certain it is that, using any dimensions whatever, we must still suppose some disturbing cause to affect the latitudes with errors far greater than the errors of observation. The paper in question has been severely criticised by Delambre in the *Conn. des Temps*, 1816, *Additions*. For our own part, we can scarcely imagine how any one who had been concerned with geodetic surveys, or who even knew their object, could compose such a memoir as that to which we allude.

* Most of these, it appears, were suggested by Mr. Cavendish (whose experiments we shall shortly describe.) And it appears that nearly all the preliminary calculations of the attraction of Skiddaw,

Figure of the Earth.

Paper will be found well worth the attention of any practical person. The attraction of 960 prisms was calculated at each observatory; the attraction at the North observatory was found to be to that at the South observatory nearly in the proportion of 7 : 9. And the sum of the attractions was found (supposing the density of the mountain equal to the mean density of the Earth) to be $\frac{1}{9933}$ of the Earth's attraction. But the sum of the disturbances in the direction of gravity as determined from the astronomical observations being $= 11''.6$, the sum of the attractions was, in fact, $=$ gravity $\times$ tan $11''.6 = \frac{1}{17781} \times$ gravity $= \frac{1}{17804} \times$ Earth's attraction, (allowing for centrifugal force.) Consequently the density of the mountain was to the Earth's mean density as 9933 to 17804, or nearly as 5 : 9.

Mineralogical structure of the mountain.

But this supposed that the mountain was homogeneous. The geological characters of its rocks were examined by Professor Playfair, (*Phil. Trans.* 1811,) he found that the upper part consisted of quartz whose mean Specific Gravity $= 2.6398$; and the lower part of mica slate and hornblend slate, whose mean Specific Gravity $= 2.8326$, and of limestone whose mean Specific Gravity $= 2.7661$. Two separate calculations were made; one on the supposition that the rocks were separated by vertical surfaces, and another supposing them separated by surfaces nearly horizontal. The former gave for the Earth's mean density 4.559, the latter 4.867, that of water being 1. Dr. Hutton (*Phil. Trans.* 1821) says that the number should be rather greater.

Cavendish's apparatus for observeing the attraction of leaden balls

The next experiment was that of Mr. Cavendish on the attraction of leaden balls. (*Phil. Trans.* 1798.) His apparatus is represented in fig. 51. x, x, are balls of lead about 2 inches in diameter, suspended to the ends of a light deal rod h, h. This is suspended by the wire $l\,g$, forming, in fact, a balance of torsion. The piece to which the top of the wire is attached, carries a wheel which is turned by the endless screw K F, so that the wire can be twisted till the resting-place of the balls is any required position. $n\,n$ are small graduated scales carried by the rod. The whole of this apparatus is enclosed in a mahogany box, F E A B C D D C B A E F. At A and A are small glass windows, and near these are scales serving as a vernier for measuring the motion of the scales n. These are illuminated by lamps L and L, and viewed by telescopes T and T from the outside of the room. The leaden balls W, W (each weighing 2,439,000 grains) are suspended by copper rods attached to the piece $r\,r$ which is suspended to a beam. By means of a rope passing round the pulley M M, the balls W, W can be moved without entering the room. The support of the balance of torsion and its cases is independent of the walls.

The first wire by which the deal rod was supported was of copper silvered, of which one foot weighed 2.4 grains. After a few experiments with this, it was found that the attraction of the large balls made the rod touch the sides of the case; and a stiffer wire was then used.

Determi tion of t Earth' mean Densit

Disturba produce by curre of air.

It was found at first, that a very small difference of temperature between the balls and the air produced currents of air within the mahogany case which materially disturbed the experiment. The cautions subsequently used seem to have prevented any bad effect from this cause.

Method observat

The method of observing was the following. The large balls being in the *midway position* (their supporting rod at right angles to the deal rod) the position of the deal rod was read off from the scales n. The large balls were then brought so as nearly to touch the case, sometimes in the *positive position* (in which their attraction made the rod move so as to increase the number on the scales) and sometimes in the *negative position*. By their attraction on the small balls, the rod was immediately put in motion, and vibrated backwards and forwards. The greatest extent of vibration was observed; the mean of two consecutive extreme points on one side was taken, and the intermediate extreme point on the other side; and the point midway between these was considered to be the point at which the rod would rest under the action of the balls and the torsion of the wire. The time of passing the middle point was also ascertained, by observing the time of passing two points near the middle, and then (when the middle point was determined) calculating the time of passing it. This being done for vibrations separated by a considerable number, the time of vibration was accurately found. With the wire finally used, the change from the position of rest without the action of the lead balls to the middle position when they were applied, seldom exceeded 3 divisions, (each division $\frac{1}{20}$th of an inch,) and the time of vibration was about 7 minutes. With the first wire the change was about 14 divisions, and the time nearly 15 minutes.

Metho calcul

The middle point is evidently the place where the attraction of the large balls is equal to the force of torsion of the wire. The time of vibration also depends on both of these forces. For suppose that at the middle point the distance of the small balls from the large ones was A, and the space through which they had been moved (to which the force of torsion is proportional) B; then putting W and T to represent these forces respectively at the distance 1, we shall have this equation $\frac{W}{A^2} = TB$. And at the distance x beyond this, and further from the balls, the whole force tending to bring the balls to the middle point is $T\,(B + x) - \frac{W}{(A - x)^2} = TB - \frac{W}{A^2} + \left(T - \frac{2\,W}{A^3}\right) x$ nearly, $= \left(T - \frac{2\,W}{A^3}\right) x$; and this is the force on which the time of vibration depends. Thus there are, in fact, two equations to be solved, from which the attraction of the balls and the torsion of the wire could be determined. Besides this, the attraction of the mahogany case was calculated. The attraction of the leaden balls being thus determined, and compared with the attraction of the Earth, the proportion between the Earth's mean density and the density of lead was found; and thus the Earth's mean density is obtained. The result of 29 experiments (as corrected by Dr. Hutton, *Phil. Trans.* 1821) is 5.31, that of water being 1. The smallest number given by one experiment is 4.86, and the largest 5.79.

We are upon the whole inclined to prefer this result to that of the observations on Schehallien. It cannot

---

&c. were made by Mr. Cavendish. This we have ascertained from an inspection of his papers, which we have had an opportunity of examining through the kind permission of his Grace the Duke of Devonshire.

Result probably preferable to the former.

be denied that the greatest delicacy was necessary to obtain any result, and that the determination is much less certain than the determination (such as it is) by the Schehallien experiment. But we consider that the quantity determined in the latter may be something very different from the attraction of the mountain. We have seen that at Arbury Hill, and some other places, there is evidence of disturbance to an amount nearly as great as the attraction of Schehallien, and without any known cause. May not such unknown causes have operated as well in the Schehallien experiment, and have increased or diminished the apparent effect of the mountain?

Considering the Earth's mean density as somewhat greater than 5, and the mean density of the rocks at the surface as 2.6, the proportion of the Earth's mean density to the superficial density is not very different from that of 2 : 1.

We have mentioned in our first Section the attempt made by the Baron de Zach to measure the attraction of a mountain near Marseilles. We have only to add that no calculation of the Earth's density was founded on these observations.

The attraction of a mountain might be found by observing the length of the seconds' pendulum on the top; if gravity should thus be found to be greater than gravity at the level of the sea in the same latitude diminished in the duplicate proportion of the distance from the Earth's centre, the excess would be attributable to the attraction of the mountain. Bouguer (as we have mentioned in Section 7.) observed the pendulum on one of the peaks of the Andes; but the circumstances were unfavourable, and we should have no confidence in the results. In the present century (see the *Additions* to the *Milan Ephemeris*) M. Carlini made similar observations in much more favourable circumstances at the hospice of Mont Cenis, at an elevation of 6375 feet above the level of the sea. The pendulum we have described at the beginning of Section 7: twenty experiments were made with it; they were reduced like the French measures, and corrected for elevation by the rule of inverse squares; the length at the level of the sea thus found was in mètres 0,993708. But the observations of Biot at Bordeaux, nearly at the level of the sea, corrected for the small difference of latitude, gave 0.993498. The difference is due to the attraction of the mountain mass. Representing this by a segment of a sphere, 1 geographic mile in height and 11 in diameter at the base, of Specific Gravity 2.66, the mean density of the Earth is calculated to be 4.39. Perhaps this experiment would have been more satisfactory if the pendulum had been made exactly like the French pendulums, or if an invariable pendulum had been used. As it stands, there is one considerable source of error,* namely, the erroneous reduction fōr the effect of the air (mentioned in Section 7.) The barometer at Mont Cenis being several inches lower than at Bordeaux, this error would be serious. Besides, we could hardly trust to a comparison between two places at so great a distance. On the whole, we do not think that any estimation of the Earth's density can be founded on this experiment.

The result erroneous and doubtful if corrected.

Section 12.—*Conclusion.*

Conclusion.

1. The measures of the Earth, the observations of pendulums, and the lunar inequalities, agree in showing that the Earth's form does not differ much from that of an ellipsoid of revolution whose ellipticity is (we think certainly) greater than $\frac{1}{300}$, and whose major semiaxis is about 20,923,700 English feet.

2. The phenomena of precession and nutation give an ellipticity rather smaller; but as no result can be deduced from them except on an assumed law of density, this value cannot be put in opposition to the others.

3. As the results of the pendulum observations, the lunar inequalities, and the precessional phenomena, can only be used to determine the Earth's form by the intermediation of the principle of gravitation, the very near coincidence of the results is a strong argument in favour of the truth of that principle.

4. The same things make it highly probable that the Earth has once been in a fluid or semi-fluid state.

5. None of these results can be obtained without the admission of considerable anomalies, all of which, however, appear to be consistent with the principle of gravitation.

6. The mean density of the Earth considerably exceeds, and is probably double of the density of the superficial rocks.

7. The near agreement of the proportion between these as deduced from an assumed law with the proportion found by the experiments with leaden balls (where it is assumed in the calculation that the law of gravitation holds good at the distance of a few inches) makes it probable that the law is sensibly true to very small distances.

G. B. AIRY.

Observatory, Cambridge,

---

* If we correct this, by doubling the usual reduction, (the pendulum-balls being spherical,) the length at Bordeaux is 0.993553, and that at Mont Cenis, reduced for elevation, 0.993754; whence the mean density of the Earth = 4.59.

POSTSCRIPT.

Figure of the Earth.

The author has discovered a small error in the Table of the observed lengths of the seconds' pendulum. The reduction applied to the length of the Paris pendulum for elevation above the sea is that due to the *decimal* pendulum. In consequence, the length at Paris, and all the lengths depending on it, ought to be increased by .00013; a quantity which does not sensibly affect any of the results. This correction applies to Nos. 18, 25, 31, 33, 40, 44, 47, 49; and half of it to Nos. 42, 45, 48.

The multiplier 0.6 has been used (in reducing the foreign observations) in preference to 0.66, as it seems probable that the density at the Earth's surface is greater, and the mean density less, than Dr. Young supposed. The multiplier 0.66 is adopted for the English observations from the calculations of the respective observers; the effects of this inconsistency are not sensible.

Postscr

In the determination of the length of the seconds' pendulum at Königsberg, a correction is included which is not applied to any of the other observations. The reason is that the effect of this correction is to increase the length of the seconds' pendulum; and it appears that the observations on which Bessel principally relied, give a smaller length than those made in the usual way. The difference depends probably on the difference of the apparatus employed.

TIDES AND WAVES.

INTRODUCTION.

WE propose, in this article, to enter at some length into the mathematical theories, and the experimental observations, applying to the two subjects of Tides and Waves of water. But we do not intend to treat them with the same extension. We shall give the various theories of Tides in detail sufficient to enable the reader to understand the present state of the science which regards them; and we shall advert to the principal observations which throw light either on the ordinary phænomena of tides, or on the extraordinary deviations that occur in peculiar circumstances. In thus treating the Tides, it will be necessary for us to enter largely into the theory of Waves. We shall take advantage of this circumstance for the introduction of several propositions, not applying to the theory of Tides, but elucidating some of the ordinary observations upon small Waves. But these investigations will be limited to that class which is most closely connected with tides, namely, that in which similar waves follow each other in a continuous series, or in which the same mathematical process may be used as when similar waves follow each other. In this class will be included nearly all the phænomena of waves produced by natural causes, and therefore possessing general interest. But it will not include the waves of discontinuous nature produced by the sudden action of arbitrary causes, which have been the subject of several remarkable mathematical memoirs, but which possess no interest for the general reader.

The general plan of this Essay will be as follows:—

I. We shall describe cursorily the ordinary phænomena of Tides.

II. We shall explain the *Equilibrium-Theory of Tides*, including the first tidal theory given by Newton, and the more detailed theory of his successors, especially Daniel Bernoulli.

III. We shall give a sketch of Laplace's investigations, (founded essentially on the theory of the *motion* of water,) in the general form in which he first attempted the theory, as well as with the arbitrary limitations which he found it necessary to use for practical application.

IV. We shall give an extended Theory of Waves on water, applying principally to the motion of water in canals of small breadth, but with some indications of the process to be followed for the investigation of the motion of Waves in extended surfaces of water.

V. The results of a few Experiments on Waves will be given, in comparison with the preceding theory.

VI. We shall investigate the mathematical expressions for the Disturbing Forces of the Sun and Moon which produce the Tides, and shall use them in combination with the theory of Waves to predict some of the laws of Tides.

VII. We shall advert to the methods which have been used, or which may advantageously be used, for Observation of Tides, and for the Reduction of the Observations.

VIII. We shall give the results of extensive observations of the Tides, as well with regard to the change of the phænomena of tides at different times in the same place, as with respect to the relation which the time and height of tide at one place bear to the time and height at other places, and shall compare these with the results of the preceding theories, as far as possible.

And as Conclusion, we shall point out what we consider to be the present Desiderata in the Theory and Observations of Tides.

SECTION I.—ORDINARY PHÆNOMENA OF TIDES.

Phænomena of River Tides.

(1.) If we suppose an observer stationed on the bank of a river,* at no great distance from the sea, (for instance, on the bank of the Thames any where below London Bridge, on the Humber below the mouth of the Trent, or on the Severn below the Passages,) he will remark the following changes in the state of the water.

Semidiurnal Tide.

(2.) The first and most important change is, that the surface of the water rises and falls regularly twice in every day. A short series of observations will show however that this statement is not quite correct; the tides of each succeeding day are somewhat later than those of the preceding day: the average retardation from day to day being about 40 minutes. In a short time he will find that the times of occurrence of high water bear a very close relation to the time of the Moon's appearance in certain positions; and that the language of the persons who are most accustomed to observe the tides conveys at once this relation. Thus, at Ipswich, high water occurs when the moon is south nearly: at London Bridge high water occurs when the moon is nearly south-west: at Bristol, it takes place when the moon is E.S.E. These are rude statements, but they are sufficiently accurate for many purposes; and they show at once the close connection between the time of high water and the time of the moon's passage over the meridian. In fact, so completely is this recognized, that, in order to give the time of high water upon any day, it is usually thought sufficient to

Its time is related to the apparent position of the moon.

---

* We commence with this case, because, judging from the notions of sea-faring persons upon many points connected with the Tides, which are correct as regards rivers, but incorrect as regards the sea, (some of which will hereafter be indicated,) it is the case from which ideas of tidal movements have usually been taken with the greatest facility.

state the time of high water on the days of new moon and full moon, when the moon passes the meridian at twelve o'clock nearly. This time is called the *Establishment* of the port. Then to find (roughly) the time of high water on any other day, it is only necessary to add the Establishment to the time of the moon's passage.

The rules, as we have mentioned them, indicate the time of only *one* high water in the day: but the reader must understand that there will always be *another* high water in the same day, preceding or following that which we have mentioned by 12 hours 20 minutes nearly. On those days, however, in which high water occurs within 20 minutes of noon, there is no other high water on the same civil day.

The interval between high water and moon's transit is variable.

(3.) On closer examination it will be found that the interval between the time of the moon's passage over the meridian and the time of high water varies sensibly with the moon's age. At new moon, full moon, first quarter, and third quarter, (or rather on the day following each of these phases,) the interval between the time of the moon's passage and the time of high water is nearly the same: but from new moon to first quarter, and from full moon to third quarter, the high water occurs earlier than would be inferred by using that same interval; and from first quarter to full moon, and from third quarter to new moon, it occurs later than the same interval would give it.

Spring and Neap Tides.

(4.) If the observer examines the height of the water, he will find that the height at high water and the depression at low water are not always the same. On the days following new moon and full moon, high water is higher and low water lower than at any other time: these are called *Spring Tides*. On the days following the first and third quarters, high water is lower and low water higher than at any other time: these are called *Neap Tides*. The whole variation of height at spring tides is nearly double that at neap tides. There are other variations of height depending on other circumstances; but they require, for the most part, very numerous observations to establish the fact of their existence, and to give a measure of their amount. In many places, however, the tide which occurs at one certain part of the day (the afternoon for instance) is, during one half of the year, sensibly higher than the other tide which occurs upon the same day, and, during the other half of the year, sensibly lower.

The duration of the fall is longer than the duration of the rise.

The water continues to run up the river after high water.

(5.) Upon examining the circumstances of a single tide, the following facts will attract notice. The interval from high water to low water is greater than that from low water to high water: the difference between these intervals is sensibly greater at spring tides than at neap tides. The current in the river runs upwards for some time after high water, and after changing its direction, continues to run downwards for some time after low water, when it again changes its direction and runs upwards. This phænomenon is often so much misrepresented in the language of nautical men, that the mistake deserves particular notice. From the habit of observing tides in places where the current ceases at high water and at low water, sailors conceive that high water may always be inferred from the cessation of the current; and therefore it is not unusual for persons on the banks of the Thames to say that "it is high water in the centre of the channel long after it is high water at the shore." The observer who is not convinced of the absurdity of supposing the water in the middle of the channel to stand at one time considerably higher and at another time considerably lower than at the shore, will satisfy himself most easily as to the general fact by stationing himself at one of the central piers of a bridge, (as London Bridge,) when he will see that the water continues to run upwards even after its surface has dropped nearly two feet.

(6.) Now suppose that the observer examines the state of the tide in different parts of the same river. Commencing with the mouth of the river, (for instance Margate or Sheerness on the Thames, or Swansea or Cardiff on the Severn,) he will find that there is very little difference, or perhaps none which is appreciable, between the interval from high water to low water, and that from low water to high water. He will also find that the current runs up the channel for a long time (sometimes approaching to three hours) after high water, and runs down the channel for as long a time after low water. In going up the river, he will find that the time of high water occurs later and later, but yet that the velocity with which high water travels up the river is so great as entirely to banish the idea of explaining the Tide by supposing the same mass of water to have been moved all the way up the river. For instance, if at Margate the high water occurs on a certain day at twelve o'clock, it will occur at Sheerness at 24 minutes past one, at Gravesend at 15 minutes past two, and at London Bridge at a few minutes before three; having thus described in less than three hours a course of about 70 miles. He will also find that the interval from low water to high water diminishes as he goes up the river: thus, on the lower parts of the Severn, the rise and fall occupy little more than six hours each; but at Newnham on the Severn the whole rise of the water is effected in an hour and a half, the descent occupying nearly eleven hours. In cases like the last-mentioned, the first rise of the tide is sudden, and if the banks of the river are shoaly, the water spreads over the flat sands with a roaring surf, which travels rapidly up the river, presenting the phænomenon called a *bore* or *boar*, (sometimes *bour's-head*,) in French *barre* or *mascaret*. In other cases, however, when the difference of durations of rise and fall is considerable, there are in each high water two, or sometimes three distinct rises and falls of the water. The phænomena of bore and double tide are always much more conspicuous in spring tides than in neap tides.

(7.) If the estuary or mouth of the river contracts very much, the elevation and depression of the water will become very great. Thus at the entrance of the Bristol Channel the whole rise at spring tides is about 18 feet, at Swansea about 30 feet, and at Chepstow about 50 feet. Similar high tides occur at St. Malo and other parts of the great bay formed on the northern coast of France by the projection of land towards Cherbourg, and tides still higher in the head of the Bay of Fundy (Baie Française) on the Eastern coast of North America. But when the tide has fairly entered a river, its range of elevation and depression generally diminishes. Thus at Newnham, on the Severn, the range is reduced to about 18 feet, and it is still less at Gloucester.

(8.) Quitting now the phænomena of river-tides; if observations are made in a bay communicating with the open sea, the results will be found to be much more simple. The water will rise during 6 hours 10 minutes and will fall during an equal time; the whole rise and fall will usually be less than in rivers; a very slight current will be directed towards the head of the bay during the rise, and from it during the fall of the water. The variations of spring and neap tides, and the relation of the time of high water to the time of the moon's passage over the meridian, follow the same general laws as in rivers.

(9.) In long and narrow seas (for instance the English Channel) the tide in mid-channel follows the same laws as at a station near the mouth of a river, rising and falling in equal times, and running in a direction which may be considered analogous to the direction up a river, for three hours before and three hours after high water; and in the opposite direction, for three hours before and three hours after low water. But near the sides of the channel, and especially near the mouths of bays or estuaries branching from the channel, the change of tide follows a very peculiar law. The water is never stationary, as in river-tides, when changing from flow to ebb, but the direction of the current changes in 12 hours 20 minutes through all the points of the compass. As a general rule, supposing the observer's face turned in the direction which is analogous to the direction up a river; near the shores on his left hand the course of the tide-current revolves in the same direction as the hands of a watch, and near the shores on the right hand it revolves in the opposite direction. Near the headlands which separate different bays, there is usually, at certain times of the tide, a very rapid current, called a *race*.

(10.) The elevations and depressions of tides in the open seas are much smaller than in contracted seas or rivers, sometimes not exceeding one or two feet; the stream of the tide is generally insensible.

(11.) In seas of small extent (as the Mediterranean) the Tide is nearly insensible.

(12.) In some circumstances, phænomena which are scarcely perceptible in ordinary localities become paramount. Thus, in some positions near Behring's Straits, the difference of morning and evening tides, which is scarcely sensible in England, becomes so great that, in certain parts of the lunation, there appears to be only one tide in the day. Other phænomena peculiar to these localities, but less obvious to ordinary observation, will be noticed hereafter.

(13.) The phænomena which we have described must necessarily, for the most part, have been remarked by all nations dwelling on the borders of the ocean. Thus Cæsar, in his account of the invasion of Britain, (*De Bello Gallico*, lib. iv.) alludes to the nature of spring tides as perfectly well understood in connection with the moon's age. Some of the peculiarities of river tides, however, were not published in scientific works till the beginning of the last century; and some of the properties of the tides in the English and other channels were not known till the end of that century. Upon the whole, the statement above may be supposed to represent pretty well all that was known of the Tides about the year 1800: and it will serve to point out to the reader the leading facts, to whose explanation a Theory of the Tides ought to be directed. In the present century, the elaborate discussions of immense collections of accurate tide-observations by M. Laplace, Sir John W. Lubbock, and Professor Whewell, have brought to light and reduced to law many irregularities which were before that time unknown. We prefer, however, delaying the particular mention of these until we have discussed the various forms in which theory has been put for the purpose of explaining the grand facts of the Tides.

SECTION II.—EQUILIBRIUM-THEORY OF TIDES.

Inadequacy of all theories of the Tides, and the cause of it.

(14.) Before entering upon either of the theories explaining the Tides, we must allude to their inadequacy, perhaps not to the *explanation* of the facts already observed, but certainly to the *prediction* of new ones. This inadequacy does not appear to arise from any defect in the principles upon which the theory is based, (although perhaps our ignorance of the laws of friction among the particles of water, and between water and the sides of the channels which contain it, may be considered a failure of this kind,) but from the extreme difficulty of investigating mathematically the motions of fluids under all the various circumstances in which the waters of the sea and of rivers are found. For the problem of the Tides, it is evident, is essentially one of the *motion* of fluids. Yet so difficult are the investigations of motion that, till the time of Laplace, no good attempt was made to determine, by theory, the laws of the Tides, except on the supposition that the water was *at rest*. Since that time theories of *motion* have been applied; and it is hoped that in the present Treatise it will be found that something has been added to the preceding investigations of motion, possessing in some degree a practical character. Yet the theory, even in this state, reaches very few cases. Indeed, throughout the whole of this subject, the selection of the proper theoretical ground of explanation is a matter of judgment. In some cases we may conceive that we are justified in using the Equilibrium-theory; in others the Wave-theory will apply, completely or partially; in a few cases, the results of observation in one locality will be considered as a fundamental set of experiments, upon which the explanation of the phænomena in other localities will be grounded without further reduction to theory; and as a last resource, in almost every case, we shall be driven to the same arbitrary suppositions which Laplace introduced. Nevertheless, we conceive that our mathematical theory, pursued into some degree of detail, will be far from useless. In the instances which it does not master completely, it will show that there are ample grounds for the arbitrary alterations of constants introduced by Laplace in his suppositions, to which we have more than once alluded. It will show that we are precluded from further advance, partly by our almost necessary ignorance of the forms of the bottom in deep seas, and partly by the imperfection of our mathematics. It will leave no doubt whatever that the first principles of our explanation are correct. Begging the reader to receive the first part of this paragraph as an apology on the part of mathematicians for applying to the motion of Tides a theory so evidently inadequate as the Equilibrium-theory, we shall now proceed to give that theory, nearly in the terms of its proposers.

Popular explanation of equilibrium-theory.

(15.) The popular explanation of the Equilibrium-theory is very simple. If we conceive the earth to be covered wholly or in a great degree with water, and consider that the attraction of the moon upon different particles (according to the law of gravitation) is inversely as the square of their distance, and is therefore greatest for those particles which are nearest to it: then it will be obvious that the moon attracts the water on that side which is next to her, more than she attracts the great mass of the earth, and therefore tends to raise the water from the earth on the side next to her; but she also attracts the great mass of the earth more than she attracts the water upon the side most distant from her, and therefore tends to draw the earth from the water on the side most distant from her; which will produce exactly the same effect as if a force tended to draw the water away from the earth on that side. Thus the moon's action tends to raise the water on two opposite sides of the earth; and similarly the sun's action tends to raise the water on two opposite sides. The close relation, however, which the times of high water bear to the times of the moon's passage, shows that the moon's influence in raising the tides must be much greater than the sun's. If the sun and moon are together, as seen from the earth, the elevations produced by these two bodies will coincide in place, and will therefore be added together. Thus Spring Tides will be produced. In other relative positions of the sun and moon, it may happen that the elevation produced by the sun will occur at a place where the moon causes depression: the action of the sun there tends to counteract that of the moon, and Neap Tides will be produced.

Newton's first theory of the motion of the sea.

(16.) The theory of Newton is rather a collection of hints for a theory than any thing else. In the *Principia*, lib. I. prop. 66, cor. 19, he has (by a remarkable deduction from the Lunar Theory) considered the motion of water in a canal passing round the earth in or near to the earth's equator, and has arrived at the singular conclusion that the water would be lowest in that part which is most nearly under the body (the sun or moon) whose attraction causes the motion of the water. This conclusion we shall find to be entirely supported by more complete investigations. In lib. III. prop. 24, he has modified this conclusion, and seems to suppose that in free seas the high water ought to follow the moon's transit over the meridian (conceiving, for the moment, the moon's attraction to be the sole exciting cause of the Tides) in three hours, or at least in less than six hours. To this he appears to have been led by erroneous reasoning of the same kind as that which, in lib. I. prop. 66, cor. 20, has introduced an incorrect inference as to the Solar Nutation of the Earth's axis. We shall find hereafter that the introduction of friction into our theories of the motion of water will lead to a conclusion somewhat similar. The only part in which he uses numerical calculation is in lib. III. prop. 36, and 37, the subjects of which are, "*Invenire vim Solis ad Mare movendum*," "*Invenire vim Lunæ ad Mare movendum*." The following is his method of computation (the demonstration of the different parts of which we defer till we treat of the more complete theory of Bernoulli). First he refers to the Lunar Theory for a calculation of the force which the sun exerts to draw the moon, when in quadratures, towards the earth, and he finds it to be $\frac{1}{638092}$ part of gravity at the earth's surface. Then he remarks that the similar force upon the water at the earth's surface, in the position distant 90° of terrestrial arc from the point to which the sun is vertical, is less than the force upon the moon, in the proportion in which the water's distance from the centre of the earth is less than the moon's distance from the centre of the earth, or in the proportion of 1 : 60·5: and therefore the force which depresses the water, at the points 90° distant from those vertically under the sun, is $\frac{1}{38604600}$ of gravity. Then he observes that, in the points which are under the sun and opposite to the sun, the disturbing force of the sun tends to raise the water, and is twice as great as the depressing force already found. He then considers that the same general effect will be produced if we put away the depressing force entirely, and augment the elevating force by the same quantity, and thus we may consider that the sole cause of the disturbance of the water is an elevating force, at the point under the sun and the point opposite to the sun, equal to $\frac{1}{12868200}$ of gravity; the elevating force in other points being proportional to the versed sine of double the sun's altitude above the horizon of any point. In order to compute the effect of this force in raising the water, he compares this force with the centrifugal force ($\frac{1}{289}$ of gravity) at the earth's equator, produced by the diurnal rotation of the earth; it is therefore $\frac{289}{12868200}$ of the centrifugal force at the equator. Then, having found from his theory of the Figure of the Earth (supposed homogeneous) that the centrifugal force would raise the fluids at the equator 85820 Paris feet, and supposing the proportion of the elevations produced by the tidal force and the centrifugal force to be the same as the proportion of those forces, he obtains this result, that the action of the sun would raise the water, in the parts immediately under it and opposite to it, by 1 foot 11¼ inches Paris measure, or a little more than 2 feet English. Of the various steps of this process we shall here observe only that, though indirect, they are correct; and that the result (on the supposition of the earth's being homogeneous, and without rotation) represents correctly the elevation which the sun's action would produce.

Newton's calculation of the force of the Sun.

(17.) In order to ascertain the effect which the moon's action would produce, it is necessary to know the mass of the moon. For this there were in Newton's time no direct means: and he was, therefore, obliged to refer to the phænomena of the Tides themselves, as observed in places where, from local causes, the rise of the tide is very considerable. He quotes the observations of Sturmy on the tides in the Severn, at the mouth of the Avon, which give 45 feet for equinoctial spring tides, 25 feet for equinoctial neap tides: and those of Colepresse, on the tides at Plymouth, which give 16 feet for the mean height (intermediate between spring and neap) and 9 feet difference between springs and neaps. Preferring the proportion deduced from the former, he considers the height of equinoctial spring tides to be to that of equinoctial neap tides as 9 : 5. These tides (as will be seen hereafter) are in one case the effect of the moon augmented by the effect of the sun; and in the other case the effect of the moon diminished by that of the sun. If no correction were needed, we should infer at once that the power of the moon is to that of the sun as 7 : 2. But Newton remarks, that the greatest tides at Bristol do not happen till 43 hours after syzygies, "*ob aquarum reciprocos motus*," meaning, probably, that the oscillations, like the oscillations of a pendulum, have a kind of inertia, which (on purely mechanical principles) prevents them from attaining their greatest magnitude till the force which causes them has past its greatest magnitude. This we shall find, when we treat of Waves, to be incorrect, except we take account of friction. Assuming this, however, Newton proceed

His modified theory of motion.

to correct for the position of the luminaries *at the instant* of Bristol high tide: remarking that, as the sun is $18\frac{1}{4}$ degrees from the moon at spring tides, and $90°\pm18\frac{1}{4}°$ at neap tides, it is not the whole force of the sun which in one case increases and in the other case diminishes the moon's effect, but the whole force of the sun × cos 37°: and also that, as the moon's declination, 43 hours after an equinoctial syzygy, is about 22°, it is not the whole force of the moon that is concerned, but the whole force of the moon × $\cos^2 22°$. These corrections appear to us inconsistent with what has gone before: for if the tides are increasing from the accumulated action of the sun and moon during a long time, it seems clearly inaccurate to correct the results of observation for the places of those bodies at the very instant of observation. Then he observes that the moon is not, at syzygies, at her mean distance. All corrections applied, he finds that the force of the moon is to that of the sun as 4·4815 to 1: and, therefore, as the sun's force would raise the water 1 foot, $11\frac{1}{2}$ inches, the moon's force would raise it 8 feet, 8 inches. This, he remarks, is amply sufficient to account for all the motions of the tides.

(18.) The proportion of the moon's tidal force to the sun's tidal force is used by Newton (as a different value found in nearly the same manner has been used by Laplace) as the basis on which he calculates the moon's mass for application to other parts of the theory of gravitation. We shall see grounds hereafter for questioning the propriety of this calculation.

(19.) Assuming that Newton intended here (as he has done in several parts of Optics) only to exhibit, as far as he was able, grounds for a numerical calculation relating to the subject of Tides, but not bearing directly upon any of its specific phænomena, we must allow that (in spite of the apparent inconsistency of his corrections) it is a wonderful first attempt. That it had no further meaning will be sufficiently evident, not only from the proposition already cited, lib. I., prop. 66, cor. 19, but also from an examination of his 24th proposition of the third book, and the first corollary of his 27th proposition. In these he has treated the general explanation of the Tides as a matter of Wave-theory entirely, (though not without errors,) particularly in regard to the interference of semidiurnal tides, and in explaining the small rise and fall at some islands in the open sea by the oscillation of the whole mass of water between the bounding continents. As a philosopher, we conceive Newton to have shown himself here superior to his successors.

(20.) In explaining the more complete equilibrium-theory, we shall not confine ourselves to the methods of Daniel Bernoulli, or any other writer, but shall present the theory in the form which appears most convenient. The problem which we shall conceive to be presented to us for solution is this: suppose the earth to be a spherical solid nucleus, either homogeneous, or consisting of a series of spherical concentric strata, (each stratum having the same density and the same thickness in its whole extent,) which nucleus is covered with water: and suppose the disturbing forces of the sun and moon to act upon the water: to find the shape which the water will assume.

Tides and Waves.

Tides the same on a spherical earth as on a spheroid.

(21.) We have designedly used the word *spherical* for the form of the earth, because the investigation of the alteration produced in the form which, if undisturbed, would be spheroidal, would prove rather troublesome, and would lead to no result which we shall not obtain without it. As the earth's ellipticity is small, (the difference between its major axis and its minor axis being only about $\frac{1}{300}$ of either,) and as the whole elevation of the water, on the equilibrium-theory, is but a few feet, the reader will have no difficulty in comprehending that the tidal elevation of the water on the spheroid, though without doubt theoretically different from that on a sphere, will practically differ by a quantity which is quite insensible. In the same manner the reader will understand that, supposing the water to be disturbed by the action of the sun, and supposing the action of the moon to be then introduced, the additional disturbance which it will cause will be (as far as the senses can discover) the same as it would have caused if it had acted on water not disturbed by the action of the sun. And thus the whole disturbance which the two luminaries will produce upon the water surrounding a spheroidal nucleus will be found with sufficient accuracy by investigating the disturbance which each of them, separately considered, would produce in the water surrounding a spherical nucleus, and by adding those two disturbances together.

The tide produced by each of the attracting luminaries the same as if the other did not exist.

(22.) Our first effort will now be directed to the estimation of the disturbing force of the sun upon the water. We shall use the following notation:—

K, the mean density of the earth's spherical nucleus: R, its radius.

k, the density of the water: r, the radius of the external spherical surface of the water when undisturbed by the sun and moon.

(The density is supposed to be estimated by the acceleration which a cubical unit of matter acting by its attraction during a unit of time will produce in a body whose distance is the unit of distance: the velocity and acceleration being referred to the same units.)

E, the whole mass of the earth and water.

g, the numerical expression, referred to the same units, for the acceleration which gravity at the earth's surface causes in bodies falling freely.

x, y, z, the rectangular coordinates of any point in the fluid, the centre of the spherical nucleus being the origin, and z being parallel to the line joining the centres of the sun and the earth.

D, the sun's distance: D_m, the sun's mean distance: P, the sun's parallax: P_m, the sun's mean parallax: T, the periodic time of the earth's revolution round the sun, or the length of a sidereal year: S, the sun's mass, estimated by the acceleration which it will produce (in the same manner as for the density, above).

D′, the moon's distance: D'_m, the moon's mean distance: P′, the moon's parallax: P'_m, the moon's mean parallax: T′, the periodic time of the moon's revolution round the earth: M, the moon's mass.

Actual forces of the Sun upon any particle of the water.

(23.) The distance of the sun from the point whose co-ordinates are x, y, z, is $\sqrt{\{x^2+y^2+(D-z)^2\}}$, and the attraction of the sun upon that point, according to the law of gravitation, is $\frac{S}{x^2+y^2+(D-z)^2}$. This force is in the direction of the line drawn from the point in question to the sun. Our expression for this force supposes it to be estimated as an accelerating force; the statical pressure which corresponds to it may be resolved into three pressures in the directions of x, y, z; and, by the principle that accelerations of a given particle are proportional to the pressures which cause them, the accelerating forces which act in these directions may be deduced from the given accelerating force by the same laws of resolution as those for statical pressures. Thus we find for the resolved parts of the sun's accelerating force on the particle in question,

$$\text{In the direction of } x \qquad \frac{-Sx}{\{x^2+y^2+(D-z)^2\}^{\frac{3}{2}}}$$

$$\text{In the direction of } y \qquad \frac{-Sy}{\{x^2+y^2+(D-z)^2\}^{\frac{3}{2}}}$$

$$\text{In the direction of } z \qquad \frac{S(D-z)}{\{x^2+y^2+(D-z)^2\}^{\frac{3}{2}}}.$$

Expansions of the expressions.

(24.) Now the proportion of the earth's radius to the distance of the sun is extremely small; and the value of $\frac{x}{D}$, $\frac{y}{D}$, or $\frac{z}{D}$, is necessarily smaller. It will be allowable, therefore, to expand these expressions approximately, retaining no higher powers of x, y, z, than the second. (Indeed these latter terms are wholly insensible for the sun; and we retain them only because, in the expressions which we shall infer by analogy for the forces of the moon, they may be considered sensible.) With this restriction, observing that

$$\frac{1}{\{x^2+y^2+(D-z^2\}^{\frac{3}{2}}}=\frac{1}{D^3}\left\{1-\frac{2z}{D}+\frac{x^2+y^2+z^2}{D^2}\right\}^{-\frac{3}{2}}=\frac{1}{D^3}\left\{1+\frac{3z}{D}+\frac{12z^2-3x^2-3y^2}{2D^2}\right\},$$

we have

$$\text{Sun's force in the direction of } x=\frac{-Sx}{D^3}-\frac{3Sxz}{D^4}$$

$$\text{Sun's force in the direction of } y=\frac{-Sy}{D^3}-\frac{3Syz}{D^4}$$

$$\text{Sun's force in the direction of } z=\frac{S}{D^2}+\frac{2Sz}{D^3}+\frac{S(6z^2-3x^2-3y^2)}{2D^4}.$$

Disturbing forces of the Sun upon every particle.

(25.) These expressions represent the *whole* force of the sun upon any particle. But it is evident that, to find the force which disturbs the form of the water in reference to the position of the earth, we must not use the *whole* force of the sun upon any particle, but the *excess* of the sun's force on the particle *above* the sun's force on the centre of gravity of the earth. In order to find the sun's force on the centre of gravity of the earth, we must multiply each particle of the earth by the force which acts upon it; we must add together all these products, and we must divide the sum by the sum of all the particles of the earth. Now, using the expressions above, (which apply to the earth as well as to the water,) we may easily see that, if we multiply each particle of the earth by the force $\frac{-Sx}{D^3}$, and add all the products together, the sum will be 0, because for every particle which has a certain positive value of x there will be another particle having an equal negative value of x, and their products will, when added, destroy each other. The same remark applies to the terms depending on y, z, xz, and yz. But it does not apply to the term $\frac{S}{D^2}$ or to that depending on x^2, y^2, and z^2.

(26.) Now for the term $\frac{S}{D^2}$ we have only to remark that, upon multiplying it by each of the particles, adding all the products, and dividing the sum by the sum of the particles, we again obtain $\frac{S}{D^2}$. For the other terms we may proceed thus:—The sum of all the products of each particle by its value of z^2, throughout the sphere, will be the same as the sum of the products of each particle by its value of x^2 or y^2, because, supposing the sphere at one time divided by planes perpendicular to z, and at another time by planes perpendicular to x or y, the sections for similar values of x, y, or z, will be similar. The sum, therefore, for $6z^2$ will be equal to that for $3x^2+3y^2$, and, therefore, that for $6z^2-3x^2-3y^2$ will be 0. The only remaining term, therefore, for the sun's force on the centre of gravity of the earth, is $\frac{S}{D^2}$, in the direction of z.

(27.) Subtracting this term, therefore, from the force in the same direction upon the particle under consideration, we have the following expressions for the sun's disturbing force,

$$\text{In the direction of } x \qquad \frac{-Sx}{D^3}-\frac{3Sxz}{D^4}$$

$$\text{In the direction of } y \qquad \frac{-Sy}{D^3}-\frac{3Syz}{D^4}$$

In the direction of z $\qquad -\frac{+2Sz}{D^3}+\frac{S(6z^2-3x^2-3y^2)}{2D^4}$

Sect. II. Equilibrium Theory of Tides.

The density of the fluid supposed insignificant. Mathematical condition which determines the form of the fluid when in equilibrium.

(28.) We shall now proceed to investigate the form which the water covering the solid nucleus will receive from the action of these forces in addition to the attraction of the nucleus and the mutual attraction of the particles of water. And first we may remark that, if the attraction of the particles of the water is insensible, (or if the density of the water is insensible in comparison with that of the nucleus,) the problem is very simple. Referring to our Treatise on the FIGURE OF THE EARTH, section 2, article 7., we find that the condition for the possibility of equilibrium of the water is that $Xdx+Ydy+Zdz$ shall be a complete differential, or, in more correct language, that it shall be possible for us to find some function U, such that $\frac{dU}{dx}=X$, $\frac{dU}{dy}=Y$, $\frac{dU}{dz}=Z$; X, Y, Z, being the whole forces in the directions of x, y, z. In article 9. of the same Treatise it is shown that, when the forces are produced by attraction to any number of particles, this condition is always satisfied; and, therefore, it is satisfied here (which will also be easily seen on substituting the expressions which we shall immediately exhibit). In article 8. of the same Treatise, it is proved that the form of the external surface will be determined by making $Xdx+Ydy+Zdz=0$, or $U=C$. To apply this now, we must add, to the expressions above, the resolved parts of the attraction of the nucleus. That attraction is the same as if all the matter of the nucleus were collected at its centre; and it is, therefore, $\frac{4\pi}{3}\cdot\frac{R^3K}{x^2+y^2+z^2}$. The resolved parts in the directions of x, y, z, are respectively

$$-\frac{4\pi}{3}\cdot\frac{R^3Kx}{(x^2+y^2+z^2)^{\frac{3}{2}}},\qquad -\frac{4\pi}{3}\cdot\frac{R^3Ky}{(x^2+y^2+z^2)^{\frac{3}{2}}},\qquad -\frac{4\pi}{3}\cdot\frac{R^3Kz}{(x^2+y^2+z^2)^{\frac{3}{2}}}.$$

Hence the whole forces acting on any particle of the water are

$$\frac{dU}{dx}=X=-\frac{4\pi}{3}\cdot\frac{R^3Kx}{(x^2+y^2+z^2)^{\frac{3}{2}}}-\frac{Sx}{D^3}-\frac{3Sxz}{D^4}$$

$$\frac{dU}{dy}=Y=-\frac{4\pi}{3}\cdot\frac{R^3Ky}{(x^2+y^2+z^2)^{\frac{3}{2}}}-\frac{Sy}{D^3}-\frac{3Syz}{D^4}$$

$$\frac{dU}{dz}=Z=-\frac{4\pi}{3}\cdot\frac{R^3Kz}{(x^2+y^2+z^2)^{\frac{3}{2}}}+\frac{2Sz}{D^3}+\frac{S(6z^2-3x^2-3y^2)}{2D^4}.$$

From these we easily find

$$U=\frac{4\pi}{3}\cdot\frac{R^3K}{(x^2+y^2+z^2)^{\frac{1}{2}}}+\frac{S(2z^2-x^2-y^2)}{2D^3}+\frac{S(2z^3-3x^2z-3y^2z)}{2D^4}$$

Equation to the surface of the water.

and the equation to the external surface of the water will therefore be

$$C=\frac{4\pi}{3}\cdot\frac{R^3K}{(x^2+y^2+z^2)^{\frac{1}{2}}}+\frac{S(2z^2-x^2-y^2)}{2D^3}+\frac{S(2z^3-3x^2z-3y^2z)}{2D^4}.$$

We may remark, that the very same equation would have been obtained if we had considered only the disturbing force which acts in the direction of a tangent to the Earth's surface. For, the equation which we have used for the external surface amounts to this, that the whole force is perpendicular to the external surface. Therefore the inclination of the surface of the water to the surface of the sphere will depend entirely on the proportion of the tangential force to the force directed towards the centre of the sphere. The only tangential force is the tangential disturbing force, which must therefore be retained; but the force directed to the centre of the sphere consists of the attraction of the sphere and the minute disturbing force; and it is indifferent, for the inclination of which we have spoken, whether we retain that minute portion or not. If we retain it, we consider all the forces; if we omit it, we use no disturbing force but that which is tangential. We shall see hereafter that a similar rule is true when we consider the forces producing the *motion* of the sea.

Expansion supposing the form to differ little from a sphere

(29.) Since the difference of the form from a spherical form will be exceedingly small, we may for $(x^2+y^2+z^2)^{\frac{1}{2}}$, which is the distance of any point at the surface from the sphere's centre, put $r+q$ (then q is the elevation of the water above the height which it would have had if undisturbed by the attraction of the sun): and in substituting this expression in the first term on the right hand side of the equation we may neglect the square of q; and in substituting it in the factors of the other terms, which are exceedingly small, we may omit q entirely. In these small terms, therefore,

$$2z^2-x^2-y^2=2z^2-(r^2-z^2)=3z^2-r^2,$$

$$z(2z^2-3x^2-3y^2)=z\{2z^2-3(r^2-z^2)\}=z(5z^2-3r^2);$$

and in the larger term

$$\frac{1}{(x^2+y^2+z^2)^{\frac{1}{2}}}=\frac{1}{r+q}=\frac{1}{r}-\frac{q}{r^2}.$$

Substituting, the equation becomes

$$C=\frac{4\pi}{3}R^3K\left(\frac{1}{r}-\frac{q}{r^2}\right)+\frac{S(3z^2-r^2)}{2D^3}+\frac{Sz(5z^2-3r^2)}{2D^4},$$

or

$$q=r-\frac{3r^2C}{4\pi R^3K}+\frac{3r^2}{4\pi R^3K}\left\{\frac{S(3z^2-r^2)}{2D^3}+\frac{Sz(5z^2-3r^2)}{2D^4}\right\};$$

which will be more conveniently written

$$q=C'+\frac{3r^2}{4\pi R^3K}\left\{\frac{S(3z^2-r^2)}{2D^3}+\frac{Sz(5z^2-3r^2)}{2D^4}\right\}.$$

(30.) In order to determine the value of C′, we must observe that the whole volume included within the external surface of the water is equal to the sphere whose radius is r, and therefore if we estimate the sum of all the quantities of water which are raised above the surface of the sphere, (depressions below the surface being considered negative,) that sum will $=0$. Now conceive that there is traced upon the surface of the sphere a series of circles at small distances, resembling the parallels of a terrestrial globe, the poles of all the circles being at the point which is nearest to the sun, or z having the same value through the whole circumference of each circle. Let θ be the angle made by the axis of z with the line drawn from the centre of the sphere to any point of one of these circles, $\theta+\delta\theta$ the similar angle for the next circle. The surface of the sphere included between these two circles will $=2\pi.r\sin\theta.r\delta\theta$ nearly, and therefore the volume of water elevated above that ring upon the sphere $=2\pi.q.r^2\sin\theta.\delta\theta$ nearly; which, since $z=r\cos\theta$, is $=-2\pi qr.\delta z$ nearly. We have, therefore, to find the sum of all the values of

$$-2\pi C'r\,\delta z-\frac{3r^3}{2R^3K}\left\{\frac{S(3z^2-r^2)}{2D^3}+\frac{S(5z^3-3rz)}{2D^4}\right\}\delta z,$$

or to find

$$-\int_z 2\pi C'r-\frac{3r^3}{2R^3K}\int_z\left\{\frac{S(3z^2-r^2)}{2D^3}+\frac{S(5z^3-3r^2z)}{2D^4}\right\}$$

Expression for the elevation of the water.

through the whole extent of the sphere; that is, between the limits $z=-r$, $z=+r$. The value of this integral is $-4\pi C'r^2$. Making this $=0$, we have $C'=0$, and therefore

$$q=\frac{3r^2}{4\pi R^3K}\left\{\frac{S(3z^2-r^2)}{2D^3}+\frac{Sz(5z^2-3r^2)}{2D^4}\right\},$$

or

$$=\frac{3r^4}{4\pi R^3K}\left\{\frac{S}{2D^3}(3\cos^2\theta-1)+\frac{r}{D}.\frac{S}{2D^3}.\cos\theta\,(5\cos^2\theta-3)\right\}.$$

(31.) In order to put this expression into a form adapted to numerical computation, we must deliver it from the quantities K and S. First, to remove K: since $\frac{4\pi R^3}{3}$ is the volume of the nucleus, $\frac{4\pi R^3K}{3}$ is its mass, expressed by the acceleration which it would cause at distance 1, as we have assumed in (22.); and, therefore, $\frac{4\pi R^3K}{3r^2}$ is the acceleration which it would cause at the surface of the water; but this acceleration, being that of ordinary falling bodies, is expressed by g: therefore $\frac{3r^4}{4\pi R^3K}=\frac{r^2}{g}$. Secondly, to remove S. In our treatise on Physical Astronomy, page 655, equation (24.), it is shown that $T=\frac{2\pi.a^{\frac{3}{2}}}{\sqrt{(M+m)}}$; which will be expressed in the notation of this Treatise if we remark that a is the mean distance of the revolving body $=D_m$; and that $M+m$ is the sum of the masses of the two bodies, which, as the earth is very small in comparison with the Sun, wiil not sensibly differ from S. T is the periodic time $=1$ year. Thus $T=\frac{2\pi.D_m^{\frac{3}{2}}}{\sqrt{S}}$, or $\frac{S}{D_m^3}=\frac{4\pi^2}{T^2}$; and therefore, $\frac{S}{D^3}=\left(\frac{D_m}{D}\right)^3.\frac{4\pi^2}{T^2}$. Also $\frac{r}{D}=\sin P$. Thus the expression for q becomes

Elevation expressed in a form fit for calculation.

$$\frac{2\pi^2r^2}{T^2g}.\left(\frac{D_m}{D}\right)^3.\{3\cos^2\theta-1+\sin P.\cos\theta.(5\cos^2\theta-3)\}.$$

This expression is in a form entirely fit for calculation; it is only necessary to remark that the same units must be used throughout: thus, if g expresses the acceleration in inches produced by gravity in one second of time, r must be expressed in inches, and T in seconds of time. To avoid the introduction of very large numbers, we may make use of the elements of the moon's motion. The same equation of Physical Astronomy (neglecting the perturbations of the moon) gives us $T'=\frac{2\pi.D'^{\frac{3}{2}}_m}{\sqrt{\left(\frac{4\pi R^3K}{3}+M\right)}}$. Let the moon's mass be $\frac{1}{n}$ part of the earth's, or $M = \frac{1}{n} \cdot \frac{4\pi R^3 K}{3}$: then $T' = \frac{2\pi . D'^{\frac{3}{2}}_m}{\sqrt{\frac{4\pi R^3 K}{3}} \sqrt{\left(1+\frac{1}{n}\right)}}$; from which $\frac{3r^4}{4\pi R^3 K} = \frac{T'^2 \left(1+\frac{1}{n}\right) r^4}{4\pi^2 D'^3_m}$,

and

$$q = \frac{T'^2}{2T^2} \cdot \left(1+\frac{1}{n}\right) \cdot \frac{r^3}{D'^3_m} r \cdot \left(\frac{D_m}{D}\right)^3 . \{3\cos^2\theta - 1 + \sin P . \cos\theta \, (5\cos^2\theta - 3)\}$$

$$= \frac{n+1}{2n} \cdot \left(\frac{T'}{T}\right)^2 . (\sin P'_m)^3 . r . \left(\frac{D_m}{D}\right)^3 . \{3\cos^2\theta - 1 + \sin P . \cos\theta \, (5\cos^2\theta - 3)\}.$$

If we suppose the moon's mass $\frac{1}{80}$ of the earth, and give the values commonly adopted for the other quantities, this becomes

$$\frac{81}{160} \cdot \left(\frac{27 \cdot 32}{365 \cdot 25}\right)^2 . (\sin 57' . 1'')^3 \times 20900000 \times \left(\frac{D_m}{D}\right)^3 . \{3\cos^2\theta - 1 + \sin 8'' \cdot 7 . \cos\theta \, (5\cos^2\theta - 3)\},$$

where the earth's mean semidiameter is expressed in English feet. Performing the numerical computation upon either of these expressions, the formula becomes

Calculation of the elevation of the water.

$$q = 0 \cdot 2710 \text{ foot} \times \left(\frac{D_m}{D}\right)^3 . \{3\cos^2\theta - 1 + \sin 8'' \cdot 7 . \cos\theta \, (5\cos^2\theta - 3)\},$$

or

$$= 0 \cdot 2710 \text{ foot} \times \left(\frac{D_m}{D}\right)^3 \times (3\cos^2\theta - 1),$$

the last part of the preceding formula being quite insensible.

(32.) Omitting for the present the consideration of the factor $\left(\frac{D_m}{D}\right)^3$, which never differs much from 1, we find that the greatest positive value of the formula (denoting elevation of the water) occurs when $\theta = 0$, or $\theta = 180°$, for which cases $3\cos^2\theta - 1 = 2$, and the elevation of the water $= 0 \cdot 542$ foot. Now θ is the angle contained between the line drawn from the earth's centre to the sun and the line drawn from the earth's centre to any point on the surface which is under consideration. Consequently, the value $\theta = 0$ belongs to that point of the earth's surface, or of the surface of the water, which is immediately under the sun; and the value $\theta = 180°$ belongs to that point of the surface of the water which is farthest from the sun. The sun's action, therefore, would raise the water 0·542 foot on that side which is next to the sun, and also on that side which is farthest from the sun.

Greatest elevation.

(33.) The greatest negative value of the formula (denoting depression of the water) occurs when $\theta = 90°$, for which case $3\cos^2\theta - 1 = -1$, and the depression of the water is 0·2710 foot. Now θ is $= 90°$ for all those parts of the surface of the water which are determined by making a plane to pass through the earth's centre perpendicular to the line joining the earth's centre with the sun. The sun's action, therefore, would depress the water 0·2710 foot in the zone, surrounding the earth, which is intermediate between the point under the sun and the point that is farthest from the sun.

Greatest depression.

(34.) It appears, therefore, that the elevation of the water produced by the sun on one part of the earth, where the elevation is greatest, is double of the depression produced on other parts where the depression is greatest. Suppose now that the water always assumes the form which we have found, and that the earth revolves within the coating of water. (This supposition, absurd as it is, is the only one upon which it is possible to apply the equilibrium-theory.) And suppose an observer to be stationed upon a small island projecting above the water, and to watch there the rise and fall of the surface of the water. To fix our ideas, suppose the earth's axis of revolution to be perpendicular to the line joining the sun and the earth, and suppose the observer to be at the earth's equator. Then, in the course of a revolution, he will be carried successively through the point which is nearest to the sun, through the zone intermediate between the point nearest to the sun and the point most distant from it, through the point most distant from the sun, again through the intermediate zone, and to the point which is nearest to the sun. He will, therefore, have been carried twice through the part where the elevation is greatest, and twice through the part where the depression is greatest. The greatest elevation, as we have found, is double of the greatest depression. From this circumstance many persons have imagined that, in all tides, under all local circumstances whatever, the line of mean water, or the line at which the surface of the water would stand if undisturbed by tidal action, is to be found by taking a line whose height above low water is one-third of the height of high water above low water; so that the elevation of high water above that line will be double the depression of low water below it. This (as we shall afterwards show) is inconsistent with the laws of Waves on deep water, upon which, without doubt, the phænomena of Tides depend entirely: but, moreover, it is inconsistent with the equilibrium-theory itself. For, to ascertain the *mean* height of the water, we must not suppose the sun and moon actually removed from

Elevation apparently double the depression.

Elevation above mean really equal to the depression below mean.

our system, but we must suppose an estimation to be made of the form which the water would assume under the action of their *mean* forces; and, considering this as the mean state of the water, we must compare the disturbed state with this, in order to ascertain the true value of the disturbance from mean state. Now the mean elevation of the water at our imaginary island, under the sun's mean action, will evidently be found by supposing the earth to turn uniformly round, by taking the actual elevation of the water in each momentary position, and by taking the mean of all those actual elevations. Putting A for the coefficient 0·2710 foot $\times\left(\frac{D_m}{D}\right)^3$, the elevation of the water, above the position which it would have had if no sun existed, is $A\,(3\cos^2\theta-1)$: and if the sphere turns uniformly round, θ will pass uniformly through all the values from 0 to 2π: we have, therefore, to find the mean of all the values of $A\,(3\cos^2\theta-1)$ when θ increases uniformly from 0 to 2π. Putting it under the form $A\left\{\frac{3}{2}(1+\cos 2\theta)-1\right\}$, or $A\left\{\frac{1}{2}+\frac{3}{2}\cos 2\theta\right\}$, and remarking that, while θ increases from 0 to 2π, $\cos 2\theta$ goes through equal positive and negative values, the mean is $\frac{A}{2}$. And this is the elevation of the water under the action of the sun's mean force. Subtracting this from the actual elevation, or $A\,(3\cos^2\theta-1)$, we have for the effect of the periodic tidal force $A\left(3\cos^2\theta-\frac{3}{2}\right)$. The greatest tidal elevation is found by making $\theta=0$, or 180°, or $\cos^2\theta=1$, and is therefore $A\times\frac{3}{2}$: the greatest tidal depression is found by making $\theta=90°$, or $\cos\theta=0$, which gives tidal elevation $=-A\times\frac{3}{2}$, or tidal depression $=A\times\frac{3}{2}$. The greatest tidal elevation, and the greatest tidal depression, are therefore equal, even on the equilibrium-theory.

Elevation produced by the moon.

(35.) We shall now proceed to investigate the effect of the moon upon the water, still supposing the density of the water to be insignificant in comparison with that of the earth. The expression of (30.), *mutatis mutandis*, will apply to the elevation produced by the moon: supposing here that θ' is the angle between the line drawn from the earth's centre to the point under consideration, and the line drawn from the earth's centre to the moon. Putting q' then for the elevation produced by the moon,

$$q'=\frac{3r^4}{4\pi R^3 K}\left\{\frac{M}{2D'^3}(3\cos^2\theta'-1)+\frac{r}{D'}\cdot\frac{M}{2D'^3}\cdot\cos\theta\,(5\cos^2\theta'-3)\right\}$$

To reduce this to calculation we must remark that $\frac{4\pi}{3}R^3K=$ earth's mass $=n\times M$; and therefore

$$\frac{3r^4}{4\pi R^3 K}\times\frac{M}{2D'^3}=\frac{r^4}{2n\,D'^3}=\frac{1}{2n}\cdot r\cdot\left(\frac{r}{D'_m}\right)^3\cdot\left(\frac{D'_m}{D'}\right)^3=\frac{1}{2n}\cdot r\cdot\left(\sin 57'.\ 1''\right)^3\cdot\left(\frac{D'_m}{D'}\right)^3.$$

The numerical value of this depends entirely upon the value of n, or the proportion of the earth's mass to the moon's. If (as we supposed before) $n=80$, and $r=20900000$ feet, the expression becomes

$$q'=\frac{20900000}{160}\left(\sin 57'.\ 1''\right)^3\cdot\left(\frac{D'_m}{D'}\right)^3\left\{3\cos^2\theta'-1+(\sin 57'.1'')\,\frac{D'_m}{D'}\cos\theta'.\ (5\cos^2\theta'-3)\right\}$$

$$=0\cdot5959 \text{ foot}\times\left(\frac{D'_m}{D'}\right)^3\times\left(3\cos^2\theta'-1\right)+0\cdot0100 \text{ foot}\times\left(\frac{D'_m}{D'}\right)^4\times\cos\theta'.(5\cos^2\theta'-3).$$

If we supposed the moon's mass to be $\frac{1}{40}$ of the earth, (which is very nearly the supposition of Newton,) the numerical coefficients would be respectively 1·1918 foot and 0·0200 foot. The phænomena of nutation (using the numbers in the FIGURE OF THE EARTH, page 235, and supposing $\frac{a}{b}=\frac{50\cdot3}{9\cdot25}$) give $n=82$.

Elevation a little greater on the side next to the moon than on the opposite side.

Whichever of these values of n, or of any intermediate to these two, we decide on adopting, it is clear that the last term of the formula is insignificant; its greatest numerical values, when $n=80$, being ± 0·02 foot. We shall therefore omit the consideration of it in future. We may remark that, theoretically considered, its meaning is that the water is raised a little higher on the side next to the moon than on the side most distant from the moon. For when $\theta'=0$, $\cos\theta'$ is positive, and the term $\cos\theta'\,(5\cos^2\theta'-3)$ is numerically added to $3\cos^2\theta'-1$, which is also positive: but when $\theta'=180°$, $\cos\theta'$ is negative, and the term $\cos\theta'\,(5\cos^2\theta'-3)$ is numerically subtracted from $3\cos^2\theta'-1$, which is positive. In the intermediate zone, $\cos\theta'=0$, and the height of the water is not altered by this term.

Investigation supposing the density of the water not insignificant.

(36.) We shall defer the examination of the effects of the variations of $\frac{D'_m}{D'}$, of the composition of the effects of the sun and moon, and of their positions in declination, &c., and shall proceed to investigate the elevation of the water on the supposition that the density of the water is not insignificant in comparison with that of the earth. The modification which this produces in the theory is, that the attraction of the water upon its own particles must be found. The problem now becomes very similar to that of the Figure of the Earth, and we shall solve it in the same way, namely, synthetically, by supposing the form to be spheroidal, and showing that, with proper proportion of the axes, the equations of equilibrium will be satisfied. For the developments of the formulæ requisite, we shall refer, for the most part, to the article on the FIGURE OF THE EARTH.

Method of conducting this investigation.

(37.) We shall assume, then, that the form of the external surface of the water is that of a prolate spheroid, its axis being directed to the sun (omitting, for the present, the forces of the moon). And we shall consider that the forces which act on the water are, the attraction of the spherical nucleus, the attraction of the water, whose interior boundary is spherical and whose exterior boundary is spheroidal, and the disturbing forces of the sun found in (27.). As the attractions of the particles of water, as well as all other attractions, satisfy the condition $X=\frac{dU}{dx}$, $Y=\frac{dU}{dy}$, $Z=\frac{dU}{dz}$, it will only be necessary for us to determine the forces which act on the particles at the surface, to find from them the expression for U, to form the equation $U=C$ for the exterior surface, and to try whether this equation can be made to coincide with the assumed spheroidal equation.

Attraction of an entire spheroid of water.

(38.) The attraction of the water upon a point at its surface will be found by subtracting the attraction of a bulk equal to the spherical nucleus from the attraction of the spheroid of water supposed entire. Let the semiaxis of the spheroid in the direction of z, or towards the sun, be b; the semiaxes at right angles to this (or in the plane of x, y,) $b(1-\zeta)$. Comparing this with the assumption in the FIGURE OF THE EARTH, sec. ii. art. 30., it is evident that the formulæ of article 32. of that treatise will apply here, if we put $-\zeta$ for ϵ, and omit the terms depending on centrifugal force. Thus we have, for the attraction of the watery spheroid supposed entire,

In the direction of x, $\quad -\frac{4\pi}{3}k\left(1+\frac{2}{5}\zeta\right)x$

In the direction of y, $\quad -\frac{4\pi}{3}k\left(1+\frac{2}{5}\zeta\right)y$

In the direction of z, $\quad -\frac{4\pi}{3}k\left(1-\frac{4}{5}\zeta\right)z.$

The attraction of a sphere of the same density whose radius is R would be

In the direction of x, $\quad -\frac{4\pi}{3}k\,R^3\frac{x}{(x^2+y^2+z^2)^{\frac{3}{2}}}$

In the direction of y, $\quad -\frac{4\pi}{3}k\,R^3\frac{y}{(x^2+y^2+z^2)^{\frac{3}{2}}}$

In the direction of z, $\quad -\frac{4\pi}{3}k\,R^3\frac{z}{(x^2+y^2+z^2)^{\frac{3}{2}}}.$

Attraction of the water covering the spherical nucleus.

Subtracting these from the former we obtain for the real attractions of the water,

In the direction of x, $\quad -\frac{4\pi}{3}k\left(1+\frac{2}{5}\zeta\right)x+\frac{4\pi}{3}k\,R^3\frac{x}{(x^2+y^2+z^2)^{\frac{3}{2}}}$

In the direction of y, $\quad -\frac{4\pi}{3}k\left(1+\frac{2}{5}\zeta\right)y+\frac{4\pi}{3}k\,R^3\frac{y}{(x^2+y^2+z^2)^{\frac{3}{2}}}$

In the direction of z, $\quad -\frac{4\pi}{3}k\left(1-\frac{4}{5}\zeta\right)z+\frac{4\pi}{3}k\,R^3\frac{z}{(x^2+y^2+z^2)^{\frac{3}{2}}}.$

Attraction of the nucleus of earth.

(39.) The attractions of the spherical nucleus of earth will be

In the direction of x, $\quad -\frac{4\pi}{3}KR^3\frac{x}{(x^2+y^2+z^2)^{\frac{3}{2}}}$

In the direction of y, $\quad -\frac{4\pi}{3}KR^3\frac{y}{(x^2+y^2+z^2)^{\frac{3}{2}}}$

In the direction of z, $\quad -\frac{4\pi}{3}KR^3\frac{z}{(x^2+y^2+z^2)^{\frac{3}{2}}}.$

Whole force which acts on the water.

Combining these with the attractions of the water found above, and with the sun's disturbing forces found in (27.), omitting the last terms of the latter, we have

$$X=-\frac{4\pi}{3}k\left(1+\frac{2}{5}\zeta\right)x-\frac{4\pi}{3}(K-k)\,R^3\frac{x}{(x^2+y^2+z^2)^{\frac{3}{2}}}-\frac{Sx}{D^3}$$

$$Y=-\frac{4\pi}{3}k\left(1+\frac{2}{5}\zeta\right)y-\frac{4\pi}{3}(K-k)\,R^3\frac{y}{(x^2+y^2+z^2)^{\frac{3}{2}}}-\frac{Sy}{D^3}$$

$$Z=-\frac{4\pi}{3}k\left(1-\frac{4}{5}\zeta\right)z-\frac{4\pi}{3}(K-k)\,R^3\frac{z}{(x^2+y^2+z^2)^{\frac{3}{2}}}+\frac{2Sz}{D^3}.$$

(40.) The equation $U=C$ becomes therefore

$$-\frac{4\pi}{3}k\left\{\frac{x^2+y^2+z^2}{2}+\zeta\,.\frac{x^2+y^2-2z^2}{5}\right\}+\frac{4\pi}{3}(K-k)\frac{R^3}{(x^2+y^2+z^2)^{\frac{1}{2}}}+\frac{S}{2D^3}(2z^2-x^2-y^2)=C$$

Equation to the surface deduced from the forces.

If we make $(x^2+y^2+z^2)^{\frac{1}{2}}=r+q$, and retain the first power of q, only in those terms which are not multiplied by ζ or $\frac{S}{2D^3}$, we obtain

$$-\frac{4\pi}{3}k\left\{\frac{r^2}{2}+rq+\zeta\frac{r^2-3z^2}{5}\right\}+\frac{4\pi}{3}\frac{(K-k)\,R^3}{r}-\frac{4\pi}{3}\frac{(K-k)\,R^3}{r^2}q+\frac{S}{2D^3}(3z^2-r^2)=C$$

or

$$q\times\frac{4\pi}{3}\left\{kr+\frac{(K-k)\,R^3}{r^2}\right\}=-\frac{4\pi}{3}k\frac{r^2}{2}+\frac{4\pi}{3}.\frac{(K-k)\,R^3}{r}-C+\left\{\frac{4\pi k}{15}\zeta+\frac{S}{2D^3}\right\}(3z^2-r^2).$$

The equation to the prolate spheroid is $\frac{x^2+y^2}{b^2(1-\zeta)^2}+\frac{z^2}{b^2}=1$, or $x^2+y^2+2\zeta(x^2+y^2)+z^2=b^2$. And the point now to be determined is, whether this equation can be made to coincide with that above. Putting $r+q$ for $(x^2+y^2+z^2)^{\frac{1}{2}}$, and omitting q in the term multiplied by ζ, this equation becomes

$$r^2+2r.q=b^2-2\zeta(x^2+y^2)=b^2+2\zeta(z^2-r^2)=b^2+\frac{2}{3}\zeta(3z^2-3r^2)=b^2-\frac{4}{3}\zeta r^2+\frac{2}{3}\zeta(3z^2-r^2),$$

or

$$2rq=b^2-\left(1+\frac{4}{3}\zeta\right)r^2+\frac{2}{3}\zeta(3z^2-r^2):$$

and therefore in the prolate spheroid

$$q\times\frac{4\pi}{3}\left\{kr+\frac{(K-k)\,R^3}{r^2}\right\}=\frac{2\pi}{3}\left\{k+\frac{(K-k)\,R^3}{r^3}\right\}\times\left\{b^2-(1+\frac{4}{3}\zeta)\,r^2\right\}+\frac{2\pi}{3}\left\{k+\frac{(K-k)\,R^3}{r^3}\right\}.\frac{2\zeta}{3}.(3z^2-r^2).$$

Spheroidal form found to be possible.

This expression is evidently of the same form as that found above from the condition of equilibrium: and it will exactly coincide with it if the two terms on the right hand side of one are respectively equal to the two terms on the right hand side of the other. The comparison of the first terms gives the value of C; the comparison of the second terms gives the equation

$$\frac{4\pi k}{15}\zeta+\frac{S}{2D^3}=\frac{4\pi}{9}\left\{k+\frac{(K-k)\,R^3}{r^3}\right\}\zeta.$$

From the latter,

$$\frac{S}{2D^3}=\zeta\times\left\{\frac{4\pi k}{9}-\frac{4\pi k}{15}+\frac{4\pi}{9}.\frac{(K-k)\,R^3}{r^3}\right\}=\frac{4\pi}{3}\zeta.\left\{\frac{2k}{15}+\frac{(K-k)\,R^3}{3r^3}\right\}$$

and

$$\zeta=\frac{S}{2D^3}.\frac{1}{\frac{4\pi}{3}.\left\{\frac{2k}{15}+\frac{(K-k)\,R^3}{3r^3}\right\}}.$$

Ellipticity determined

The spheroidal form is therefore a possible form of equilibrium, and the proportion of the axes must be $1:1-\zeta$, where ζ has the value just found.

(41.) The value of q, found above from the properties of the spheroid, is $\frac{\zeta}{3r}(3z^2-r^2)+$ constant; which constant will be found, by the reasoning of (30.), to be $=0$; and therefore $q=\frac{\zeta}{3r}(3z^2-r^2)$. Substituting the value of ζ,

$$q=\frac{S}{2D^3}.\frac{15r^2}{4\pi\{2kr^3+5(K-k)\,R^3\}}.(3z^2-r^2)$$

$$=\frac{15r^4}{4\pi\{2kr^3+5(K-k)\,R^3\}}.\frac{S}{2D^3}.(3\cos^2\theta-1).$$

To reduce this to a form fit for calculation, we may, as before, put $\frac{S}{D^3}=\left(\frac{D_m}{D}\right)^3.\frac{4\pi^2}{T^2}$: to remove K, we must remark that the attraction is nearly the same as if the whole mass were united at the centre of the sphere; but the whole mass (omitting small quantities) is $\frac{4\pi}{3}\left\{(r^3-R^3)\,k+R^3K\right\}$: its attraction on a point at the surface of the water is therefore $\frac{4\pi}{3}\cdot\left\{kr+(K-k)\frac{R^3}{r^2}\right\}$, which (as before) must be made $=g$: therefore $K=\frac{3g}{4\pi\left\{\frac{k}{K}r+\left(1-\frac{k}{K}\right)\frac{R^3}{r^2}\right\}}$, and the expression for q becomes

$$\frac{10\,\pi^2r^2}{T^2g}\cdot\left(\frac{D_m}{D}\right)^3\cdot\frac{\frac{k}{K}r^3+\left(1-\frac{k}{K}\right)R^3}{2\frac{k}{K}r^3+5\left(1-\frac{k}{K}\right)R^3}\,(3\cos^2\theta-1).$$

Expression for elevation in the spheroid.

If the depth of fluid covering the solid nucleus be small, r may be considered $=R$, and then

$$q=\frac{10\,\pi^2r^2}{T^2g}\left(\frac{D_m}{D}\right)^3\;\frac{1}{5-\frac{3k}{K}}\,(3\cos^2\theta-1).$$

(42.) When the density of the fluid is insignificant, $\frac{k}{K}=0$, and the expression for q becomes

$$\frac{2\pi^2r^2}{T^2g}\left(\frac{D_m}{D}\right)^3\cdot(3\cos^2\theta-1)$$

as we have found before. When the density of the fluid is equal to that of the solid nucleus, $\frac{k}{K}=1$, and

$$q=\frac{5\pi^2r^2}{T^2g}\left(\frac{D_m}{D}\right)^3\cdot(3\cos^2\theta-1)$$

or it is equal to the former result $\times\frac{5}{2}$. This remarkable difference is produced entirely by the attraction of the elevated portions of water and the diminution of attraction where the water is depressed. Converted into numbers, this value becomes 0·6775 foot $\times\left(\frac{D_m}{D}\right)^3\cdot(3\cos^2\theta-1)$: and the whole difference between the elevations of high and low water is 2·0325 feet. This result nearly coincides with Newton's, as it ought. The circumstances of the earth and water will be represented most nearly by taking $\frac{k}{K}=\frac{2}{11}$. The same results as to the proportion of the elevations found on different assumptions of the proportion of the densities of earth and water, which we have found for the effect of the sun, apply in all respects to the effect of the moon.

(43.) We shall now consider the effect of the combination of the tides produced by the Sun and the Moon; the place of observation being at any point on the earth's surface, which is supposed to be carried round by the earth's daily rotation, while the form of the water continues the same in respect of the positions of the Sun and Moon; and the positions of the Sun and Moon being any whatever. For simplicity of notation, we shall put S′ for the factor of $\left(\frac{D_m}{D}\right)^3\cdot(3\cos^2\theta-1)$ in the expression for the Solar Tide, and M′ for the factor of $\left(\frac{D'_m}{D'}\right)^3\cdot(3\cos^2\theta'-1)$ in the expression for the Lunar Tide; also we shall put $\frac{P}{P_m}$ for $\frac{D_m}{D}$, and $\frac{P'}{P'_m}$ for $\frac{D'_m}{D'}$, to which they are almost exactly equal.

Combination of Solar and Lunar Tides.

(44.) In figure 1, let p be the pole of the earth, t the place at which the tide is observed, u the point to which the moon is vertical, v the point to which the sun is vertical. Then the elevation of the water at t is

$$M'\left(\frac{P'}{P'_m}\right)^3\cdot(3\cos^2tu-1)+S'\left(\frac{P}{P_m}\right)^3\cdot(3\cos^2tv-1).$$

Draw a meridian pw fixed in space, and draw meridians through t, u, v; let s, m be the celestial right ascensions of the sun and moon, and l the terrestrial longitude of the place, as measured from that fixed meridian; σ, μ the celestial declinations of the sun and moon, and λ the terrestrial latitude of the place. Then $\cos tu=\sin\lambda.\sin\mu+\cos\lambda.\cos\mu.\cos\overline{l-m}$: $\cos tv=\sin\lambda.\sin\sigma+\cos\lambda.\cos\sigma.\cos\overline{l-s}$; and the elevation of the water is

$$M'\left(\frac{P'}{P'_m}\right)^3\cdot\left\{(1-3\sin^2\lambda).\left(\frac{3}{2}\cos^2\mu-1\right)+\frac{3}{2}\sin 2\lambda.\sin 2\mu.\cos\overline{l-m}+\frac{3}{2}\cos^2\lambda.\cos^2\mu.\cos 2.\overline{l-m}\right\}$$

$$+S'\left(\frac{P}{P_m}\right)^3\cdot\left\{(1-3\sin^2\lambda).\left(\frac{3}{2}\cos^2\sigma-1\right)+\frac{3}{2}\sin 2\lambda.\sin 2\sigma.\cos\overline{l-s}+\frac{3}{2}\cos^2\lambda.\cos^2\sigma.\cos 2.\overline{l-s}\right\}$$

of which the different parts may be more advantageously combined in the following form:

$$(1-3\sin^2\lambda).\left\{M'\left(\frac{P'}{P'_m}\right)^3\cdot\left(\frac{3}{2}\cos^2\mu-1\right)+S'\left(\frac{P}{P_m}\right)^3\cdot\left(\frac{3}{2}\cos^2\sigma-1\right)\right\}$$

$$+\frac{3}{2}\sin 2\lambda.\left\{M'\left(\frac{P'}{P'_m}\right)^3\cdot\sin 2\mu.\cos\overline{l-m}+S'\left(\frac{P}{P_m}\right)^3\cdot\sin 2\sigma.\cos\overline{l-s}\right\}$$

$$+\frac{3}{2}\cos^2\lambda.\left\{M'\left(\frac{P'}{P'_m}\right)^3\cdot\cos^2\mu.\cos 2.\overline{l-m}+S'\left(\frac{P}{P_m}\right)^3\cdot\cos^2\sigma.\cos 2.\overline{l-s}\right\}.$$

We shall consider the different terms of this expression in order.

Tides of long period.

(45.) The first line does not depend upon l, m, or s, and is therefore independent of the right ascensions of the sun and moon or the hour of the day. It does not therefore represent a *Tide* in the ordinary sense of the word. Nevertheless it depends upon μ and σ, and therefore will vary with the variation of the declination of the sun and moon. But it is indifferent whether the declination is north or south. As the moon's declination goes through all its changes in respect of magnitude (without regard of sign) in half a lunation, the term depending on M′ will produce a slow tide, going through all its changes in 14 days nearly. There will also be a slow tide produced by the term depending on S′, going through its changes in half a year. These Tides do not exist for any place at which the sine of latitude $=\sqrt{\frac{1}{3}}$: near the equator, the water is high (as depending on this cause) when the moon and sun are in the equator; near the earth's pole, it is low at the same time; the greatest change of surface at the equator, supposing the sine of the greatest declination to be $\frac{2}{5}$, will be $\frac{6}{25}\left\{M'\left(\frac{P'}{P'_m}\right)+S'\left(\frac{P}{P_m}\right)^3\right\}$ nearly; the greatest change at the pole will be $\frac{12}{25}\left\{M'\left(\frac{P'}{P'_m}\right)^3+S'\left(\frac{P}{P_m}\right)^3\right\}$.

Diurnal Tides.

(46.) The second line consists of two parts, each of which is a multiple of the cosine of $\overline{l-m}$ or $\overline{l-s}$. This then represents two tides; of which one goes through all its changes, while the distance of the meridian passing through the place from the meridian passing through the moon (or the moon's hour-angle) changes by 360°; and the other goes through all its changes while the sun's hour-angle changes by 360°. Each of these then produces a *diurnal* tide; and their combined effect will be represented by a single *diurnal* tide of varying extent, and which follows the moon's transit at a variable interval. For, the line may be put in this form:

$$+\frac{3}{2}\sin 2\lambda\left\{M'\left(\frac{P'}{P'_m}\right)^3\sin 2\mu.\cos\overline{l-m}\quad+S'\left(\frac{P}{P_m}\right)^3\sin 2\sigma.\cos(\overline{l-m}+\overline{m-s})\right\}$$

Observing that $\cos(\overline{l-m}+\overline{m-s})=\cos\overline{m-s}.\cos\overline{l-m}-\sin\overline{m-s}.\sin\overline{l-m}$, this may be thus expressed:

$$+\frac{3}{2}\sin 2\lambda\left\{M'\left(\frac{P'}{P'_m}\right)^3\sin 2\mu+S'\left(\frac{P}{P_m}\right)^3\cdot\sin 2\sigma.\cos\overline{m-s}\right\}\cos\overline{l-m}$$

$$-\frac{3}{2}\sin 2\lambda.S'\left(\frac{P}{P_m}\right)^3\cdot\sin 2\sigma.\sin\overline{m-s}.\sin\overline{l-m}.$$

Remarking that $A.\cos\overline{l-m}-B\sin\overline{l-m}=\sqrt{A^2+B^2}\left\{\frac{A}{\sqrt{A^2+B^2}}\cos\overline{l-m}-\frac{B}{\sqrt{A^2+B^2}}\sin\overline{l-m}\right)\right\}$

$$=\sqrt{A^2+B^2}\left\{\cos E.\cos\overline{l-m}-\sin E.\sin\overline{l-m}\right\},\text{ where }\tan E=\frac{B}{A};$$

$$=\sqrt{A^2+B^2}.\cos\overline{l-m+E};$$

this may be put in the following form:

$$+\frac{3}{2}\sin 2\lambda\sqrt{\left\{M'^2\left(\frac{P'}{P'_m}\right)^6\cdot\sin^2 2\mu+2M'S'\left(\frac{P'P}{P'_mP_m}\right)^3\sin 2\mu.\sin 2\sigma.\cos\overline{m-s}+S'^2\left(\frac{P}{P_m}\right)^6\sin^2 2\sigma\right\}}\times\cos\overline{l-m+E}$$

where

$$\tan E = \frac{S'\left(\frac{P}{P_m}\right)^3 . \sin 2\sigma . \sin \overline{m-s}}{M'\left(\frac{P'}{P'_m}\right)^3 \sin 2\mu + S'\left(\frac{P}{P_m}\right)^3 \sin 2\sigma . \cos \overline{m-s}}.$$

On this diurnal tide we may make the following remarks.

(47.) 1st. It is 0 at the equator (where $\lambda = 0$), and at the pole (where $\lambda = 90°$), and greatest for places at latitude 45°. For these the greatest value (which occurs when $m-s=0$, or at new moon) is

$$+\frac{3}{2}\left\{M'\left(\frac{P'}{P'_m}\right)^3 \sin 2\mu' + S\left(\frac{P}{P_m}\right)^3 \sin 2\sigma\right\} \cos \overline{l-m}:$$

and as the greatest value of $\sin 2\mu$ and $\sin 2\sigma$ will be about $\frac{3}{4}$, the greatest diurnal tide will be about $\frac{9}{8}\left\{M'\left(\frac{P'}{P'_m}\right)^3 + S'\left(\frac{P}{P_m}\right)^3\right\} \cos \overline{l-m}$: and the greatest oscillation produced by the diurnal tide will be $\frac{9}{4}\left\{M'\left(\frac{P'}{P'_m}\right)^3 + S'\left(\frac{P}{P_m}\right)^3\right\}$.

Changes in the diurnal Tide.

(48.) 2d. The position of the meridian passing through the place of observation, with reference to the position of the meridian passing through the place of the moon, at the time of high water as produced by the diurnal tide, is determined by the equation $l-m+E=0$, or $m-l=+E$. This is the moon's hour-angle to the east of the meridian at the time of high diurnal tide. If now we examine the expression for $\tan E$, we find that E undergoes the following changes. If $\sin \overline{m-s}$ is positive, and μ and σ are both positive, E is a positive angle and not very great, since $\frac{S'}{M'}$ is a fraction, as will be inferred from the remark on the relative influence of the sun and moon in (15.) But if, while σ retains the same sign, μ changes its sign (in consequence of the moon crossing the equator), the denominator will successively become small, 0, and negative. E therefore increases suddenly to 90°, and to an angle not much less than 180°. This change of angle shows that the phænomena of this Tide are very rapidly reversed when the moon crosses the equator: that, instead of its high water occurring when the moon is a little way east of the upper meridian, it occurs when the moon is a little way east of the lower meridian. At the time of the moon's crossing the equator the tide will be small: for it will depend on S′ only. This supposes that $\sin \overline{m-s}$ has not changed sign; if it diminishes to 0 and then becomes negative, $\tan E$ gradually becomes a smaller negative quantity and then becomes positive, or E exceeds 180°; and the high water takes place when the moon is west of the lower meridian. The reader can easily examine the changes which occur in other positions of the two luminaries; but the following rules will be found to comprehend nearly the whole.

Rule for the time of diurnal high water.

If we consider the sidereal *day* to be defined as the time between the first point of Aries passing the meridian and the first point of Libra passing the meridian; and the sidereal *night* to be the time between the passages of the first point of Libra and of the first point of Aries; and suppose the latitude of the place of observation to be north; then the high water produced by diurnal tide always occurs *in* the sidereal day, if we neglect the sun's action, or *in or near* the sidereal day if the sun's action be small; and its time is that of the moon's passage over the upper or lower meridian (according as her longitude is less or greater than 180°) *exactly* if the sun's action be neglected, or *nearly* if the sun's action be small. The sidereal time of the high tide is later and later each successive day; the magnitude of the tide is greatest when the high tide occurs nearly at the middle of the sidereal day; and when the sudden shift takes place from the end of sidereal day to the beginning of sidereal day, the diurnal tide is extremely small.

Semidiurnal Tide.

(49.) We shall now consider the third line of the expression in (44.). It consists of two parts, each of which goes through its changes twice, while $l-m$ for one, or $l-s$ for the other, increases by 360°. Each of these, therefore, produces a semidiurnal tide (the term semidiurnal being, for one, referred to the length of the lunar day, and, for the other, being referred to the length of the solar day). These two tides may be compounded into one semidiurnal tide, by the same process as that in (46.); and the expression for the elevation of the water from this cause becomes

$$+\frac{3}{2}\cos^2 \cdot \sqrt{\left\{M'^2\left(\frac{P'}{P'_m}\right)^6 \cos^4\mu + 2M'S'\left(\frac{P'P}{P'_m P_m}\right)^3 \cos^2\mu . \cos^2\sigma . \cos 2.\overline{m-s} + S'^2\left(\frac{P}{P_m}\right)^6 \cos^4\sigma\right\}} \times \cos \overline{2(l-m)+F}$$

where

$$\tan F = \frac{S'\left(\frac{P}{P_m}\right)^3 \cos^2\sigma . \sin 2.\overline{m-s}}{M'\left(\frac{P'}{P'_m}\right)^3 \cos^2\mu + S'\left(\frac{P}{P_m}\right)^3 \cos^2\sigma . \cos 2.\overline{m-s}}.$$

We shall proceed to discuss several cases of this formula.

(50.) 1st. The coefficient is greatest for places at the equator, and is 0 at the poles; for all parts of the earth, therefore, it may be considered to have a sensible value. In the succeeding statements of value we shall express the values corresponding to the equator: those for other points will be found by multiplying by $\cos^2\lambda$.

Spring Tides.

(51.) 2nd. Suppose that $m-s$ is 0° or 180° (that is, that it is new moon or full moon): the expression becomes

$$\frac{3}{2}\left\{M'\left(\frac{P'}{P'_m}\right)^3\cos^2\mu+S'\left(\frac{P}{P_m}\right)^3\cos^2\sigma\right\}\times\cos 2.\overline{l-m}.$$

The extent of oscillation of the surface of the water will here be

$$3\left\{M'\left(\frac{P'}{P'_m}\right)^3\cos^2\mu+S'\left(\frac{P}{P_m}\right)^3\cos^2\sigma\right\}.$$

The value of $\cos\sigma$ will not much differ from that of $\cos\mu$; therefore the expression will be nearly

$$3\cos^2\mu\left\{M'\left(\frac{P'}{P'_m}\right)^3+S'\left(\frac{P}{P_m}\right)^3\right\}.$$

This will be greatest, *cæteris paribus*, when $\cos\mu=1$, that is, for new or full moon, when the sun is at either equinox. For a solstitial new or full moon, $\cos^2\mu=\frac{21}{25}$ nearly, and the expression is

$$3.\frac{21}{25}\left\{M'\left(\frac{P'}{P'_m}\right)^3+S'\left(\frac{P}{P_m}\right)^3\right\}.$$

Neap Tides.

(52.) 3rd. Suppose that $\overline{m-s}$ is 90° or 270° (that is, that the moon is in quadratures): the expression becomes

$$\frac{3}{2}\left\{M'\left(\frac{P'}{P'_m}\right)^3\cos^2\mu-S'\left(\frac{P}{P_m}\right)^3\cos^2\sigma\right\}\times\cos 2.\overline{l-m};$$

and the whole extent of oscillation is

$$3\left\{M'\left(\frac{P'}{P'_m}\right)^3\cos^2\mu-S'\left(\frac{P}{P_m}\right)^3\cos^2\sigma\right\}.$$

If the sun is at either equinox, the moon will be at solstice, and the whole extent of oscillation is nearly $3\left\{M'\left(\frac{P'}{P'_m}\right)^3.\frac{21}{25}-S'\left(\frac{P}{P_m}\right)^3\right\}$. If the sun is at either solstice, the moon will be at equinox, and the whole extent of oscillation is $3\left\{M'\left(\frac{P'}{P'_m}\right)^3-S'\left(\frac{P}{P_m}\right)^3.\frac{21}{25}\right\}$. Combining these remarks with those of the last paragraph, we find that the syzygial tides are greatest, and the quadratural tides are least, at the equinoxes, and that these are respectively the greatest and least of all the tides.

(53.) 4th. If we put $M'+N$ for $M'\left(\frac{P'}{P'_m}\right)^3\cos^2\mu$, and $S'+T$ for $S'\left(\frac{P}{P_m}\right)^3\cos^2\sigma$, and consider that, in consequence of the small variation of the factors $\left(\frac{P'}{P'_m}\right)^3\cos^2\mu$ &c., N and T will be small, and their powers above the first may therefore be neglected without great error, the whole extent of oscillation is expressed by

$$3\sqrt{\left\{M'^2+2M'S'\cos 2.\overline{m-s}+S'^2+(2M'+2S'\cos 2.\overline{m-s})N+(2S'+2M'\cos 2.\overline{m-s})T\right\}}$$

$$=3\sqrt{\left\{M'^2+2M'S'\cos 2.\overline{m-s}+S'^2\right\}}+3\frac{M'+S'\cos 2.\overline{m-s}}{\sqrt{\{M'^2+2M'S'\cos 2.\overline{m-s}+S'^2\}}}N+3\frac{S'+M'\cos 2.\overline{m-s}}{\sqrt{\{M'^2+2M'S'\cos 2.\overline{m-s}+S'^2}}T.$$

If $P'=P'_m+p'=P'_m\left(1+\frac{p'}{P'_m}\right)$, then $\left(\frac{P'}{P'_m}\right)^3\cos^2\mu=1+3\frac{p'}{P'_m}-\sin^2\mu$ nearly; and if $P=P_m+p$, then $\left(\frac{P}{P_m}\right)^3\cos^2\sigma=1+\frac{3p}{P_m}-\sin^2\sigma$ nearly. Consequently $N=\frac{3M'p'}{P'_m}-M'\sin^2\mu$, and $T=\frac{3S'p}{P_m}-S'\sin^2\sigma$. Substituting these in the last formula, we find the following approximate expression for the whole extent of oscillation:

Approximate expression for the oscillation of the

$$3\sqrt{\left\{M'^2+2M'S'\cos 2.\overline{m-s}+S'^2\right\}}$$

$$+9\frac{M'^2+M'S'\cos 2.\overline{m-s}}{P'_m\sqrt{\{M'^2+2M'S'\cos 2.\overline{m-s}+S'^2\}}}p'$$

water produced by semidiurnal Tide.

$$-3\frac{M'^2+M'S'\cos 2.\overline{m-s}}{\sqrt{\{M'^2+2M'S'\cos 2.\overline{m-s}+S'^2\}}}\sin^2\mu$$

$$+9\frac{S'^2+M'S'\cos 2.\overline{m-s}}{P_m\sqrt{\{M'^2+2M'S'\cos 2.\overline{m-s}+S'^2\}}}p$$

$$-3\frac{S'^2+M'S'\cos 2.\overline{m-s}}{\sqrt{\{M'^2+2M'S'\cos 2.\overline{m-s}+S'^2\}}}\sin^2\sigma.$$

This form is convenient for calculation. For the first or principal term depends upon no variable except $\overline{m-s}$, the angle by which the moon's right ascension exceeds the sun's right ascension, and may therefore be expanded in a single table to any extent: the other terms depend each upon two variable quantities (of which one is $\overline{m-s}$, and the other is the difference of parallax from the mean, or the declination), and will therefore be contained each in a table of double entry, which, however, needs not to be extensive. It is nearly in this form that the tables have been constructed which have lately been used for the prediction of tides.

Retard of high water upon the moon's transit.

(54.) 5th. The time of high water is determined by making $2(l-m)+F=0$, or $l-m=-\frac{F}{2}$. Now $l-m$ is evidently the angle by which the place of observation has travelled to the east of the meridian passing through the moon, or it is the time (expressed as an hour-angle) by which the moon has apparently passed the meridian of the place. Remarking now that the difference between F and tan F is so small (for these investigations) that we may use one for the other, and also that, as tan F or F is expressed in parts of radius, it must, in order to give an expression in minutes of time, be multiplied by $\frac{24\times 60}{2\pi}$, we find for the retardation of high water after the moon's passage over the meridian, expressed in minutes of time,

$$-\frac{24\times 60}{4\pi}\times\frac{(S'+T).\sin 2.\overline{m-s}}{M'+N+(S'+T)\cos 2.\overline{m-s}}.$$

These minutes, it is to be remarked, are strictly minutes of *lunar* time (that is, of time in which the measure of 24 hours is the interval between two transits of the moon): but they will not sensibly differ from solar minutes. Expanding to the first power of N and T, the retardation is

$$-\frac{360^m}{\pi}\times\left\{\frac{S'\sin 2.\overline{m-s}}{M'+S'\cos 2.\overline{m-s}}-\frac{S'\sin 2.\overline{m-s}}{(M'+S'\cos 2.\overline{m-s})^2}N+\frac{M'\sin 2.\overline{m-s}}{(M'+S'\cos 2.\overline{m-s})^2}T\right\};$$

Approximate expression for the retardation.

which, as before, will be conveniently expressed for calculation in the following form:

$$-\frac{360^m}{\pi}.\frac{S'\sin 2.\overline{m-s}}{M'+S'\cos 2.\overline{m-s}}$$

$$+\frac{1080^m}{\pi}.\frac{M'S'.\sin 2.\overline{m-s}}{P'_m(M'+S'\cos 2.\overline{m-s})^2}p'$$

$$-\frac{360^m}{\pi}.\frac{M'S'.\sin 2.\overline{m-s}}{(M'+S'.\cos 2.\overline{m-s})^2}\sin^2\mu$$

$$-\frac{1080^m}{\pi}.\frac{M'S'.\sin 2.\overline{m-s}}{P_m(M'+S'\cos 2.\overline{m-s})^2}p$$

$$+\frac{360^m}{\pi}.\frac{M'S'.\sin 2.\overline{m-s}}{(M'+S'.\cos 2.\overline{m-s})^2}\sin^2\sigma.$$

Principal changes in the retardation.

(55.) The changes in the value of this expression which are most interesting to the general reader are principally those of the first term. It appears that when $\overline{m-s}$ is greater than 0° and less than 90°, or greater than 180° and less than 270°, this term is negative; that is, high water should precede the moon's transit while the moon is passing from syzygy to quadrature. While the moon is passing from quadrature to syzygy, high water should follow the moon's transit. The greatest value of this acceleration or retard for the mean values M′ and S′ will be found by differentiating the first term with respect to $\overline{m-s}$, and making the differential coefficient $=0$: this gives $\cos 2.\overline{m-s}=-\frac{S'}{M'}$, from which tan F at its maximum value $=\pm\frac{S'}{\sqrt{(M'^2-S'^2)}}$, and

Expression for greatest retard.

$\sin F = \pm \frac{S'}{M'}$. This expression is useful, because, in a long series of observations, it is possible to determine the value of F with considerable accuracy, and that determination will immediately give us the value of the fraction $\frac{S'}{M'}$, or the proportion of the Sun's mean force to the Moon's mean force.

Expressions referred to mean declination.

(56.) In the expressions for N and T, we have proceeded on the supposition, that it is most convenient to refer the actual values of $M'\left(\frac{P'}{P'_m}\right)^3 \cos^2\mu$ and $S'\left(\frac{P}{P_m}\right)^3 \cos^2\sigma$ to the values which they would have, if the respective parallaxes had their mean values, and if the declinations were 0. With regard to the parallaxes, there is no need for alteration; but with regard to the declinations, it has sometimes been found more convenient to refer to a declination Δ, which gives for $\cos^2\Delta$ a value that is nearly a mean among all the values of $\cos^2\mu$ or $\cos^2\sigma$ (conditions that are sensibly equivalent) which occur in observation. This gives for Δ a value of 16° 35′ nearly. Then the term $M'\left(\frac{P'}{P'_m}\right)^3 \cos^2\mu$ must be expressed in the form $M'\left(\frac{P'}{P'_m}\right)^3 . (\cos^2\Delta + \overline{\cos^2\mu - \cos^2\Delta})$ or $M' \cos^2\Delta \left\{1 + \frac{3p'}{P'_m} + \frac{\cos^2\mu - \cos^2\Delta}{\cos^2\Delta}\right\}$. If we put M_Δ for $M' \cos^2\Delta$, and call the last expression $M_\Delta + N$, we obtain $N = \frac{3M_\Delta p'}{P'_m} - M_\Delta \frac{\sin^2\mu - \sin^2\Delta}{\cos^2\Delta}$. A similar change must be made in the value of T. And thus it appears, that the expressions of (53.) and (54.) may still be retained, provided that we put M_Δ and S_Δ instead of M' and S', and that instead of $\sin^2\mu$ and $\sin^2\sigma$ we put $\frac{\sin^2\mu - \sin^2\Delta}{\cos^2\Delta}$ and $\frac{\sin^2\sigma - \sin^2\Delta}{\cos^2\Delta}$. Then the greatest value of F which we have spoken of in (55.) will be the mean of all the greatest values of acceleration or retard produced in a very long series of observations; since then, not only will the positive and negative values of p' and p, (the excesses and defects of actual parallax as referred to mean parallax,) destroy each other, but also the positive and negative values of $\sin^2\mu - \sin^2\Delta$ and $\sin^2\sigma - \sin^2\Delta$, (the excesses and defects of the actual values of $\sin^2\mu$ and $\sin^2\sigma$, as referred to their mean values,) will destroy each other; and thus a value of F will be obtained, from which $\frac{S_\Delta}{M_\Delta}$ or its equal $\frac{S'}{M'}$ can immediately be found.

(57.) With regard to the three principal parts into which we have resolved the lunisolar tide, we may make the following remarks:—

The first part treated in (45.) &c., is so slow in its period that it will generally be lost among the others whose recurrence is so much more frequent. If, however, we wished to examine its law, we should remark, that its variations depend chiefly on the variations of $\sin^2\mu$ and $\sin^2\sigma$. And we see that $\sin^2\mu$ will be (for a few lunations) nearly proportional to the square of the sine of the moon's longitude from a given point, and therefore nearly proportional to the square of the sine of an angle increasing proportionally to the time (which we will call $At + B$, putting t for the time), or that $\sin^2\mu \propto \sin^2(At + B) \propto \frac{1}{2} - \frac{1}{2}\cos(2At + 2B)$. From this it appears that the fluctuation of the surface of the water, dependent on this cause, would be expressed (omitting the constant terms) by a multiple of $\cos(2At + 2B)$. In like manner the fluctuation depending on $\cos^2\sigma$ would be expressed by $\cos(2Ct + 2D)$.

(58.) The fluctuations depending on the second and third parts, treated of from (46.) to (53.) are, as we have seen, expressed by cosines of multiples of $l - m$ and $l - s$, which for a few tides can be expressed nearly enough by cosines of multiples of $l - m$. This angle is nearly proportional to the time, and thus these fluctuations can be expressed in the same form as those above.

(59.) If we considered the variations which the factors of these different terms undergo, arising from the change of parallax, declination, &c., it would be found that they would all be expressed by series of cosines of multiples of the time; which combined as factors with the cosines of the former would produce cosines of new multiples of the time.

All the fluctuations may be expressed by cosines.

(60.) Thus it appears that the fluctuation of the water will be expressed by a multitude of terms, each of which will be of the form $C \cos(2At + 2B)$. If any one of these terms existed alone, the following curious law would be true. Suppose the lines of the extreme elevation and extreme depression of the surface of the water to be marked upon a wharf-wall; and suppose a circle to be described upon the wall, touching those two lines; then if the circumference of that circle be divided into equal parts, the fall of the water will expose the successive equal parts in successive equal times. For, since the whole fluctuation is 2C, C is the radius of our circle; and the elevation of any point of the circumference above the mean (or above the centre of the circle) is $C \times$ cosine angle from the top; but the tidal term gives for that elevation $C \times$ cosine $(2At + 2B)$, and therefore $2At + 2B$ must be the same thing as that angle from the top; and, therefore, that angle, and the circumference which is proportional to it, must have increased proportionally to the time. But this law does not hold for an assemblage of a multitude of such terms.

(61.) We have now given a tolerably complete investigation of the equilibrium-theory. But before quitting this section we will point out roughly how far it agrees with observation.

(62.) The most conspicuous tide, on the coasts of Europe at least, is the semidiurnal. The acceleration or retard of this tide on the moon's transit, does not at one port in a hundred agree in any measure with the result of this theory. The extreme differences of acceleration or retard (F of article 55., &c.) agree better, but are not exactly the same at all ports. They do not occur on the days on which this theory predicts them, but always later. The absolute elevation of the tide is great at one port and small at another, without any relation to the quantity calculated from the theory. The proportions of the elevations however at the same port, in different stages of the lunation, agree pretty well with the theory (though not equally at all ports); yet the critical phænomena (spring and neap tides) occur later than the theory gives them, and that by a quantity which is not the same as the delay of extreme values of F, mentioned above. The peculiar phænomena of river tides are not touched by this theory.

(63.) The diurnal tide ought to be discovered, in observation, in one of the following ways. If the diurnal tide were much greater than the semidiurnal, there would appear, to common observation, to be only one tide in the day with some irregularities. If it were much smaller, its effect would be shown in either or both the following ways. If its high water occurred nearly at one high water of semidiurnal tide, its low water would occur nearly at another high water of semidiurnal tide; and one of the semidiurnal tides would be increased and the other would be diminished. If its high water occurred between two semidiurnal high waters, then at the first semidiurnal high water the surface would still be rising in consequence of diurnal tide, and the compound high water would be later; and at the second semidiurnal high water the surface would be falling in consequence of diurnal tide, and the compound high water would therefore be past; consequently the interval between these two high waters would be less than it ought to be on the usual laws of semidiurnal tide. The diurnal tide ought, in these latitudes, to be equal or nearly equal to the semidiurnal tide. Yet in the Thames it is absolutely insensible; and in other parts, as well of England as of other parts of Europe and America, though discoverable, it is not notorious, and has only been found from the observations made by men of science. It has been found to be very conspicuous at some places near the equator and some places near the pole, where it ought not to be discoverable or scarcely discoverable.

The Tides of longer period have scarcely been observed.

(64.) Combining these remarks with those which we made at the introduction of this theory (14.), it must be allowed that it is one of the most contemptible theories that was ever applied to explain a collection of important physical facts. It is entirely false in its principles, and entirely inapplicable in its results. Yet, strange as it may appear, this theory has been of very great use. It has served to show that there are forces in nature following laws which bear a not very distant relation to some of the most conspicuous phænomena of the Tides; and, what is far more important, it has given an algebraic form to its own results, divided into separate parts analogous to the parts into which the tidal phænomena may be divided, admitting easily of calculation and of alteration, and thus at once suggesting the mode of separating the tidal movements, and affording numerical results of theory with which they are to be compared. The greatest mathematicians and the most laborious observers of the present age have agreed equally in rejecting the *foundation* of this theory and comparing all their observations with its *results*. And, till theories are perfect (a thing scarcely to be hoped for in any subject, and less in the Tides than in any other), this is one of the most important uses of theory.

SECTION III.—LAPLACE'S THEORY OF TIDES.

Laplace's theory is a theory of motion.

(65.) In the theory which we are now about to describe, a prodigious step was made towards a rational explanation, on mathematical principles, of the tidal phænomena. The idea of a state of equilibrium was entirely laid aside, and the motion of the water was legitimately investigated, on the supposition that it is in motion, and subject to all the laws of fluids in motion. It was found necessary, however, in order to make the application of mathematics practicable, to start with two suppositions, which are inapplicable to the state of the earth. These are: that the earth is covered with water; and that the depth of this water is the same through the whole extent of any parallel of latitude. Under these suppositions it is evident that the theory is far from being one of practical application; though it clearly approaches much nearer to truth than the theory of equilibrium which we have already described.

Suppositions by which it is limited.

(66.) It would be useless to offer this theory in the same shape in which Laplace has given it; for the part of the *Mécanique Céleste*, which contains the Theory of Tides, is perhaps on the whole more obscure than any other part of the same extent in that work. We shall give the theory in a form equivalent to Laplace's, and, indeed, so nearly related to it, that a person familiar with the latter will perceive the parallelism of the successive steps. The results at which we shall arrive are the same as those of Laplace.

(67.) We shall commence with a few considerations of a general nature, based upon the suppositions that we have already enunciated, and the additional supposition that the depth of the sea is small compared with the radius of the earth; and taking for granted a knowledge of the principal results of the equilibrium theory.

(68.) The motion of the water which forms the variable elevations of the Tides at different parts of the earth must be conceived to be principally a horizontal oscillation, the water on both sides of the highest point at any time having run towards that point in order to raise the surface there, and, consequently, (as the highest point occupies different positions at different times,) the water at any particular place running sometimes in one direction and sometimes in another. Combining this with the general result of the equilibrium-theory as to semidiurnal Tides, (namely, that the water is equally raised at two opposite points,) it will easily be seen that, if a canal were traced through the water, forming a great circle of the earth, it would (in certain positions at least of the sun and moon) be divided into four parts, in two of which the water is running in one direction, and in the other two it is running in the opposite direction. Suppose that in one of these parts

A small vertical motion of the water implies a large horizontal motion.

the length is 1000 times as great as the depth, and suppose that the water is depressed one foot through its whole extent. It is evident that the volume of the water (omitting the factor depending on the breadth of the canal), for which a new place is to be found, is = the length of the canal × 1 foot, which = 1000 × depth of the canal × 1 foot, or = depth of the canal × 1000 feet. Consequently the water at one end of the canal, if that at the other end remained unmoved in horizontal place, must have moved 1000 feet, or 1000 times as far as the whole vertical motion of any part. The whole of the extraneous *vertical* forces then which act upon the particles of the water may be omitted in our investigations. For these forces are of two kinds. One is that which depends upon the acceleration or retardation of the particles of water in their upward or downward direction: thus, if the water has been raised 1 foot in 6 hours, the force of which we speak is the pressure which must have acted, in order, by its action continued for 6 hours, to produce a motion of 1 foot. It is clear that this is insignificant in comparison with that force which in the same time has produced a motion of 1000 feet. The force of the other kind is the disturbing force of the sun or moon: now the pressure which this causes among the particles of the water depends not only upon the magnitude of the force, but also upon the depth of the column or the length of the canal through which it acts: and, therefore, though its resolved vertical part may be as great as its resolved horizontal part, yet as the vertical part acts only upon a column of water 5 or 6 miles deep (at the utmost), and the horizontal part acts along the whole length of a canal 5000 or 6000 miles long, the pressure among the particles of water which is caused by the former will be insignificant in comparison with that caused by the latter. As regards both these kinds of force then, the vertical force may be put out of consideration. But the same remark does not apply to the vertical force of gravity, nor to the difference in the pressure which it produces, depending on the small tidal difference of elevation of the water at different places. For the force of gravity, as we have seen in (16.), is nearly forty millions of times as great as the sun's disturbing force, and therefore the force of gravity acting on one foot of additional elevation of water would cause as great an additional pressure among the particles of water as the sun's disturbing force acting along a canal whose length is 8000 miles.

Extraneous vertical forces, and forces depending on vertical motion, may be omitted.

Vertical force of gravity on the small elevations of water must not be omitted.

(69.) From this we gather that the only forces which we shall have to consider are: the vertical force of gravity, the resolved disturbing forces of the sun and moon in the horizontal direction at each place, and the forces arising from the horizontal accelerations or retardations of the water in each place. We shall suppose the density of the water insignificant, and gravity therefore will depend simply upon the attraction of the solid earth, and the centrifugal force arising from the earth's rotation.

(70.) Now as the depth of the water is very small compared with the radius of the earth, the horizontal disturbing force will be very nearly the same at the bottom of the water as at the top. Consequently we may conceive the whole motion of the water to be of such a kind that particles which were originally in a vertical line remain in a vertical line, although that vertical line may have had a motion on the earth's surface. The elevation of the water must be supposed to be produced merely by the approach of different vertical lines, (arising from their difference of horizontal velocities,) and the consequent forcing up of the water between them: the depression, by their separation, and the consequent drop of the water to fill up the space between them. The reader will remark, that this is not the most general supposition that we can make in regard to the motion of water, but it is one which is possible, and which is sufficient for our theory. Algebraically speaking, it is not our object to obtain a *general solution* of the equations applying to fluids, but a *particular integral* adapted to the case under consideration.

Partic origin in a ve line n suppo be al in a v line.

(71.) We shall now proceed to put the theory into a mathematical form. In figure 2, let P be the pole of the earth, PA a meridian fixed in space, PS a meridian fixed upon the earth's surface, and therefore travelling away from PA with a uniform angular velocity which we will call n; so that, at the end of the time t, PS will make with PA the angle nt: PT the meridian passing through the original place T of any point of the water whose motion is required. We shall suppose that in the quiescent state of the water the angle SPT would have been ϖ, but that in consequence of the tidal disturbance the particle of water is moved to T′, and the angle ϖ is altered by the variable angle v, so that SPT′ $= \varpi + v$, and APT′ $= nt + \varpi + v$. We shall conceive that the original polar distance of the water at T was θ; but that in consequence of the tidal disturbance it is now $\theta + u$. Also we shall put γ for the depth of the water at T, supposed quiescent, and w for its tidal elevation above the quiescent state when at T′. Here γ, in conformity with the supposition made in (65.), is to be considered a function of θ only: u, v, and w are all to be considered as functions of θ, ϖ, and t.

Investigation of the equation of continuity.

(72.) The equation which we shall first form is that which expresses that, however any part of the fluid is transported by the tidal and rotatory motions, it occupies still the same volume. Take another point U′ corresponding to another particle of water U, which was originally on the same meridian with T, and whose polar distance was originally $\theta+\delta\theta$, and therefore is now $\theta+u+\left(1+\frac{du}{d\theta}\right)\delta\theta$ nearly. The angle APU′ has the value which $nt+\varpi+v$ receives when $\theta+\delta\theta$ is used instead of θ in forming the value of v: it is therefore $nt+\varpi+v+\left(\frac{dv}{d\theta}\right)\delta\theta$ nearly. Also take two points, V′ and W′, corresponding to two points V and W, whose polar distances were originally θ, and $\theta+\delta\theta$, but which were upon a meridian making with PS the angle $\varpi+\delta\varpi$. The polar distances of these two points have now respectively the values $\theta+u+\frac{du}{d\varpi}\delta\varpi$ and $\theta+u+\left(1+\frac{du}{d\theta}\right)\delta\theta+\frac{du}{d\varpi}\delta\varpi$, and their angular distances from PA have respectively the values $nt+\varpi+v+\left(1+\frac{dv}{d\varpi}\right)\delta\varpi$ and $nt+\varpi+v+\left(1+\frac{dv}{d\varpi}\right)\delta\varpi+\frac{dv}{d\theta}\delta\theta$. The distance, therefore, from T′ to U′ (if r be the radius of the spherical or spheroidal surface of the water) is sensibly equal to $r\left(1+\frac{du}{d\theta}\right)\delta\theta$, and that from V′ to W′ is the same. Also the difference of angular distances from PA, between T′ and V′, is sensibly equal to $r\left(1+\frac{dv}{d\varpi}\right)\delta\varpi$, and that between U′ and W′ is sensibly the same. Now the area of the surface upon which the water originally stood is seen without difficulty to be $r\delta\theta\times r\sin\left(\theta+\frac{\delta\theta}{2}\right).\delta\varpi$: and, therefore, its original volume

$$=r\delta\theta\times r\sin\left(\theta+\frac{\delta\theta}{2}\right).\delta\varpi\times\gamma.$$

The area upon which it now stands is not estimated so readily, because its sides are inclined; namely, one pair making with the meridian the small angle $\frac{1}{r\delta\theta}\times r.\sin\theta.\frac{dv}{d\theta}\delta\theta=\sin\theta.\frac{dv}{d\theta}$, and the other pair making with the parallel the small angle $\frac{1}{r\sin\theta\delta\varpi}\times r\frac{du}{d\varpi}\delta\varpi=\frac{1}{\sin\theta}.\frac{du}{d\varpi}$. These small inclinations do not, however, produce any sensible effect on the area. The reader will perceive this most readily by estimating the area of a parallelogram *abed*, figure 3, whose sides are inclined to the sides of the rectangle *acgf*. For the area of *abed*

$$\begin{aligned}&=ab\times ad\times\sin bad=ab\times ad\times\sin(90^\circ-bac-daf)=ab\times ad\times\cos(bac+daf)\\&=ab\times ad\times(\cos bac.\cos daf-\sin bac.\sin daf)\\&=(ab.\cos bac)\times(ad.\cos daf)\times(1-\tan bac.\tan daf\\&=ac.af.(1-\tan bac.\tan daf),\end{aligned}$$

which it is evident differs from $ac.af$ only by the product of $ac.af$ into a small quantity of the second order. In like manner we may estimate the area T′U′W′V′ without regard to the inclination of its sides; and it becomes, therefore,

$$r\left(1+\frac{du}{d\theta}\right)\delta\theta\times r\sin\left\{\theta+u+\left(1+\frac{du}{d\theta}\right)\frac{\delta\theta}{2}\right\}\times\left(1+\frac{dv}{d\varpi}\right)\delta\varpi.$$

The depth of the water, which at the original place was γ, is now altered, from two causes: first, because $\theta+u$, upon which it depends, differs from θ; and, secondly, because there is the tidal elevation of the surface; it is, therefore, $\gamma+\frac{d\gamma}{d\theta}u+w$. The volume of the water standing upon T′V′W′U′ is, therefore,

$$r\left(1+\frac{du}{d\theta}\right)\delta\theta\times r\sin\left\{\theta+u+\left(1+\frac{du}{d\theta}\right)\frac{\delta\theta}{2}\right\}\times\left(1+\frac{dv}{d\varpi}\right)\delta\varpi\times\left(\gamma+\frac{d\gamma}{d\theta}u+w\right)$$

$$=r\delta\theta\times r\sin\left(\theta+\frac{\delta\theta}{2}\right).\delta\varpi\times\gamma\times\left(1+\frac{du}{d\theta}\right)\times\left\{1+\text{cotan}\,\overline{\theta+\frac{\delta\theta}{2}}.\overline{u+\frac{du}{d\theta}.\frac{\delta\theta}{2}}\right\}\times\left(1+\frac{dv}{d\varpi}\right)\times\left(1+\frac{u}{\gamma}.\frac{d\gamma}{d\theta}+\frac{w}{\gamma}\right).$$

Making this equal to the original volume, or

$$r\delta\theta\times r\sin\left(\theta+\frac{\delta\theta}{2}\right)\delta\varpi\times\gamma,$$

we have

$$1=\left(1+\frac{du}{d\theta}\right)\times\left\{1+\text{cotan}\,\overline{\theta+\frac{\delta\theta}{2}}.\overline{u+\frac{du}{d\theta}.\frac{\delta\theta}{2}}\right\}\times\left(1+\frac{dv}{d\varpi}\right)\times\left(1+\frac{u}{\gamma}.\frac{d\gamma}{\delta\theta}+\frac{w}{\gamma}\right);$$

or, multiplying out these quantities, rejecting products of the small terms, and rejecting the insignificant terms depending on $\delta\theta$,

$$0=\frac{du}{d\theta}+u\,\text{cotan}\,\theta+\frac{dv}{d\varpi}+\frac{u}{\gamma}.\frac{d\gamma}{d\theta}+\frac{w}{\gamma}.$$

If we multiply this by γ, it becomes

$$0=\frac{d}{d\theta}(u\gamma)+u\gamma.\text{cotan}\,\theta+\gamma\frac{dv}{d\varpi}+w;$$

and if we multiply again by $\sin\theta$, it becomes

$$0=\frac{d}{d\theta}(u\gamma\sin\theta)+\gamma\sin\theta.\frac{dv}{d\varpi}+w.\sin\theta.$$

This is the equation expressing that the same water always occupies the same volume: it is frequently called the *equation of continuity*.

Explanation of the pressure of fluids.

(73.) We now proceed to investigate the equations applying strictly to the *motion* of the water. We will first allude in a few words to the general equations of motion of incompressible fluids, referring to our article HYDRODYNAMICS, page 276, or to other treatises, for a more detailed exposition. Let the places of the particles of a fluid at any instant of time be defined by three rectangular coordinates: suppose x, y, z, to be the coordinates of one point, and p the pressure among the particles at that point. The pressure may perhaps be most easily conceived in the following manner:—Suppose a plane to be inserted in the fluid, and suppose the fluid on one side of the plane to be removed; it will be necessary to apply a pressure to this plane, in order to maintain the remaining fluid in the same state (whether of repose, or of motion or change of motion); and the pressure for every square unit of surface on this plane is our quantity p. This pressure ought in strictness to be estimated as a statical pressure by the number of pounds and ounces under the action of gravity, at a given place on the earth's surface: but it will be preferable to take, instead, a quantity which bears a constant ratio to it, namely, the acceleration which this pressure will, by acting for one unit of time, cause in a cubic unit of the fluid.

Investigation of the rectangular equations of the motion of fluids.

(74.) Conceive, then, a small parallelopiped to be inclosed by planes corresponding to the coordinates x, $x+h$; $y, y+k$; $z, z+l$; h, k, and l being extremely small. The pressure per unit of surface on that end whose ordinate is x, is p; but the area of that end is kl; therefore the actual pressure is pkl. The actual pressure on the other end is $kl\times$ the value of p corresponding to $x+h$, or it is $kl\times\left(p+\frac{dp}{dx}h\right)$. The former of these tends to push the parallelopiped forward in the direction of x: the latter tends to push it backward. The actual pressure, then, tending to push it backward, is $\frac{dp}{dx}hkl$; and as the volume of the parallelopiped is hkl, the accelerating force in the direction opposite to that in which x is measured is $\frac{dp}{dx}$. If there is acting an extraneous accelerating force, tending to urge the particles in the direction of x, and represented by X, then the real accelerating force in the direction of x is $\mathrm{X}-\frac{dp}{dx}$. Consequently, (MECHANICS, page 91,) $\frac{d^2x}{dt^2}=\mathrm{X}-\frac{dp}{dx}$. Similarly, $\frac{d^2y}{dt^2}=\mathrm{Y}-\frac{dp}{dy}$; $\frac{d^2z}{dt^2}=\mathrm{Z}-\frac{dp}{dz}$.

Equality of pressure in moving fluids requires investigation.

(75.) It is to be remarked, that here we conceive the quantity p to be the same in the three equations which we have just found. That this is true when a fluid is in equilibrium (or that fluids press equally in all directions) there is no doubt: indeed it can be shown to be a necessary consequence of the possibility of division of the fluid by planes in all directions, and of the perpendicularity of the pressure of the fluid on any such plane. It is not so self-evidently certain for fluids in variable motion. Without expressing any doubt of its truth, we wish at the same time to call the reader's attention to the difference of evidence for the principle in the different cases.

Investigation of the polar equations of the motion of fluids.

(76.) To apply this to the movement of the sea: let x be parallel to the axis of revolution of the earth, y directed towards the first point of Aries, and z at right angles to these. And put θ' for $\theta+u$, ϖ' for $\varpi+v$: r for the distance of any particle from the earth's centre. Then $x=r.\cos\theta'$, $y=r.\sin\theta'.\cos\overline{nt+\varpi'}$, $z=r.\sin\theta'.\sin\overline{nt+\varpi'}$. Our equations of motion, which depend on x, y, z, must be transformed into others depending on r, θ', ϖ'. We must, then, instead of $\frac{dp}{dx}$, put $\frac{dp}{dr}.\frac{dr}{dx}+\frac{dp}{d\theta'}.\frac{d\theta'}{dx}+\frac{dp}{d\varpi'}.\frac{d\varpi'}{dx}$: for $\frac{dp}{dy}$ we must put $\frac{dp}{dr}.\frac{dr}{dy}+\frac{dp}{d\theta'}.\frac{d\theta'}{dy}+\frac{dp}{d\varpi'}.\frac{d\varpi'}{dy}$; and for $\frac{dp}{dz}$ we must put $\frac{dp}{dr}.\frac{dr}{dz}+\frac{dp}{d\theta'}.\frac{d\theta'}{dz}+\frac{dp}{d\varpi'}.\frac{d\varpi'}{dz}$. And, in forming the quantities $\frac{dr}{dx}$, $\frac{d\theta'}{dx}$, &c., we must express r, θ', and ϖ', in terms of no variable quantities whatever, except x, y, and z. For then it is clear that we have $\frac{dp}{dx}$, &c. exactly in the same manner as if p was explicitly expressed in terms of x, y, and z. Now

$$r^2=x^2+y^2+z^2;$$

therefore

$$\frac{dr}{dx}=\frac{x}{r};\quad \frac{dr}{dy}=\frac{y}{r};\quad \frac{dr}{dz}=\frac{z}{r}.$$

Also

$$\tan\theta'=\frac{\sqrt{y^2+z^2}}{x}$$

differentiating, and observing that $\cos^2\theta'=\frac{x^2}{r^2}$,

$$\frac{d\theta'}{dx}=\frac{-\sqrt{y^2+z^2}}{r^2};\quad \frac{d\theta'}{dy}=\frac{xy}{r^2\sqrt{y^2+z^2}};\quad \frac{d\theta'}{dz}=\frac{xz}{r^2\sqrt{y^2+z^2}}.$$

And

$$\tan\overline{nt+\varpi'}=\frac{z}{y};\quad \cos^2\overline{nt+\varpi'}=\frac{y^2}{y^2+z^2}:$$

therefore

$$\frac{d\varpi'}{dx}=0;\quad \frac{d\varpi'}{dy}=\frac{-z}{y^2+z^2};\quad \frac{d\varpi'}{dz}=\frac{y}{y^2+z^2}.$$

Substituting these, the equations of motion become

$$\begin{aligned}
&\frac{dp}{dr}\cdot\frac{x}{r}-\frac{dp}{d\theta'}\cdot\frac{\sqrt{y^2+z^2}}{r^2} &&=X-\frac{d^2x}{dt^2}\\
&\frac{dp}{dr}\cdot\frac{y}{r}+\frac{dp}{d\theta'}\cdot\frac{xy}{r^2\sqrt{y^2+z^2}}-\frac{dp}{d\varpi'}\cdot\frac{z}{y^2+z^2} &&=Y-\frac{d^2y}{dt^2}\\
&\frac{dp}{dr}\cdot\frac{z}{r}+\frac{dp}{d\theta'}\cdot\frac{xz}{r^2\sqrt{y^2+z^2}}+\frac{dp}{d\varpi'}\cdot\frac{y}{y^2+z^2} &&=Z-\frac{d^2z}{dt^2}.
\end{aligned}$$

(77.) From these we obtain

$$\begin{aligned}
\frac{dp}{dr}&=X\frac{x}{r}+Y\frac{y}{r}+Z\frac{z}{r}-\frac{x}{r}\cdot\frac{d^2x}{dt^2}-\frac{y}{r}\frac{d^2y}{dt^2}-\frac{z}{r}\cdot\frac{d^2z}{dt^2}\\
\frac{dp}{d\theta'}&=-X\sqrt{y^2+z^2}+\frac{Yxy+Zxz}{\sqrt{y^2+z^2}}+\frac{1}{\sqrt{y^2+z^2}}\left\{(y^2+z^2)\frac{d^2x}{dt^2}-xy\frac{d^2y}{dt^2}-xz\frac{d^2z}{dt^2}\right\}\\
\frac{dp}{d\varpi'}&=Zy-Yz+z\frac{d^2y}{dt^2}-y\frac{d^2z}{dt^2}.
\end{aligned}$$

Now

$$\begin{aligned}
x\frac{d^2x}{dt^2}+y\frac{d^2y}{dt^2}+z\frac{d^2z}{dt^2}&=\frac{d}{dt}\left(x\frac{dx}{dt}+y\frac{dy}{dt}+z\frac{dz}{dt}\right)-\left\{\left(\frac{dx}{dt}\right)+\left(\frac{dy}{dt}\right)^2+\left(\frac{dz}{dt}\right)^2\right\}\\
&=\frac{1}{2}\cdot\frac{d^2(r^2)}{dt^2}-\left(\frac{dr}{dt}\right)^2-r^2\left(\frac{d\theta'}{dt}\right)^2-r^2\sin^2\theta'\left(n+\frac{d\varpi}{dt}\right)^2:
\end{aligned}$$

therefore

$$-\frac{x}{r}\cdot\frac{d^2x}{dt^2}-\frac{y}{r}\cdot\frac{d^2y}{dt^2}-\frac{z}{r}\cdot\frac{d^2z}{dt^2}=-\frac{1}{2r}\cdot\frac{d^2(r^2)}{dt^2}+\frac{1}{r}\left(\frac{dr}{dt}\right)^2+r\left(\frac{d\theta'}{dt}\right)^2+r\sin^2\theta'\left(n+\frac{d\varpi}{dt}\right)^2.$$

And

$$\begin{aligned}
(y^2+z^2)\frac{d^2x}{dt^2}-xy\frac{d^2y}{dt^2}-xz\frac{d^2z}{dt^2}&=y\frac{d}{dt}\left(y\frac{dx}{dt}-x\frac{dy}{dt}\right)+z\frac{d}{dt}\left(z\frac{dx}{dt}-x\frac{dz}{dt}\right)\\
=r\sin\theta'\cos\overline{nt+\varpi'}\frac{d}{dt}&\left\{-r^2\cos\overline{nt+\varpi}.\frac{d\theta'}{dt}+r^2\sin\theta'\cos\theta'.\sin\overline{nt+\varpi}.\left(n+\frac{d\varpi'}{dt}\right)\right\}\\
+r\sin\theta'\sin\overline{nt+\varpi'}.\frac{d}{dt}&\left\{-r^2\sin\overline{nt+\varpi'}\frac{d\theta'}{dt}-r^2\sin\theta'\cos\theta'.\cos\overline{nt+\varpi'}\left(n+\frac{d\varpi'}{dt}\right)\right\};
\end{aligned}$$

therefore

$$\begin{aligned}
&\frac{1}{\sqrt{y^2+z^2}}\left\{(y^2+z^2)\frac{d^2x}{dt^2}-xy\frac{d^2y}{dt^2}-xz\frac{d^2z}{dt^2}\right\}\\
&=-\cos\overline{nt+\varpi'}.\frac{d}{dt}\left(r^2\cos\overline{nt+\varpi'}.\frac{d\theta'}{dt}\right)-\sin\overline{nt+\varpi'}\frac{d}{dt}\left(r^2\sin\overline{nt+\varpi'}.\frac{d\theta'}{dt}\right)\\
&+\cos\overline{nt+\varpi'}.\frac{d}{dt}\left(r^2\sin\theta'\cos\theta'\left(n+\frac{d\varpi'}{dt}\right)\times\sin\overline{nt+\varpi'}\right)\\
&-\sin\overline{nt+\varpi'}.\frac{d}{dt}\left(r^2\sin\theta'.\cos\theta'\left(n+\frac{d\varpi'}{dt}\right)\times\cos\overline{nt+\varpi'}\right).
\end{aligned}$$

If for the moment we put U for $r^2\cos\overline{nt+\varpi'}.\frac{d\theta'}{dt'}$, V for $r^3\sin\overline{nt+\varpi'}.\frac{d\theta'}{dt}$, W for $r^2\sin\theta'.\cos\theta'\left(n+\frac{d\varpi'}{dt}\right)$, this expression becomes

$$-\frac{1}{r^2\frac{d\theta'}{dt}}\times\left\{U\frac{dU}{dt}+V\frac{dV}{dt}\right\}$$

$$+\frac{1}{r^2\sin\theta'\cos\theta'.\left(n+\frac{d\varpi'}{dt}\right)}\left\{W.\cos\overline{nt+\varpi'}.\frac{d}{dt}\left(W.\sin\overline{nt+\varpi'}\right)-W.\sin\overline{nt+\varpi}.\frac{d}{dt}\left(W.\cos\overline{nt+\varpi'}\right)\right\}$$

$$=-\frac{1}{2r^2\frac{d\theta'}{dt}}\times\frac{d}{dt}\left(U^2+V^2\right)+\frac{1}{r^2\sin\theta'.\cos\theta'.\left(n+\frac{d\varpi'}{dt}\right)}\times W^2.\frac{d}{dt}\left(nt+\varpi'\right)$$

$$=-\frac{1}{2r^2\frac{d\theta'}{dt}}.\frac{d}{dt}\left(r^4\left(\frac{d\theta'}{dt}\right)^2\right)+\frac{1}{r^2\sin\theta'.\cos\theta'.\left(n+\frac{d\varpi'}{dt}\right)}\times r^4.\sin^2\theta'.\cos^2\theta'.\left(n+\frac{d\varpi'}{dt}\right)^2\times\left(n+\frac{d\varpi'}{dt}\right)$$

$$=-\frac{d}{dt}\left(r^2\frac{d\theta'}{dt}\right)+r^2.\sin\theta'.\cos\theta'.\left(n+\frac{d\varpi'}{dt}\right)^2.$$

And

$$z\frac{d^2y}{dt^2}-y\frac{d^2z}{dt^2}=\frac{d}{dt}\left(z\frac{dy}{dt}-y\frac{dz}{dt}\right)$$

$$=\frac{d}{dt}\left\{r\sin\theta'.\sin\overline{nt+\varpi'}\frac{d}{dt}\left(r\sin\theta'.\cos\overline{nt+\varpi'}\right)-r\sin\theta'.\cos\overline{nt+\varpi'}\frac{d}{dt}\left(r\sin\theta'\sin\overline{nt+\varpi}\right)\right\}$$

$$=-\frac{d}{dt}\left\{r^2\sin^2\theta'\left(n+\frac{d\varpi'}{dt}\right)\right\}$$

$$=-2r\frac{dr}{dt}\sin^2\theta'\left(n+\frac{d\varpi'}{dt}\right)-2r^2\sin\theta'.\cos\theta'\frac{d\theta'}{dt}\left(n+\frac{d\varpi'}{dt}\right)-r^2\sin^2\theta'.\frac{d^2\varpi'}{dt^2}.$$

Polar equations of the motion of fluids.

Substituting these, our equations become

$$\frac{dp}{dr}=X\frac{x}{r}+Y\frac{y}{r}+Z\frac{z}{r}-\frac{1}{2r}.\frac{d^2(r^2)}{dt^2}+\frac{1}{r}\left(\frac{dr}{dt}\right)^2+r\left(\frac{d\theta'}{dt}\right)^2+r\sin^2\theta'\left(n+\frac{d\varpi'}{dt}\right)^2$$

$$\frac{dp}{d\theta'}=-X\sqrt{y^2+z^2}+\frac{Yxy+Zxz}{\sqrt{y^2+z^2}}-\frac{d}{dt}\left(r^2\frac{d\theta'}{dt}\right)+r^2\sin\theta'\cos\theta'\left(n+\frac{d\varpi'}{dt}\right)^2$$

$$\frac{dp}{d\varpi'}=Zy-Yz-2r\frac{dr}{dt}\sin^2\theta'\left(n+\frac{d\varpi'}{dt}\right)-2r^2\sin\theta'.\cos\theta'.\frac{d\theta'}{dt}\left(n+\frac{d\varpi'}{dt}\right)-r^2\sin^2\theta'\frac{d^2\varpi'}{dt^2}.$$

Limited equations applicable to the motion of the sea.

(78.) The equations as we have just given them are complete. But, in conformity with the remarks in (69.), we may considerably reduce the number of terms. For, if we omit the motion in the direction perpendicular to the surface, we may entirely omit $\frac{dr}{dt}$ and $\frac{d^2r}{dt^2}$. Also, as the tidal oscillation is very small in proportion to the earth's dimensions, we may in every case omit the squares of $\frac{d\theta'}{dt}$ and $\frac{d\varpi'}{dt}$ and their product. Thus the equations become

$$\frac{dp}{dr}=X\frac{x}{r}+Y\frac{y}{r}+Z\frac{z}{r}+r\sin^2\theta'\left(n^2+2n\frac{d\varpi'}{dt}\right)$$

$$\frac{dp}{d\theta'}=-X\sqrt{y^2+z^2}+\frac{Yxy+Zxz}{\sqrt{y^2+z^2}}-r^2\frac{d^2\theta'}{dt^2}+r^2\sin\theta'.\cos\theta'.\left(n^2+2n\frac{d\varpi'}{dt}\right)$$

$$\frac{dp}{d\varpi'}=Zy-Yz-2r^2\sin\theta'\cos\theta'\frac{d\theta'}{dt}.n-r^2\sin^2\theta'\frac{d^2\varpi'}{dt^2}.$$

But θ' enters only as the representative of $\theta+u$: so that, supposing u small, $\frac{dp}{d\theta'}$ will not sensibly differ from $\frac{dp}{d\theta}$; $\sin\theta'$ and $\cos\theta'$ in the factors will not sensibly differ from $\sin\theta$ and $\cos\theta$; and $\frac{d\theta'}{dt}$ is $=\frac{du}{dt}$, because θ does not depend on the time. Also $\frac{dp}{d\varpi'}$ will not sensibly differ from $\frac{dp}{d\varpi}$, and $\frac{d\varpi'}{dt}=\frac{dv}{dt}$. Thus the equations of motion become

$$\frac{dp}{dr} = \mathrm{X}\frac{x}{r} + \mathrm{Y}\frac{y}{r} + \mathrm{Z}\frac{z}{r} + r\sin^2\theta\left(n^2 + 2n\frac{dv}{dt}\right)$$

$$\frac{dp}{d\theta} = -\mathrm{X}\sqrt{y^2+z^2} + \frac{\mathrm{Y}xy + \mathrm{Z}xz}{\sqrt{y^2+z^2}} - r^2\frac{d^2u}{dt^2} + r^2\sin\theta.\cos\theta.\left(n^2 + 2n\frac{dv}{dt}\right)$$

$$\frac{dp}{d\varpi} = \mathrm{Z}y - \mathrm{Y}z - 2r^2\sin\theta.\cos\theta.\frac{du}{dt}n - r^2\sin^2\theta\frac{d^2v}{dt^2}.$$

(79.) We shall now proceed to express the forces X, Y, Z. For convenience we shall divide each into two parts, $\mathrm{X}=\mathrm{X}'+\mathrm{X}''$, $\mathrm{Y}=\mathrm{Y}'+\mathrm{Y}''$, $\mathrm{Z}=\mathrm{Z}'+\mathrm{Z}''$: where X′, Y′, Z′, relate only to the attractions of the earth, and X″, Y″, Z″ only to those of the disturbing bodies. We shall also suppose p divided into three parts, p', p'', p''', of which the first is that part which depends on the earth's attraction and the factor n^2, the second depends only on the disturbing forces, and the third only on the differentials of u and v. And we shall put r' for the distance from the earth's centre to the surface of the undisturbed watery spheroid; so that $r'+w$ is the value of r, at the surface of the water as disturbed by the Tide. First we will remark, as a point particularly worthy of the reader's attention, that here we must not introduce what is usually called *centrifugal force*. For our equations proceed at once from the equations by rectangular co-ordinates, and in these the whole relations between the forces and the motions are absolutely included. The assertion of the existence of *centrifugal force* is in fact merely an assertion that, in order to maintain bodies or fluids in an assumed state of circular motion, a *centripetal* force must be applied. We shall soon see that the effects of centrifugal force, as regards the figure of the earth, are fully taken into account without introducing that expression at all. The point deserves a little more notice than has commonly been given to it in theories of the Figure of the Earth and similar subjects.

The forces divided into two parts.

The pressures divided into three parts.

Centrifugal force is not to be introduced.

(80.) The expressions for X′, Y′, Z′, or the attractions of the terrestrial spheroid on a particle of the sea, will be derived from those for Z′, X′, Y′, in Article 66. of the FIGURE OF THE EARTH, observing that here (in conformity with the notation used by Laplace in this investigation) we have taken x for the axis of rotation, instead of z, as in the FIGURE OF THE EARTH. Those expressions suppose the form of the terrestrial spheroid to be the form of equilibrium of its strata supposed fluid; which supposition is not infringed by our assumption that the depth of the sea is unequal, because the depth of the sea and its inequalities are very small in comparison with the earth's ellipticity. Taking the expressions referred to, and observing that m, by Article 62. of that treatise, $=\frac{3\pi}{\mathrm{T}^2}\cdot\frac{\mathrm{b}^3}{\phi(\mathrm{b})}$, and that ϕ (b) in Article 66.$=\frac{3\mathrm{M}}{4\pi}$, so that $m=\frac{4\pi^2\mathrm{b}^3}{\mathrm{T}^2\mathrm{M}}$; and remarking that, as T is the time of rotation, and n the angular velocity of rotation, $n\mathrm{T}=2\pi$, so that $\frac{4\pi^2}{\mathrm{T}^2}=n^2$, and m therefore $=\frac{n^2\mathrm{b}^3}{\mathrm{M}}$; we obtain

Forces depending on the earth's attraction and on rotation.

$$\mathrm{X}' = -\frac{\mathrm{M}x}{r^3} - x\frac{\mathrm{b}^2(3y^2+3z^2-2x^2)}{r^7}\left(\mathrm{Me} - \frac{n^2\mathrm{b}^3}{2}\right)$$

$$\mathrm{Y}' = -\frac{\mathrm{M}y}{r^3} - y\frac{\mathrm{b}^2(y^2+z^2-4x^2)}{r^7}\left(\mathrm{Me} - \frac{n^2\mathrm{b}^3}{2}\right)$$

$$\mathrm{Z}' = -\frac{\mathrm{M}z}{r^3} - z\frac{\mathrm{b}^2(y^2+z^2-4x^2)}{r^7}\left(\mathrm{Me} - \frac{n^2\mathrm{b}^3}{2}\right).$$

Substituting these in the expressions for $\frac{dp}{dr}$, &c. in (78.), and combining the terms which depend on n^2, we have

$$\frac{dp'}{dr} = -\frac{\mathrm{M}}{r^2} + \frac{\mathrm{b}^2(2-3\sin^2\theta)}{r^4}\left(\mathrm{Me} - \frac{n^2\mathrm{b}^3}{2}\right) + n^2 r\sin^2\theta$$

$$\frac{dp'}{d\theta} = +\frac{2\mathrm{b}^2\sin\theta\cos\theta}{r^3}\left(\mathrm{Me} - \frac{n^2\mathrm{b}^3}{2}\right) + n^2r^2\sin\theta.\cos\theta$$

$$\frac{dp'}{d\varpi} = 0.$$

Integrating these,

$$p' = \frac{\mathrm{M}}{r} + \frac{\mathrm{b}^2\left(\sin^2\theta - \frac{2}{3}\right)}{r^3}\left(\mathrm{Me} - \frac{n^2\mathrm{b}^3}{2}\right) + \frac{n^2r^2}{2}\sin^2\theta + \mathrm{C}.$$

If we conceive $r=r'+r''$, r' being the value of r at the surface of the undisturbed watery spheroid, and r'' a variable quantity (which at the surface$=w$), it will be unnecessary to insert r'' in any term but the first or largest term. Thus

$$p'=\frac{M}{r'}-\frac{Mr''}{r'^2}+\frac{Mb^2e}{r'^3}\left(\sin^2\theta-\frac{2}{3}\right)+\frac{n^2}{2}\left(r'^2\sin^2\theta-\frac{b^3}{r'^3}\sin^2\theta+\frac{2b^5}{3r'^3}\right)+C.$$

Pressure depending on the earth's attraction and on rotation.

Putting for r' in the first term its approximate value b $(1+e\sin^2\theta)$, and in the other terms b only, it becomes

$$p'=\frac{M}{b}-\frac{M}{b^2}r''-\frac{2}{3}\frac{Me}{b}+\frac{n^2b^2}{3}+C.$$

The whole of this, except the second term, is constant: and we may therefore write it, $p'=I-\frac{M}{b^2}r''$. And as $\frac{M}{b^2}$ =attraction of the earth nearly, $=g$ nearly, we may write it

$$p'=I-gr''.$$

(81.) Before leaving this part of the investigation we will remark that, if at any one place where $r''=0$ the pressure is 0 (that is, if the surface be free there), it will $=0$ at every place where $r''=0$, or where $r=r'$, or where the fluid has the external boundary which we have taken from the investigations of the Figure of the Earth. And thus our process in this article, conducted without mention of centrifugal force, leads to the same result as that which was based upon it.

(82.) The equations determining p'' will be

$$\frac{dp''}{dr}=X''\frac{x}{r}+Y''\frac{y}{r}+Z''\frac{z}{r}$$

$$\frac{dp''}{d\theta}=-X''\sqrt{y^2+z^2}+\frac{Y''xy+Z''xz}{\sqrt{y^2+z^2}}$$

$$\frac{dp''}{d\varpi}=Z''y-Y''z.$$

Relative co-ordinates of the sun or moon.

Now let S be the mass of the sun; D its distance from the earth's centre; D' its distance from the particle at x, y, z; s its right ascension; σ its declination. Then x' for the sun$=D\sin\sigma$; $y'=D\cos\sigma.\cos s$; $z'=D\cos\sigma.\sin s$;

$$x'-x=D\sin\sigma-r\cos\theta,$$

$$y'-y=D\cos\sigma.\cos s-r\sin\theta.\cos\overline{nt+\varpi},$$

$$z'-z=D\cos\sigma.\sin s-r\sin\theta.\sin\overline{nt+\varpi};$$

$$\sqrt{\{(x'-x)^2+(y'-y)^2+(z'-z)^2\}}=D'=\sqrt{\{D^2-2Dr(\sin\sigma.\cos\theta+\cos\sigma.\sin\theta.\cos\overline{nt+\varpi-s})+r^2\}};$$

and, preserving only the first power of r,

$$\frac{1}{\{(x'-x)^2+(y'-y)^2+(z'-z)^2\}^{\frac{3}{2}}}=\frac{1}{D'^3}=\frac{1}{D^3}\times\left\{1+\frac{3r}{D}(\sin\sigma.\cos\theta+\cos\sigma.\sin\theta.\cos\overline{nt+\varpi-s})\right\}.$$

Now the whole force which the sun exerts upon the particle at x, y, z, in the direction of x, is $\frac{x'-x}{D'}\times\frac{S}{D'^2}=\frac{S(x'-x)}{D'^3}$. But the whole of this is not disturbing force upon the water in regard to its movement upon the earth. In order to find this, we must, as in (25.), subtract the force which the sun exerts upon the earth's centre of gravity, which is the same as if the whole mass of the earth were collected at its centre, and is therefore $=\frac{Sx'}{D^3}$ in the direction of x. Subtracting this, we have

$$X''=\frac{S(x'-x)}{D'^3}-\frac{Sx'}{D^3}=Sx'\left(\frac{1}{D'^3}-\frac{1}{D^3}\right)-\frac{Sx}{D'^3}$$

Disturbing forces of the sun or moon.

Similarly

$$Y'=Sy'\left(\frac{1}{D'^3}-\frac{1}{D^3}\right)-\frac{Sy}{D'^3}$$

$$Z''=Sz'\left(\frac{1}{D'^3}-\frac{1}{D^3}\right)-\frac{Sz}{D'^3}.$$

(83.) The expressions at the beginning of last article therefore become

$$X''\frac{x}{r}+Y''\frac{y}{r}+Z''\frac{z}{r}=\frac{S}{r}(x'x+y'y+z'z)\left(\frac{1}{D'^3}-\frac{1}{D^3}\right)-\frac{Sr}{D'^3}$$

$$-X''\sqrt{y^2+z^2}+\frac{Y''xy+Z''xz}{\sqrt{y^2+z^2}}=\frac{S}{\sqrt{y^2+z^2}}\left(x.\overline{y'y+z'z}-x'.\overline{y^2+z^2}\right)\left(\frac{1}{D'^3}-\frac{1}{D^3}\right)$$

$$Z''y-Y''z \qquad\qquad =S.\overline{z'y-y'z}.\left(\frac{1}{D'^3}-\frac{1}{D^3}\right).$$

Substituting in these the values of x, y, z, in terms of r, θ, and ϖ, and those of x', y', z', in terms of D, σ, s; we find (retaining only the principal power of r),

$$\frac{dp''}{dr}=\frac{Sr}{D^3}\{3\,(\sin\sigma.\cos\theta+\cos\sigma.\sin\theta.\cos\overline{nt+\varpi-s})^2-1\}$$

$$\frac{dp''}{d\theta}=\frac{3Sr^2}{D^3}\{\sin\sigma.\cos\theta+\cos\sigma.\sin\theta.\cos\overline{nt+\varpi-s}\}.\{-\sin\sigma.\sin\theta+\cos\sigma.\cos\theta.\cos\overline{nt+\varpi-s}\}$$

$$\frac{dp''}{d\varpi}=-\frac{3Sr^2}{D^3}\{\sin\sigma.\cos\theta+\cos\sigma.\sin\theta.\cos\overline{nt+\varpi-s}\}\cos\sigma.\sin\theta.\sin\overline{nt+\varpi-s}.$$

Pressure produced by the sun or moon.

Integrating, $$p''=\frac{Sr^2}{2D^3}\{3(\sin\sigma.\cos\theta+\cos\sigma.\sin\theta.\cos\overline{nt+\varpi-s})^2-1\}.$$

It is unnecessary to add an arbitrary constant, since one has been attached to the expression for p', to which this is to be added.

(84.) In conformity with the remarks in (68.), no regard is to be given, in this expression, to the variation in the values of r arising from the difference in the depth of particles of water. Instead of r, therefore, we may put the elliptic value r', or even the polar radius b. (This amounts to the assumption, that the Tides upon a spheroid, so nearly spherical as the earth, will not sensibly differ from those upon a sphere.) Putting b for r, and adding p' and p'', we find,

Equations for the pressure depending on the motion of the sea.

$$p=I-gr''+\frac{3Sb^2}{2D^3}\{(\sin\sigma.\cos\theta+\cos\sigma.\sin\theta.\cos\overline{nt+\varpi-s})^2-\tfrac{1}{3}\}+p'''$$

where
$$\frac{dp'''}{dr}=2nr.\sin^2\theta.\frac{dv}{dt}$$

$$\frac{dp'''}{d\theta}=-r^2\frac{d^2u}{dt^2}+2nr^2\sin\theta.\cos\theta.\frac{dv}{dt}$$

$$\frac{dp'''}{d\varpi}=-2nr^2\sin\theta.\cos\theta\frac{du}{dt}-r^2\sin^2\theta.\frac{d^2v}{dt^2}.$$

At the surface of the water, $p=0$. But at the surface $r''=w$; and, by the equation of continuity (72.) $w=-\frac{d}{d\theta}(u\gamma)-u\gamma.\text{cotan}\,\theta-\gamma\frac{dv}{d\varpi}$. Hence the tidal equation for the surface of the water becomes

$$0=I+\frac{3Sb^2}{2D^3}\{(\sin\sigma.\cos\theta+\cos\sigma.\sin\theta.\cos\overline{nt+\varpi-s})^2-\tfrac{1}{3}\}-gw+p''';$$

where w and p''' are subject to the equations expressed above.

(85.) If we expand the middle term of the tidal equation, that equation becomes

$$0=I+\frac{Sb^2}{2D^3}(\tfrac{3}{2}\cos^2\sigma-1)\,(1-3\cos^2\theta)+\frac{3Sb^2}{4D^3}\sin 2\sigma.\sin 2\theta.\cos\overline{nt+\varpi-s}$$
$$+\frac{3Sb^2}{4D^3}\cos^2\sigma.\sin^2\theta.\cos\overline{2nt+2\varpi-2s}-gw+p'''.$$

For most purposes, we may consider the variation of the terms depending on S to be produced only by the variation of $\overline{nt+\varpi-s}$, and we may consider $\frac{d}{dt}(nt+\varpi-s)$ or $n-\frac{ds}{dt}$ as a constant $=n'$, or we may represent $nt+\varpi-s$ by $n't+\varpi$ (by changing, if necessary, the origin of the time). Some of the terms therefore of the equation, depending on the disturbing force, are constant: some multiply $\cos\overline{n't+\varpi}$; and some multiply $\cos\overline{2n't+2\varpi}$. In strictness we ought to consider that σ and D are both variable; but they may be expressed in series of sines and cosines of multiples of the time; and when combined with $\cos\overline{n't+\varpi}$ and $\cos\overline{2n't+2\varpi}$ they will produce cosines of other arcs in which the coefficient of t is different, but that of ϖ is the same. The most general form therefore for one of the terms will be

General term of the pressure produced by the disturbing forces.

$$\Theta.\cos\overline{it+k\varpi},$$

where, for the first of the important terms, $\Theta=\text{A}.\sin 2\theta$, $k=1$, and $i=n'$, or differs little from n; for the second $\Theta=\text{B}.\sin^2\theta$, $k=2$, and $i=2n'$; and where, in the terms in general, k has no values but 0, 1, 2, but i may have any value between wide limits, and Θ may have any multiples of $\sin 2\theta$ and $\sin^2\theta$ added together.

(86.) The equation between w, u, and v; those between p''', u, and v; and that between w, p''', and the terms arising from the disturbing force; being all linear, we may take the terms arising from the disturbing force separately, and, finding the solution for each term, we may add all together. It will be sufficient, therefore, to proceed with the solution of the equation

$$0=\Theta\cos\overline{it+k\varpi}-gw+p'''.$$

Limited equations for the pressure, as depending on all causes.

(87.) Now we may remark, that the equation for $\frac{dp'''}{dr}$ may be neglected, not because its terms are small, but because the variation of r to which they apply is insignificant. The reasoning of (68.) applies entirely to this; but the reader may see the same thing in the solution of the equations for p''. For, after having obtained the value of p'' by means of three equations $\left(\text{for } \frac{dp''}{dr}, \frac{dp''}{d\theta}, \text{and } \frac{dp''}{d\varpi}\right)$, we have put b for r, thereby implying that the variations of r are insensible; and we have thus obtained exactly the same expression as if we had put b for r in the equations for $\frac{dp''}{d\theta}$ and $\frac{dp'}{d\varpi}$ and had neglected the equation for $\frac{dp''}{dr}$; although the terms of $\frac{dp''}{dr}$ are comparable to those of $\frac{dp''}{d\theta}$ and $\frac{dp''}{d\varpi}$. In like manner we shall here put b for r and neglect $\frac{dp'''}{dr}$. Thus we have

$$\frac{dp'''}{d\theta}=-\text{b}^2\frac{d^2u}{dt^2}+2n\text{b}^2.\sin\theta.\cos\theta.\frac{dv}{dt}$$

$$\frac{dp'''}{d\varpi}=-2n\text{b}^2.\sin\theta.\cos\theta\frac{du}{dt}-\text{b}^2\sin^2\theta\frac{d^2v}{dt^2}$$

$$w=-\frac{d}{d\theta}(u\gamma)-u\gamma.\text{cotan}\,\theta-\gamma\frac{dv}{d\varpi}$$

$$0=\Theta\cos\overline{it+k\varpi}-gw+p'''$$

Popular explanation of the terms introduced by considering the earth's rotation.

(88.) The terms multiplying n, it is to be remarked, are produced entirely by introducing the consideration of the earth's rotation. Of the origin of these terms the following popular explanation (which, however, is sufficiently accurate to be used as a basis of calculation) may be given. Suppose a particle of water to be running towards the equator (that is, suppose that u is increasing). By this motion, it is proceeding from a small parallel towards a large one, or from a place in which the movement from west to east (produced by the earth's rotation) is small, to one in which the movement from west to east is large. It is, therefore, advancing to a part of the earth whose movement towards the east is more rapid than its own, and therefore it tends to lag behind the movement of that part of the earth. Consequently there will be, in the expression for $\frac{d^2v}{dt^2}$, (which is the acceleration towards the east,) a term depending on u, which denotes that there is a retarding force when u is increasing: that is, $\frac{d^2v}{dt^2}$ will be expressed by terms of which one is a negative multiple of $\frac{du}{dt}$. Again, suppose a particle of water to be running towards the east (that is, suppose that v is increasing). The angular velocity of this particle is greater than the earth's angular velocity: therefore the centrifugal force is greater than the centrifugal force would have been if it had had no such motion towards the east; there is therefore, from this cause, an addition of centrifugal force; and this addition (like the original centrifugal force) is in the direction of the radius of the parallel, and is perpendicular to the earth's axis; resolving this into a vertical and a horizontal force, the horizontal force is directed towards the equator, or tends to increase u: that is, $\frac{d^2u}{dt^2}$ will be expressed by terms of which one is a positive multiple of $\frac{dv}{dt}$.

(89.) A general solution of the equations of (87.) is scarcely to be hoped for; it is a matter of difficulty to find, in a very limited case, a particular integral which will satisfy them. We shall begin, in the manner of Laplace, by trying whether they cannot be satisfied by expressions of the following form:

Assumption of the form of solution as regards the longitude.

$$w=a.\cos\overline{it+k\varpi}$$
$$u=b.\cos\overline{it+k\varpi}$$
$$v=c.\sin\overline{it+k\varpi}$$
$$p'''=a'''.\cos\overline{it+k\varpi}$$

where a, b, c, a'', are functions of θ only.

(90.) Substituting these expressions, the equations become

$$\cos\overline{it+k\varpi}\cdot\frac{da'''}{d\theta}=\ +\mathrm{b}^2 b.i^2\cos\overline{it+k\varpi}\ \ +2n\,\mathrm{b}^2.\sin\theta.\cos\theta.c.i.\cos\overline{it+k\varpi}$$
$$-k.a'''.\sin\overline{it+k\varpi}=\ +2n\,\mathrm{b}^2\sin\theta.\cos\theta.b.i.\sin\overline{it+k\varpi}\ \ +\mathrm{b}^2.\sin^2\theta.c.i^2.\sin\overline{it+k\varpi}$$
$$a.\cos\overline{it+k\varpi}=\ -\frac{d\,(b\gamma)}{d\theta}\cos\overline{it+k\varpi}\ \ -b\gamma.\mathrm{cotan}\,\theta.\cos\overline{it+k\varpi}\ \ -\gamma ck.\cos\overline{it+k\varpi}$$
$$0\qquad=\Theta.\cos\overline{it+k\varpi}\ \ -ga.\cos\overline{it+k\varpi}\ \ +a'''.\cos\overline{it+k\varpi}$$

or

$$\frac{da'''}{d\theta}=\mathrm{b}^2 i^2.b+2n\,\mathrm{b}^2 i.\sin\theta.\cos\theta.c$$
$$-ka'''=2n\,\mathrm{b}^2 i.\sin\theta.\cos\theta.b+\mathrm{b}^2 i^2.\sin^2\theta.c$$
$$a=-\frac{d\,(b\gamma)}{d\theta}-b\gamma\,\mathrm{cotan}\,\theta-\gamma ck$$
$$0=\Theta-g\,a+a'''.$$

The assumption is sufficient.

It is clear that our assumptions have satisfied the equations as far as regards ϖ; for every term containing ϖ has vanished upon making the substitution. Moreover we have four differential equations by which to determine four unknown quantities, and these (whatever practical difficulties we may find) are, theoretically, sufficient for their determination. It is therefore certain that a solution may be found, in the form which is expressed by the four assumptions for w, u, v, and p'''.

Inferences from the form assumed.

(91.) Before proceeding further with the solution, we may draw a few inferences from the form of the expressions that we have already found. First, since the velocity of the water in the direction of the meridian is $\mathrm{b}\frac{du}{dt}$ or $-\mathrm{b}bi\sin\overline{it+k\varpi}$, and the velocity perpendicular to the meridian is $\mathrm{b}\sin\theta.\frac{dv}{dt}$, or $\mathrm{b}c.\sin\theta.i.\cos\overline{it+k\varpi}$, the water at any given place, except in certain limited cases, is never at rest, but the direction in which it runs changes perpetually. The expression for its whole velocity at any instant is $\mathrm{b}\sqrt{\left(\left(\frac{du}{dt}\right)^2+\sin^2\theta\left(\frac{dv}{dt}\right)^2\right)}$, or $\mathrm{b}\sqrt{(b^2 i^2.\sin^2\overline{it+k\varpi}+c^2\sin^2\theta.i^2.\cos^2\overline{it+k\varpi})}$ and the tangent of the angle which its course makes with the meridian at that instant is $\dfrac{\sin\theta\frac{dv}{dt}}{\frac{du}{dt}}$, or $\dfrac{-c\sin\theta}{b}\,\mathrm{cotan}\,\overline{it+k\varpi}$. This is the same kind of rotation to which we have alluded in (9.): but we shall see hereafter that the latter arises from a different cause.

The direction of the tide-current revolves.

High or low water in solar or lunar tide will occur at the transit of the sun or moon.

(92.) Secondly, since the term $\Theta.\cos\overline{it+k\varpi}$ produces a term w of the form $a.\cos\overline{it+k\varpi}$ (where a may be positive or negative), and since, for the principal tidal terms in p'', $\cos\overline{it+k\varpi}$ will have the form $\cos\overline{nt+\varpi-s}$, or $\cos\overline{2nt+2\varpi-2s}$, which terms have their maximum or minimum values when $s=nt+\varpi$, or when the sun's distance from the fixed meridian = the distance of the place from the fixed meridian, or when the sun is on the meridian of the place: it follows that either the high or the low water of the solar tide must occur, in conformity with this theory, exactly when the sun is on the meridian. A similar law applies to the time of the lunar tide.

Time of high water altered by the variation of the forces.

(93.) Thirdly, if a factor of Θ (which depends on the sun's linear distance and declination) is expressed by $1+f\cos i't$, where i' is small (or where the term $f\cos i't$ varies slowly), then $\Theta\cos\overline{it+k\varpi}$ will become

$$\Theta\cos\overline{it+k\varpi}+\frac{\Theta f}{2}\cos\overline{(i+i')\,t+k\varpi}+\frac{\Theta f}{2}\cos\overline{(i-i')\,t+k\varpi}:$$

and since a in the expression for w depends on i, we must use $a+\frac{da}{di}i'$ in the second term, and $a-\frac{da}{di}i'$ in the third term; and the expression for w will be

$$a \cos \overline{it+k\varpi}+\frac{f}{2}\left(a+\frac{da}{di}i'\right) \cos \overline{(i+i')\,t+k\varpi}+\frac{f}{2}\left(a-\frac{da}{di}i'\right) \cos \overline{(i-i')\,t+k\varpi}$$

or

$$a\,(1+f \cos i'\,t) \cos \overline{it+k\varpi}-i'\frac{da}{dt}.\,f \sin i'\,t.\,\sin \overline{it+k\varpi}.$$

The time of high water on any given day will not now be the same as before; for, before, it occurred when $it+k\varpi=0$ or 180°, but now it occurs when

$$\tan \overline{it+k\varpi}=\frac{i'.\frac{da}{dt}.\,f.\,\sin i'\,t}{a\,(1+f\cos i'\,t)} \text{ nearly.}$$

Day of highest tide corresponds to the day of greatest force.

But the highest tide of all (the height being expressed by the square root of the sum of the squares of the coefficients of $\cos \overline{it+k\varpi}$ and $\sin \overline{it+k\varpi}$, as in (46.),) occurs when $\sqrt{\left\{a^2\,(1+f\cos i't)^2+i'^2.\left(\frac{da}{dt}\right)^2.f^2.\sin^2 i't\right\}}$ is maximum; and this is when $\cos i't=1$, or when the force which causes the tide is greatest. As far, therefore, as this theory applies, the highest solar tide ought to occur on the very day on which the solar force is greatest; and similarly the highest lunar tide ought to occur on the very day on which the lunar force is greatest.

Assumption of expression for the depth of the sea.

Laplace's method of solving the equations as depending on the latitude.

(94.) Returning now to our equations of (90.). The only way in which Laplace has attempted to solve them is the following. He has assumed, as the only law of depth on which a solution appears to be practicable, $\gamma=l-lq\cos^2\theta$. He has then shown that, taking separately the terms independent of $nt+\varpi-s$, those depending on $\cos \overline{nt+\varpi-s}$, and those depending on $\cos \overline{2nt+2\varpi-2s}$, it is possible to determine for each the value of q for which the equations can be solved, (the solution, in Laplace's manner, not being practicable for all values of q). He has shown that, to a certain degree of approximation, the same value of q will apply to the terms of different kinds. And in the simplest case (when $q=0$, or the depth is the same in all parts) he has shown that the terms in the height of the water depending on $\cos \overline{nt+\varpi-s}$ will be insensible, or the diurnal tide will be insensible. We now proceed (although by a method different in its principal parts from Laplace's) to obtain equivalent results.

(95.) From the first and second of the equations in (90.) we find

$$b=\frac{-i.\,\sin\theta.\frac{da'''}{d\theta}-2kn\cos\theta.\,a'''}{\mathrm{b}^2\,i.\,\sin\theta.(4n^2\cos^2\theta-i^2)},\qquad c=\frac{2n.\,\sin\theta.\,\cos\theta.\frac{da'''}{d\theta}+i\,k.a'''}{\mathrm{b}^2\,i.\,\sin^2\theta.\,(4n^2.\cos^2\theta-i^2)}.$$

Substituting these values in the third, which may be put in the form

$$a.\,\sin\theta=-\frac{d}{d\theta}\,(\gamma.b.\,\sin\theta)-\gamma.k.c.\,\sin\theta$$

we obtain

$$a.\,\sin\theta=\frac{d}{d\theta}\left\{\gamma.\frac{i.\,\sin\theta.\frac{da'''}{d\theta}+2kn.\,\cos\theta.\,a'''}{\mathrm{b}^2\,i.\,(4n^2.\,\cos^2\theta-i^2)}\right\}-\gamma.\frac{2kn.\,\sin\theta.\,\cos\theta.\frac{da'''}{d\theta}+ik^2.\,a'''}{\mathrm{b}^2\,i.\,\sin\theta.\,(4n^2.\,\cos^2\theta-i^2)}.$$

The equations reduced to one differential equation.

But from the fourth equation,

$$\Theta.\,\sin\theta=g.a.\,\sin\theta-a'''.\,\sin\theta.$$

Substituting in this last the value of $a.\,\sin\theta$ just found, we finally obtain

$$\Theta\ \mathrm{n}\,\theta=\frac{g}{\mathrm{b}^2\,i}.\frac{d}{d\theta}\left\{\gamma.\frac{i.\,\sin\theta.\frac{da''}{d\theta}+2kn.\,\cos\theta.\,a'''}{4n^2.\,\cos^2\theta-i^2}\right\}-\frac{g}{\mathrm{b}^2 i}.\gamma.\frac{2kn.\,\sin\theta.\,\cos\theta.\frac{da'''}{d\theta}+ik^2.\,a'''}{\sin\theta.\,(4n^2\cos^2\theta-i^2)}-a'''\sin\theta$$

a linear differential equation of the second order, in which the only unknown quantity is a'''.

(96.) If we perform the differentiation and multiply by $\sin\theta.\,(4n^2.\cos^2\theta-i^2)^2$, the equation becomes

$$\begin{aligned}\Theta.\,\sin^2\theta.\,(4n^2.\,\cos^2\theta-i^2)^2=&\ \frac{g}{\mathrm{b}^2 i}.\frac{d\gamma}{d\theta}.\,(4n^2\cos^2\theta-i^2)\,.\,(i.\,\sin^2\theta.\,\frac{da'''}{d\theta}+2kn.\,\sin\theta.\,\cos\theta.\,a''')\\ &+\frac{g}{\mathrm{b}^2 i}.\gamma.\left\{\begin{aligned}&i.\,\sin^2\theta.\,(4n^2.\,\cos^2\theta-i^2).\frac{d^2a'''}{d\theta^2}+i.\,\sin\theta.\,\cos.\,\theta\,(8n^2\sin^2\theta+4n^2\cos^2\theta-i^2)\,\frac{da'''}{d\theta}\\ &+\,(i^2k^2+2i^2kn.\,\sin^2\theta-4i\,k^2n^2.\,\cos^2\theta+8kn^3.\,\sin^2\theta.\,\cos^2\theta)\,.a'''\end{aligned}\right\}\\ &-\sin^2\theta.\,(4n^2.\,\cos^2\theta-i^2)^2.\,a'''\end{aligned}$$

If, with Laplace, we suppose $\gamma = l . (1 - q . \cos^2 \theta)$, $\frac{d\gamma}{d\theta} = 2lq . \sin\theta . \cos\theta$; and the equation takes the following form; in which we may remark that the factors of Θ, a''', and $\frac{d^2 a'''}{d\theta^2}$, contain only even powers of $\cos\theta$; and that the factor of $\frac{da'''}{d\theta}$ contains only odd powers of $\cos\theta$, multiplied by $\sin\theta$.

Expansion of differential equation with assumed expression for the depth.

$$\Theta \times \{ i^4 + (-8i^2 n^2 - i^4) \cos^2\theta + (16n^4 + 8i^2 n^2) \cos^4\theta - 16n^4 \cos^6\theta \} =$$

$$\frac{d^2 a'''}{d\theta^2} \times \frac{g}{\text{b}^2} \times \left\{ -i^2 l + (4ln^2 + i^2 l + i^2 lq) \cos^2\theta + (-4ln^2 - 4ln^2 q - i^2 lq) \cos^4\theta + 4ln^2 q \cos^6\theta \right\}$$

$$+ \frac{da'''}{d\theta} \times \frac{g}{\text{b}^2} \times \cos\theta . \sin\theta \times \left\{ (8ln^2 - 2i^2 lq - i^2 l) + (3i^2 lq - 4ln^2) \cos^2\theta - 4ln^2 q \cos^4\theta \right\}$$

$$+ a''' \times \frac{g}{\text{b}^2} \times \left\{ (i^2 k^2 l + 2ikln) + \left(\frac{8kln^3}{i} - 2ikln - 4k^2 ln^2 - 6iklnq - i^2 k^2 lq \right) \cos^2\theta \right.$$

$$\left. + \left(-\frac{8kln^3}{i} + \frac{8kln^3 q}{i} + 4k^2 ln^2 q . + 6iklnq \right) \cos^4\theta - \frac{8kln^3 q}{i} \cos^6\theta \right\}$$

$$+ a''' \times \{ -i^4 + (8i^2 n^2 + i^4) \cos^2\theta + (-16n^4 - 8i^2 n^2) \cos^4\theta + 16 n^4 \cos^6\theta \}.$$

It is evident that this equation can always be solved by assuming for a''' a form similar to that for Θ multiplied by a series of powers of $\cos^2\theta$ with indeterminate coefficients. The same would have held if we had assumed for γ an expression consisting of a greater number of terms with even powers of $\cos\theta$.

We shall now proceed with some steps of the solution of this equation.

(97.) Omitting the first or constant term in the equation of (85.), which, in fact, is only an arbitrary constant, to be so determined with reference to the term gw that the whole mass of the fluid will not be altered, the next term is $\frac{\text{S}\,\text{b}^2}{2\text{D}^3} \left(\frac{3}{2} \cos^2\sigma - 1 \right) (1 - 3\cos^2\theta)$. This term does not contain ϖ at all, and therefore we must make $k = 0$. But as D is slowly variable, and as σ also is variable, the factor $\frac{\text{S}\,\text{b}^2}{2\text{D}^3} \left(\frac{3}{2} \cos^2\sigma - 1 \right)$ would, if expanded, consist of a series of terms like A cos it, where i is small. Comparing A cos it $(1 - 3\cos^2\theta)$ with $\Theta \cos \overline{it + k\varpi}$ we have $\Theta = \text{A}\ (1 - 3\cos^2\theta)$, $k = 0$, i a small number. Substituting for Θ and k, and retaining only the lowest power of i in each term, the equation becomes

Equation corresponding to slow changes of the disturbing force.

$$\text{A} \times (16n^4 \cos^4\theta - 64n^4 \cos^6\theta + 48n^4 \cos^8\theta) =$$

$$\frac{d^2 a'''}{d\theta^2} \times \frac{g}{\text{b}^2} \times \left\{ 4ln^2 \cos^2\theta + (-4ln^2 - 4ln^2 q) \cos^4\theta + 4ln^2 q \cos^6\theta \right\}$$

$$+ \frac{da'''}{d\theta} \times \frac{g}{\text{b}^2} \times \cos\theta . \sin\theta \times (8ln^2 - 4ln^2 \cos^2\theta - 4ln^2 q \cos^4\theta)$$

$$+ a''' \times (-16n^4 \cos^4\theta + 16n^4 \cos^6\theta).$$

Suppose

$$a''' = \text{B}_2 \cos^2\theta + \text{B}_4 \cos^4\theta + \text{B}_6 \cos^6\theta + \&\text{c}.$$

Solution in powers of the cosine of the latitude.

Forming the expressions for $\frac{da'''}{d\theta}$ and $\frac{d^2 a'''}{d\theta^2}$, and expanding all the even powers of $\sin\theta$ in terms of $\cos\theta$, and after substituting in the equation, making the coefficient of each power of $\cos\theta = 0$, we find

$$a''' = \text{A} \times \left\{ \frac{\text{b}^2 n^2}{gl} \cos^4\theta + \frac{2q}{3} . \frac{\text{b}^2 n^2}{gl} \cos^6\theta + \frac{\text{b}^2 n^2}{gl} \left(\frac{\text{b}^2 n^2}{10gl} + \frac{q^2}{2} \right) \cos^8\theta \right.$$

$$\left. + \left(\frac{\text{b}^2 n^2}{gl} \times \left(\frac{2}{25} + \frac{62}{15.35} q \right) + \frac{14}{35} q^2 \right) \frac{\text{b}^2 n^2}{gl} \cos^{10}\theta + \&\text{c}. \right\}.$$

And

$$a = \frac{\Theta}{g} + \frac{a'''}{g}$$

$$= \frac{\text{A}}{g} (1 - 3\cos^2\theta) + \frac{\text{A}}{g} \text{ multiplied by the series just found.}$$

This is the coefficient of cos it in the expression for w, the tidal elevation of the water (89.).

(98.) If we remark that the centrifugal force at the equator is expressed by $\text{b}n^2$, it is evident that $\frac{\text{b}n^2}{g}$ is the proportion of that centrifugal force to gravity, or is the quantity which in the Treatise on the

FIGURE OF THE EARTH we have called m. The fraction $\frac{b^2 n^2}{gl}$ is therefore $=\frac{m}{\frac{l}{b}}$, and is not small, therefore, except m or $\frac{1}{289}$ be smaller than the proportion of the depth of the sea to the earth's radius, which is expressed by $\frac{l}{b}$. The form of solution adopted above will not, therefore, strictly apply if the depth is very small, as the coefficients of the series will not converge. In that case, it will be advantageous to put the solution in this form:

$$a'''=C_0+C_1.l+C_2 l^2+C_3 l^3+\&c.,$$

where C_0, C_1, C_2, C_3, &c. are functions of θ: and to substitute in the equation, and make the coefficient of each power of $l=0$. Thus we shall have

Solution in powers of the depth of the sea.

$$+A(1-3\cos^2\theta)=-C_0$$

$$0=\frac{d^2 C_0}{d\theta^2}\times\frac{g}{b^2}\times\{4n^2\cos^2\theta+(-4n^2-4n^2q)\cos^4\theta+4n^2q\cos^6\theta\}$$

$$+\frac{dC_0}{d\theta}\times\frac{g}{b^2}\times\cos\theta.\sin\theta\times(8n^2-4n^2\cos^2\theta-4n^2q\cos^4\theta)$$

$$+C_1\times(-16n^4\cos^4\theta+16n^4\cos^6\theta);$$

from which

$$C_1 l=\frac{-Agl}{b^2 n^2}.\frac{3}{2}.\frac{1+\cos^2\theta+q\cos^2\theta-3q\cos^4\theta}{\cos^2\theta},$$

and so on, the determination of each successive term being effected in the same manner. Hence a''' is expressed by the series

$$-A(1-3\cos^2\theta)-A.\frac{gl}{b^2n^2}.\frac{3}{2}.\frac{1+\cos^2\theta+q\cos^2\theta-3q\cos^4\theta}{\cos^2\theta}+\&c.$$

and

$$a=\frac{\Theta}{g}+\frac{a'''}{g}=\frac{A(1-3\cos^2\theta)}{g}+\frac{a'''}{g}=$$

$$-\frac{A}{g}.\frac{l}{bm}.\frac{3}{2}.\frac{1+\cos^2\theta+q\cos^2\theta-3q\cos^4\theta}{\cos^2\theta}+\&c.$$

The series converges by powers of $\frac{l}{bm}$, and diverges by powers of $\cos^2\theta$. Algebraically speaking, therefore, it fails near the equator: but it is probable that it would apply so near to it that, in regard to physical interpretation, the failure would be unimportant.

(99.) The fluctuation of which we have treated includes all those which Laplace denominates "*les oscillations de la première espèce.*"

(100.) The second term depending on the disturbing force, in the equation of (85.), is $+\frac{3Sb^2}{4D^3}\sin 2\sigma.\sin 2\theta.\cos\overline{nt+\varpi-s}$, or $\frac{3Sb^2}{2D^3}\sin 2\sigma.\sin\theta.\cos\theta.\cos\overline{nt+\varpi-s}$, which we will call $E.\sin\theta.\cos\theta.\cos\overline{nt+\varpi-s}$. Comparing this with the general term assumed in (85.), we have

$$\Theta=E.\sin\theta.\cos\theta$$

$$k=1$$

$$i=n-\frac{ds}{dt}.$$

In the investigation on which we are about to enter, we shall consider E as constant, (its variation depending only on the changes of distance and declination of the luminary, which are slow,) and $\frac{ds}{dt}$ as insignificant. The last assumption gives us

$$i=n.$$

Substituting these values of k and i, in the equation of (96.), and dividing by n^4, it becomes $\left(\text{since}.\frac{gl}{b^2n^2}=\frac{l}{bm}\right)$

$$\Theta\times(1-\cos^2\theta)\times(1-4\cos^2\theta)^2=$$

Tides and Waves.

Equation corresponding to diurnal Tide.

$$\frac{d^2a'''}{d\theta^2}\times\frac{l}{\mathrm{b}m}\times\{-1+(5+q)\cos^2\theta+(-4-5q)\cos^4\theta+4q\cos^6\theta\}$$

$$+\frac{da'''}{d\theta}\times\frac{l}{\mathrm{b}m}\times\cos\theta.\sin\theta\times\{(7-2q)+(-4+3q)\cos^2\theta-4q\cos^4\theta\}$$

$$+a'''\times\frac{l}{\mathrm{b}m}\times\{3+(2-7q)\cos^2\theta+(-8+18q)\cos^4\theta-8q\cos^6\theta\}$$

$$-a'''\times(1-\cos^2\theta)\times(1-4\cos^2\theta)^2.$$

We shall solve this by the same process as that used in (98.)

(101.) Suppose then

$$a'''=\mathrm{F}_0+\mathrm{F}_1\frac{l}{\mathrm{b}m}+\mathrm{F}_2\frac{l^2}{\mathrm{b}^2m^2}+\&\text{c.};$$

$\mathrm{F}_0, \mathrm{F}_1, \mathrm{F}_2$, &c. being functions of θ. Substituting this in the equation, and making the coefficient of each power of $l=0$, the first comparison (or the comparison of terms independent of l) evidently gives

$$\Theta\times(1-\cos^2\theta)\times(1-4\cos^2\theta)^2=-\mathrm{F}_0\times(1-\cos^2\theta)\times(1-4\cos^2\theta)^2,$$

or

$$\mathrm{F}_0=-\Theta=-\mathrm{E}.\sin\theta.\cos\theta.$$

From this we have $\dfrac{d\mathrm{F}_0}{d\theta}=\mathrm{E}.(1-2\cos^2\theta)$, $\dfrac{d^2\mathrm{F}_0}{d\theta^2}=+4\mathrm{E}.\sin\theta.\cos\theta.$

The second comparison (or that of terms containing the first power of l) gives

$$0=\frac{d^2\mathrm{F}_0}{d\theta^2}\times\frac{l}{\mathrm{b}m}\times\{-1+(5+q)\cos^2\theta+(-4-5q)\cos^4\theta+4q\cos^6\theta\}$$

$$+\frac{d\mathrm{F}_0}{d\theta}\times\frac{l}{\mathrm{b}m}\times\cos\theta.\sin\theta\times\{(7-2q)+(-4+3q)\cos^2\theta-4q\cos^4\theta\}$$

$$+\ \mathrm{F}_0\ \times\frac{l}{\mathrm{b}m}\times\{3+(2-7q)\cos^2\theta+(-8+18q)\cos^4\theta-8q\cos^6\theta\}$$

$$-\ \mathrm{F}_1\ \times\frac{l}{\mathrm{b}m}\times(1-\cos^2\theta)\times(1-4\cos^2\theta)^2.$$

Substituting, in the three first lines, the expressions found for F_0, $\dfrac{d\mathrm{F}_0}{d\theta}$, and $\dfrac{d^2\mathrm{F}_0}{d\theta^2}$, the equation becomes

$$0=\mathrm{E}\times\frac{l}{\mathrm{b}m}\times\sin\theta.\cos\theta\times\{-2q+18q\cos^2\theta-48q\cos^4\theta+32q\cos^6\theta\}-\mathrm{F}_1\times\frac{l}{\mathrm{b}m}\times(1-\cos^2\theta)\times(1-4\cos^2\theta)^2,$$

or

$$0=-\mathrm{E}.\sin\theta.\cos\theta\times2q.(1-\cos^2\theta).(1-4\cos^2\theta)^2-\mathrm{F}_1\times(1-\cos^2\theta).(1-4\cos^2\theta)^2;$$

from which

$$\mathrm{F}_1=-2q.\mathrm{E}.\sin\theta.\cos\theta=+2q\,\mathrm{F}_0.$$

The form of the equation between F_1 and F_2, that between F_2 and F_3, that between F_3 and F_4, &c. will be exactly the same as the form of that between F_0 and F_1: and since the form of F_1 (considered as a function of θ) is exactly the same as that of F_0, the nature of the substitution in the equation will be the same, and therefore the relation of all the successive coefficients F_1, F_2, &c. will be the same. Thus we shall have

$$\mathrm{F}_2=2q\mathrm{F}_1=-4q^2.\mathrm{E}.\sin\theta.\cos\theta$$

$$\mathrm{F}_3=2q\mathrm{F}_2=-8q^3.\mathrm{E}.\sin\theta.\cos\theta,$$

and so on. The expression for a''', therefore, is

$$-\mathrm{E}\sin\theta.\ \cos\theta-\mathrm{E}\ \sin\theta.\cos\theta\left(\frac{2ql}{\mathrm{b}m}+\frac{4q^2l^2}{\mathrm{b}^2m^2}+\frac{8q^3l^3}{\mathrm{b}^3m^3}+\&\text{c.}\right)$$

$$=-\mathrm{E}\sin\theta\cos\theta-\frac{2q\dfrac{l}{\mathrm{b}m}\mathrm{E}\sin\theta.\cos\theta}{1-\dfrac{2ql}{\mathrm{b}m}};$$

and, therefore,

$$a=\frac{\Theta}{g}+\frac{a'''}{g}=-\frac{2q\dfrac{l}{\mathrm{b}m}}{1-\dfrac{2ql}{\mathrm{b}m}}.\frac{\mathrm{E}}{g}.\sin\theta\cos\theta,$$

Finite solution corresponding to diurnal tide.

an expression in a finite form. The expression for the elevation of the water is, therefore,

$$-\frac{2q\,\frac{l}{\mathrm{b}m}}{1-\frac{2ql}{\mathrm{b}m}}\cdot\frac{\mathrm{E}}{g}.\sin\theta.\cos\theta.\cos\overline{nt+\varpi-s}.$$

When the depth is uniform, there is no diurnal tide in height.

(102.) In article (96.) we assumed the depth of the water to be represented by $l(1-q\cos^2\theta)$. If, then, the depth of the water be uniform over the whole globe, $q=0$. In that case the expression just found for the elevation of the water vanishes for every value of θ and ϖ, or for every point on the earth's surface. Thus we obtain the most remarkable and most unexpected result, that if the depth of the sea is uniform, the diurnal tide (or that depending on $\overline{nt+\varpi-s}$) is insensible. For, the expression for its elevation absolutely vanishes when the depth of the water is everywhere the same.

But there is diurnal tide in motion.

(103.) This evanescence of the tide applies, however, only to the *elevation* of the water. The *horizontal motion* is not destroyed. For, the displacement of the water in the direction of the meridian is u, and therefore its velocity in the direction of the meridian is $\frac{du}{dt}=-ib\sin\overline{it+k\varpi}$, (89.), $=-nb.\sin\overline{nt+\varpi-s}$: its displacement in longitude is v, and therefore its velocity in the direction of the parallel is $\sin\theta.\frac{dv}{dt}=ic.\sin\theta.\cos\overline{it+k\varpi}$ $=n.c.\sin\theta.\cos\overline{nt+\varpi-s}$. Now, taking the expressions for b and c in (95.), and assuming $a'''=-\mathrm{E}.\sin\theta.\cos\theta$, (to which it is reduced when $q=0$,) and $\frac{da'''}{d\theta}=\mathrm{E}(1-2\cos^2\theta)$, we obtain $b=\frac{\mathrm{E}}{\mathrm{b}^2n^2}$, $c=-\frac{\mathrm{E}\cos\theta}{\mathrm{b}^2n^2\sin\theta}$: from which the velocity in the direction of the meridian $=\frac{-\mathrm{E}}{\mathrm{b}n}\sin\overline{nt+\varpi-s}$, and that in the direction of the parallel $=\frac{-\mathrm{E}}{\mathrm{b}n}\cos\theta.\cos\overline{nt+\varpi-s}$: and the whole velocity of the water, which is the square root of the sum of the squares of these quantities, $=\frac{\mathrm{E}}{\mathrm{b}^2n}\sqrt{1-\sin^2\theta.\cos^2\overline{nt+\varpi-s}}$, and the tangent of the angle which its course makes with the parallel $=\frac{1}{\cos\theta}\tan\overline{nt+\varpi-s}$. Thus we obtain the result, that at the equator the water moves only north and south, resting for an instant at the change of motion: on every other part of the earth the water is always moving with some velocity, but the current is perpetually changing its direction: at the pole, the velocity is constant, and the direction is always transverse to the meridian which passes through the luminary. The same remarks hold when the depth of the water is not uniform: as the expressions for a''', b, and c differ from those which apply when the depth is uniform, only by having the factor $\frac{\mathrm{E}}{1-\frac{2ql}{\mathrm{b}m}}$ instead of E.

Rules for the time of high and low water in the diurnal tide.

(104.) If the place of observation is north of the equator, $\sin\theta.\cos\theta$ is positive: and if the declination of the luminary is north, $\frac{3\mathrm{Sb}^2}{2\mathrm{D}^3}\sin 2\sigma$ or E is positive: and if the luminary is on the meridian of the place, $\cos\overline{nt+\varpi-s}$ is positive, and has its greatest value. Hence, when the depth is variable, the sign of the elevation at the transit of the luminary, if on the same side of the equator as the place of observation, will be the same as that of $-q$. If the water be shallower at the poles than at the equator, q in the expression $l(1-q\cos^2\theta)$ must be positive, and therefore low water occurs at the transit of the luminary. If the water be deeper at the poles, q is negative, and the high water occurs at transit.

(105.) The numerical values of all these quantities will be computed by the process of (31.) and (35.) The mean value of $\frac{\mathrm{Sb}^2}{2\mathrm{D}^3g}$ for the Sun is 0·2710 foot: for the Moon, 0·5959 foot. If $l=\frac{7}{5}$ of a mile, $\frac{l}{\mathrm{b}m}=\frac{1}{10}$.

(106.) The fluctuations of which we have now treated are called by Laplace "*les oscillations de la seconde espèce.*"

(107.) The third term depending on the disturbing force, in the equation of (85.), is $\frac{3\mathrm{Sb}^2}{4\mathrm{D}^3}\cos^2\sigma.\sin^2\theta.\cos\overline{2nt+2\varpi-2s}$, which we shall call $\mathrm{G}.\sin^2\theta.\cos\overline{2nt+2\varpi-2s}$. Comparing this with the general term assumed in (85.), we have

$$\Theta = \mathrm{G}\sin^2\theta$$
$$k = 2$$
$$i = 2n-2\frac{ds}{dt}=2n \text{ nearly}.$$

Tides and Waves.

Equation corresponding to semi-diurnal tide.

Substituting these values in the equation of (96.), and dividing by n^4, it becomes

$$16.\mathrm{G}.\ \sin^8\theta=\frac{d^2a'''}{d\theta^2}\times\frac{l}{\mathrm{b}m}\times\{-4+(8+4q)\cos^2\theta+(-4-8q)\cos^4\theta+4q\cos^6\theta\}$$

$$+\frac{da'''}{d\theta}\times\frac{l}{\mathrm{b}m}\times\cos\theta.\sin\theta\times\{(4-8q)+(-4+12q)\cos^2\theta-4q\cos^4\theta\}$$

$$+a'''\times\frac{l}{\mathrm{b}m}\times\{24+(-16-40q)\cos^2\theta+(-8+48q)\cos^4\theta-8q\cos^6\theta\}$$

$$-16.a'''.\sin^6\theta.$$

Dividing by 4 $\sin^4\theta$, this becomes

$$4.\mathrm{G}.\sin^4\theta=\frac{d^2a'''}{d\theta^2}\times\frac{l}{\mathrm{b}m}\times\{-1+q\cos^2\theta\}$$

$$+\frac{da'''}{d\theta}\times\frac{\cos\theta}{\sin\theta}\times\frac{l}{\mathrm{b}m}\times\{(1-2q)+q\cos^2\theta\}$$

$$+\frac{a'''}{\sin^2\theta}\times\frac{l}{\mathrm{b}m}\times\{6+(2-10q)\cos^2\theta+2q\cos^4\theta\}$$

$$-4a'''.\sin^2\theta.$$

Let

$$a'''=\mathrm{H}_0+\mathrm{H}_1\frac{l}{\mathrm{b}m}+\ \&\mathrm{c}.$$

Solution in powers of the depth of the sea.

Substituting this in the equation, and comparing the coefficients of the same power of $\frac{l}{\mathrm{b}m}$, the comparison of terms independent of l gives

$$4\mathrm{G}.\sin^4\theta=-4\mathrm{H}_0\sin^2\theta,$$

or

$$\mathrm{H}_0=-\mathrm{G}\sin^2\theta.$$

This gives

$$\frac{d\mathrm{H}_0}{d\theta}=-2\mathrm{G}\sin\theta\cos\theta\ ;\ \frac{d^2\mathrm{H}_0}{d\theta^2}=\mathrm{G}(2-4\cos^2\theta).$$

The comparison of terms multiplying the first power of l gives

$$0=\frac{d^2\mathrm{H}_0}{d\theta^2}\times\frac{l}{\mathrm{b}m}\times\{-1+q\cos^2\theta$$

$$+\frac{d\mathrm{H}_0}{d\theta}\times\frac{\cos\theta}{\sin\theta}\times\frac{l}{\mathrm{b}m}\times\{(1-2q)+q\cos^2\theta\}$$

$$+\frac{\mathrm{H}_0}{\sin^2\theta}\times\frac{l}{\mathrm{b}m}\times\{6+(2-10q)\cos^2\theta+2q\cos^4\theta\}$$

$$4\mathrm{H}_1\times\frac{l}{\mathrm{b}m}\times\sin^2\theta.$$

Substituting for H_0, $\frac{d\mathrm{H}_0}{d\theta}$, and $\frac{d^2\mathrm{H}_0}{d\theta^2}$, the values found above, we obtain

$$0=\mathrm{G}\times\{-8+16q.\cos^2\theta-8q.\cos^4\theta\}-4\mathrm{H}_1.\sin^2\theta,$$

or

$$\mathrm{H}_1=\mathrm{G}\times\frac{-8+16q.\cos^2\theta-8q.\cos^4\theta}{4\sin^2\theta}=2\mathrm{G}\times\frac{-1+2q.\cos^2\theta-q.\cos^4\theta}{\sin^2\theta}.$$

By a similar process H_2 will be formed from H_1. Then

$$a'''=-\mathrm{G}\sin^2\theta-2\mathrm{G}\times\frac{1-2q.\cos^2\theta+q.\cos^4\theta}{\sin^2\theta}.\frac{l}{\mathrm{b}m}+\ \&\mathrm{c}.$$

and

$$a=\frac{\Theta}{g}+\frac{a'''}{g}=-\frac{2\mathrm{G}}{g}\times\frac{1-2q.\cos^2\theta+q.\cos^4\theta}{\sin^2\theta}.\frac{l}{\mathrm{b}m}+\ \&\mathrm{c}.$$

If the depth is uniform, or $q=0$, a will $=-\frac{2\mathrm{G}}{g}.\frac{1}{\sin^2\theta}.\frac{l}{\mathrm{b}m}+\ \&\mathrm{c}.$

Law of depth which gives a finite solution.

(108.) In general, the value of a will be expressed by an infinite series, in which the terms converge by powers of $\frac{l}{\mathrm{b}m}$ and diverge by powers of $\sin^2\theta$. But in one case the solution can be put in a finite form. Suppose $q=1$, or the depth of the water, which $=l(1-q\cos^2\theta)$, to be expressed by $l.\sin^2\theta$. Then

$$H_1=-2G.\frac{1-2\cos^2\theta+\cos^4\theta}{\sin^2\theta}=-2G\frac{(1-\cos^2\theta)^2}{\sin^2\theta}=-2G.\sin^2\theta.$$

Now since the term $H_0=-G\sin^2\theta$ gave us $H_1=-2G\sin^2\theta$, the term $H_1=-2G\sin^2\theta$ would in like manner give us $H_2=-4G\sin^2\theta$; and so on. Thus we have

$$a'''=-G\sin^2\theta-2G\sin^2\theta.\frac{l}{bm}-4G\sin^2\theta\left(\frac{l}{bm}\right)^2-\&c.$$

$$=-G\sin^2\theta-G\sin^2\theta\frac{2\frac{l}{bm}}{1-\frac{2l}{bm}}$$

and

$$a=\frac{\Theta}{g}+\frac{a'''}{g}=-\frac{2G}{g}.\frac{l}{bm}.\frac{1}{1-\frac{2l}{bm}}\sin^2\theta.$$

The expression for the elevation of the water in this case is therefore

$$-\frac{2G}{g}.\frac{l}{bm}.\frac{1}{1-\frac{2l}{bm}}.\sin^2\theta.\cos\overline{2nt+2\varpi-2s}$$

and b and c, from the expressions in (95.), are respectively $\frac{1}{b^2n^2}.\frac{G}{1-\frac{2l}{bm}}.\text{cotan}\,\theta$ and $\frac{1}{b^2n^2}.\frac{G}{1-\frac{2l}{bm}}.\frac{1+\cos^2\theta}{2\sin^2\theta}$;

and the velocity of the water in the direction of the meridian $=-\frac{2}{bn}.\frac{G}{1-\frac{2l}{bm}}.\text{cotan}\,\theta.\sin\overline{2nt+2\varpi-2s}$, and that in the direction of the parallel $=\frac{2}{bn}.\frac{G}{1-\frac{2l}{bm}}.\frac{1+\cos^2\theta}{2\sin\theta}.\cos\overline{2nt+2\varpi-2s}.$

In this case, low water occurs at the transit of the luminary.

(109.) When the luminary is on the meridian, either above or below the horizon, $\cos\overline{2nt+2\varpi-2s}=1$, and the elevation of the water is expressed by $-\frac{2G}{g}.\frac{l}{bm}.\frac{1}{1-\frac{2l}{bm}}.\sin^2\theta$; or the elevation has its maximum negative value; that is, it is low water. We have already (16.) alluded to Newton's anticipation of this result; and we shall find it confirmed by investigations in our next section.

Laplace's solution in powers of the sine of latitude.

(110.) Laplace has solved the equation, on the supposition that the depth is uniform, in a manner equivalent to the following. Make $q=0$ in the equation of (107.), and put $1-\sin^2\theta$ for $\cos^2\theta$, and it becomes

$$\begin{aligned}4G.\sin^4\theta=&-\frac{d^2a'''}{d\theta^2}\times\frac{l}{bm}\\&+\frac{da'''}{d\theta}\times\frac{\cos\theta}{\sin\theta}\times\frac{l}{bm}\\&+\frac{a'''}{\sin^2\theta}\times\frac{l}{bm}\times(8-2\sin^2\theta)\\&-4a'''.\sin^2\theta.\end{aligned}$$

Since $ga=\Theta+a'''=G\sin^2\theta+a'''$,

assume $$ga=K_2\sin^2\theta+K_4\sin^4\theta+\ \&c.\ +K_{2k}\sin^{2k}\theta+K_{2k+2}\sin^{2k+2}\theta+\ \&c.$$

or $$a'''=(K_2-G)\sin^2\theta+K_4\sin^4\theta+\ \&c.\ +K_{2k}\sin^{2k}\theta+\ \&c.$$

Substitute this in each term of the equation above, reducing the even powers of $\cos\theta$ into expressions depending on $\sin\theta$; then comparing the coefficients of successive powers of $\sin\theta$, we have

$$\begin{aligned}8(K_2-G)&=0\\12(K_4-K_4)&=0\end{aligned}$$

$$(-16K_6+10K_4)\frac{l}{bm}-4K_2=0$$

$$(-40K_8+28K_6)\frac{l}{bm}-4K_4=0$$

and generally, after the two first,

$$\{-(4k^2+12k)K_{2k+4}+(4k^2+6k)K_{2k+2}\}\frac{l}{bm}-4K_{2k}=0.$$

The first equation determines K_2; the second leaves K_4 absolutely indeterminate; the other equations determine in succession each of the succeeding coefficients from those preceding.

Explanation of the indeterminateness of one coefficient.

(111.) The indeterminateness of K_4 is a circumstance that admits of very easy interpretation. It is one of the arbitrary constants in a complete solution of the equation. It shows that we may give to K_4 any value that we please, even if $G=0$; and then, provided that we accompany our arbitrary K_4 with the corresponding values of K_6, K_8, &c., we shall have a series which expresses a value of ga that will satisfy the equation *when there is no external disturbing force whatever*, and which therefore may be added, multiplied by any number, to the expression determined as corresponding to a given force. In the next Section we shall find several instances exactly similar to this. Yet this obvious view of the interpretation of this circumstance appears to have escaped Laplace, and he has actually persuaded himself to adopt the following process. Putting the general equation among the coefficients into the form

$$\frac{K_{2k+2}}{K_{2k}}=\cfrac{2\frac{bm}{l}}{(2k^2+3k)-(2k^2+6k)\frac{K_{2k+4}}{K_{2k+2}}}$$

Error in Laplace's process.

he has unwarrantably conceived that this must apply when $k=1$ for the determination of K_4; and thus, applying the same equation to each quotient of terms which occurs in the denominator of the fraction, he finds

$$\frac{K_4}{K_2}=\cfrac{2\frac{bm}{l}}{2.1^2+3.1-(2.1^2+6.1)\times\cfrac{\frac{2bm}{l}}{2.2^2+3.2-(2.2^2+6.2)\times\cfrac{2\frac{bm}{l}}{2.3^2+3.3-\&c.}}}$$

in an infinite continued fraction. And upon this he founds some numerical calculations, adapted to different suppositions of the depth of the sea. We state, as a thing upon which no person, after examination, can have any doubt, that this operation is entirely unfounded.

Correction of Laplace's process.

(112.) In conformity with the remarks that we have just made, Laplace ought to have determined the series for ga which will satisfy the equations

$$0=-\frac{d^2a'''}{d\theta^2}\times\frac{l}{bm}+\frac{da'''}{d\theta}\times\frac{\cos\theta}{\sin\theta}\times\frac{l}{bm}+\frac{a'''}{\sin^2\theta}\times\frac{l}{bm}\times(8-2\sin^2\theta)-4a'''\sin^2\theta$$

$$ga=0+a'''$$

having a constant K_4 indeterminate; and then he ought to have added this series, either to a solution of the equation in (110). found with $K_4=0$, or to a solution in which any definite value has been used for K_4. The series which satisfies the equations above is easily found to be

$$K_4\times\left\{\sin^4\theta+\frac{5}{8}\sin^6\theta+\left(\frac{7}{16}-\frac{bm}{10.l}\right)\sin^8\theta+\left(\frac{189}{576}-\frac{79}{720}.\frac{bm}{l}\right)\sin^{10}\theta+\&c.\right.$$

Now when $\frac{bm}{l}=10$, (or the depth $=\frac{1}{2890}$ of the earth's radius) Laplace has found

$$a=\frac{G}{g}\{\sin^2\theta+20\cdot1862.\sin^4\theta+10\cdot1164.\sin^6\theta-13\cdot1047\sin^8\theta-15\cdot4488\sin^{10}\theta-\&c.\}.$$

He ought to have found

$$a=\frac{G}{g}\{\sin^2\theta+20\cdot1862.\sin^4\theta+10\cdot1164.\sin^6\theta-13\cdot1047\sin^8\theta-15\cdot4488\sin^{10}\theta-\&c.\}$$

$$+\frac{K_4}{g}\{\sin^4\theta+\frac{5}{8}\sin^6\theta+\left(\frac{7}{16}-\frac{10}{10}\right)\sin^8\theta+\left(\frac{189}{576}-\frac{790}{720}\right)\sin^{10}\theta+\&c.\}$$

where K_4 is absolutely arbitrary.

When $\frac{bm}{l}=\frac{5}{2}$, (or the depth $=\frac{1}{722}$ of the earth's radius,) Laplace has found

$$a=\frac{G}{g}\{\sin^2\theta+6\cdot1960.\sin^4\theta+3\cdot2474.\sin^6\theta+0\cdot7238.\sin^8\theta+0\cdot0919.\sin^{10}\theta+\&c.\}.$$

He ought to have found

$$a=\frac{G}{g}\{\sin^2\theta+6\cdot1960.\sin^4\theta+3\cdot2474.\sin^6\theta+0\cdot7238\sin^8\theta+0\cdot0919\sin^{10}\theta+\&c.\}$$
$$+\frac{K_4}{g}\left\{\sin^4\theta+\frac{5}{8}\sin^6\theta+\left(\frac{7}{16}-\frac{5}{2.10}\right)\sin^8\theta+\left(\frac{189}{576}-\frac{79}{720}.\frac{5}{2}\right)\sin^{10}\theta+\&c.\right\}.$$

When $\frac{bm}{l}=\frac{5}{4}$, (or the depth $=\frac{1}{361}$ of the earth's radius,) Laplace has found

$$a=\frac{G}{g}\{\sin^2\theta+0\cdot7504.\sin^4\theta+0\cdot1566.\sin^6\theta+0\cdot0157.\sin^8\theta+0\cdot0009.\sin^{10}\theta+\&c.\}.$$

He ought to have found

$$a=\frac{G}{g}\{\sin^2\theta+0\cdot7504\sin^4\theta+0\cdot1566.\sin^6\theta+0\cdot0157.\sin^8\theta+0\cdot0009.\sin^{10}\theta+\&c.\}$$
$$+\frac{K_4}{g}\left\{\sin^4\theta+\frac{5}{8}\sin^6\theta+\left(\frac{7}{16}-\frac{5}{10.4}\right)\sin^8\theta+\left(\frac{189}{576}-\frac{79}{720}.\frac{5}{4}\right)\sin^{10}\theta+\&c.\right\}.$$

It is needless to observe that Laplace's numerical calculations of the heights of the tides in certain latitudes, and his inferences, as to the latitude where there is no tide, &c., fall to the ground.

This solution is applicable to a sea bounded on its north or south side.

(113.) If, using the more complete values of a that we have just found, we proceed to form the values of a''', b, and u, we find that u will contain a series of terms multiplied by the indeterminate K_4. We may determine K_4 so that, for a given value of θ, u shall $=0$; that is to say, so that, in a given latitude, the water shall have no north and south motion. We might therefore suppose an east and west barrier (following a parallel of latitude) to be erected in the sea, and the investigation would still apply. Thus then we have a complete solution for a sea which is bounded by a shore whose course is east and west.

(114.) The fluctuations of which we have last treated are those which Laplace has called "*les oscillations de la troisième espèce.*" They constitute the ordinary semidiurnal tide.

Separate effects of the Sun and Moon are to be combined by algebraical addition.

(115.) We have throughout this Section spoken of the luminary as if only the Sun or only the Moon were efficient in producing the tides. But the reader will easily understand that the same investigations, *mutatis mutandis*, apply to the moon as to the sun; and that, when the effect of each is found separately, their compound effect will be the algebraic sum of their separate effects. For our equations throughout comprehend only the first power of the terms depending on disturbing force, and the first power of the unknown p''' and the terms originating from it; and thus, if a term f_m, depending on the Moon's action, produces the term p_m, and a term f_s, depending on the Sun's action, produces the term p_s, then, by simple addition of the equations, the equation will be produced which shows that the combined terms f_m+f_s will produce p_m+p_s. This would not be true if the squares of terms of p''' entered, because the sum of the squares of p_m and p_s is not the same as the square of their sum: and so for higher powers.

(116.) With this we shall terminate our account of Laplace's Theory of the Tides; but, before closing this Section, we must call our reader's attention, as well to the important points of the investigation in general, as to the modification which we have thought desirable to introduce into Laplace's methods. We will first advert to the latter. Laplace has commenced with the equations of motion of fluids in their most general, and (we may be permitted to say) in their most repulsive form. Proceeding from these in a way which appears at first not easy to understand, but in which, nevertheless, the same operations may be traced as in the investigations of this Essay, he arrives at the equations of (87.), the assumptions of (89.), and the equations of (90.). From this point he proceeds by a method totally different from that which we have used. Partly for the generality of an investigation applying to all degrees of density of the sea, and partly (it would seem) for the sake of introducing his own favourite equation for the attraction of bodies nearly spherical, Laplace has embarrassed his process with investigations, nowhere fully explained, and sometimes only hinted at, applying to the different terms into which (for substitution in his own equation above alluded to) the disturbing forces and other quantities are to be resolved. In asserting that this is the most obscure of the investigations of the Mécanique Céleste, we trust that we may consider ourselves supported by the circumstance that no following mathematician has entered into Laplace's method for the tides, or has even verified his most remarkable results; although Laplace has frequently alluded to one of these (the evanescence of diurnal tide in height when the depth is uniform) in a way that shows that he considered it one of the happiest of his discoveries. We add that this investigation is *unnecessarily* obscure. Although the introduction of the density of the sea has apparently enabled Laplace to give greater generality to his symbols, it has given none to his final results. Of the latter class there are two, namely, the evanescence of the diurnal tide when the depth is uniform, and the numerical calculation of the semi-diurnal tide. The former is obtained by the methods of this Treatise; and, moreover, is obtained with the utmost generality as to density of fluid: for, if the depth is nowhere altered, the attraction is not altered, and therefore it is indifferent whether we treat the attraction of the fluid *per se*, or consider it included in the attraction of the rigid body. In the latter, Laplace has himself neglected the density of the water. We trust that these remarks will be thought sufficiently to explain our abandonment of Laplace's method, and our substitution for it of a method which is (we should hope) intelligible to almost every student of the differential calculus.

(117.) If now, putting from our thoughts the details of the investigation, we consider its general plan and objects, we must allow it to be one of the most splendid works of the greatest mathematician of the past age. To appreciate this, the reader must consider, first, the boldness of the writer who, having a clear understanding of the gross imperfection of the methods of his predecessors, had also the courage deliberately to take up the problem on grounds fundamentally correct (however it might be limited by suppositions afterwards introduced); secondly, the general difficulty of treating the motions of fluids; thirdly, the peculiar difficulty of treating the motions when the fluids cover an area which is not plane but convex; and, fourthly, the sagacity of perceiving that it was necessary to consider the Earth as a revolving body, and the skill of correctly introducing this consideration. The last point alone, in our opinion, gives a greater claim for reputation than the boasted explanation of the long inequality of Jupiter and Saturn.

Negative results of Laplace's theory.

(118.) If we look to the results of the theory, it will be found that they are rather of a negative than of a positive kind. They show that, without a far more complete knowledge of the form of the bottom of the sea than we can hope to possess, it will be impossible, even with more powerful mathematics, to calculate tides *à priori*. They show that the calculations founded on the equilibrium-theory cannot be good for anything. In proving that (with sea at least of a certain shallowness) the part of the equator next to the sun or moon would be a place of *low* water, they destroy all hope of using an equilibrium-theory, even as an approximation. In establishing the remarkable result as to the non-existence of diurnal tide in height when the depth is uniform, they show that no inference can be drawn from the mere magnitude of a force as to the magnitude of its effects.

Extension required to make the theory applicable to observations.

(119.) The results of this theory, however, would give us a knowledge of the physics of tides of no contemptible kind, if, upon any supposition whatever as to depth, we were able to introduce the horizontal limitation of the sea. This implies that we should be able to solve generally the equations of (87.) without the term $\Theta . \cos \overline{it + k\varpi}$. Such a solution, in a very limited case, is given by the indeterminateness of K_4 in (112.). We see not the smallest prospect of succeeding in this with the degree of generality required (that is, of expressing the solution by $A \cos it + B \sin it$, where A and B are the most general functions of θ and ϖ): we have, however, no hesitation in pointing out this as the subject which, in the present state of theory, is most especially worthy of the attention of the theoretical investigator of tides. It is principally in this respect that the theory (in other respects imperfect) of the next Section is superior to this. [The principle of introducing such limitations in general will be found in (291.) &c.] As it is, Laplace's theory fails totally in application, from the impossibility of introducing in it the consideration of the boundaries of the sea.

(120.) It is almost unnecessary to remark that this theory gives no assistance in explaining the peculiarities of river or channel tides: and it gives no idea whatever of the difference in the proportion of the effects produced by bodies (as the Sun and Moon) whose motions in right ascension are not precisely equal; a matter which we shall find to be very important.

(121.) After considering the negative nature of the results of his theory, and the degree in which any accurate conclusions must depend upon the precise knowledge and correct mathematical treatment of a number of circumstances which are wholly unknown, Laplace at last takes refuge in the assumption that all that we are certain of is, that the disturbances of the sea will be periodical as the forces that cause those disturbances, but that their times of maximum or minimum are not necessarily the same as the times of maximum or minimum of the forces, and that their coefficients are not necessarily in the same proportion as the forces which cause them, unless the periods of the forces are exactly the same. That is to say, if the forces acting in any given manner are represented by

$$A_{,} \cos (i_{,}t + B_{,}) + A_{,,} \cos (i_{,,}t + B_{,,}) + A_{,,,} \cos (i_{,,,}t + B_{,,,}) + \&c. ;$$

then the elevation of the tide will be represented by

$$C_{,} \cos (i_{,}t + B_{,} + E_{,}) + C_{,,} \cos (i_{,,}t + B_{,,} + E_{,,}) + C_{,,,} \cos (i_{,,,}t + B_{,,,} + E_{,,,}) + \&c.,$$

where the quantities $C_{,}$, $C_{,,}$, $C_{,,,}$, $E_{,}$, $E_{,,}$, $E_{,,,}$, can only be determined from experience. And that, in the case of a canal communicating with two tidal seas, any variation in the value of $i_{,}$ ($A_{,}$ and $B_{,}$ remaining unvaried) will be accompanied by a variation of $C_{,}$ and $E_{,}$. On this point the reader is referred to (312.).

(122.) We will terminate this Section by a brief demonstration of two of Laplace's supplementary propositions which are closely related to the subject before us.

The equilibrium of the sea is

(123.) The first is, that the equilibrium of the sea is stable (that is, if its relative position with the land is disturbed, it will have a tendency to return to its former position), if the density of the land is greater stable if its density is less than that of the earth.

than that of the sea; out is unstable if the density of the land is less than that of the sea. In fig. 4, suppose the land to be more dense than the water, and suppose that at any instant each is in the form of a sphere, the centre of the terrestrial sphere being at A, and the centre of the aqueous sphere being at B. The attraction of the whole may be found by conceiving the whole large sphere to be filled with matter of the same density as water, and conceiving the small sphere to have, in addition, the density equal to the excess of the density of earth over that of water. The attractions of these spheres will be directed to their respective centres. Thus, a particle p on the surface will be drawn by one of these attractions (that of the aqueous sphere) in the direction pB, and by the other (the excess of the sphere of earth over a similar sphere of water) in the direction pA. Representing these forces by pa and pb, their compound effect will be that of a force in the direction pc. It is evident that this force is not perpendicular to the surface at p (the normal being pB), but is inclined in such a direction that it tends to carry the particle p towards e. A similar result will be found for every particle at the surface, namely, that the force on the particle tends to carry it in that direction where the water is at present deficient; and tends, therefore, to restore the equality of distribution of the water.

The equilibrium of the sea is unstable if its density is greater than that of the earth.

(124.) But if the land is less dense than the water, then, in fig. 5, we may conceive the whole of the larger sphere to be occupied with matter of the same attractive power as water, but then we must suppose the small sphere to be occupied with a repulsive substance. The particle p will then be drawn by the complete aqueous sphere in the direction pB or pb, but will be repelled by the imaginary repulsive sphere in the direction pa. The whole force, therefore, on p will be represented by pc acting in the direction inclined to the normal pB on the side opposite to that in the last article, and therefore it will tend to carry the particles of water towards that side f where there is already a redundance, and, therefore, to cause the distribution of water to become more unequal than it is at present.

Investi tion of depen ence o preces upon tides.

(125.) The second supplementary proposition is, that the amount of precession, and its subordinate portions included under the general term *nutation*, are not affected by the tidal motions of the sea. To demonstrate this, we must refer to our Treatise on the FIGURE OF THE EARTH, section 9. It will there be seen that, in consequence of the action of the Sun and Moon upon the earth, supposed to be a solid, there is impressed upon the earth a tendency to revolve round an axis, which is in the plane of the equator; and that the result of the composition of this impressed motion of rotation with the motion of rotation about its polar axis is, that the real axis of rotation (a revolution about which will represent the real motion of every particle of the earth under the effect of the two rotations) will change its position in space, in that direction which exactly corresponds to precession (including nutation). The quantity, then, upon which the amount of precession will immediately depend, is the angular velocity which the action of the sun and moon tends to give round the equatorial axis of which we have spoken; and this angular velocity is represented by the fraction, whose numerator is the moment of all the impressed forces tending to produce rotation round that equatorial axis, and whose denominator is the moment of inertia of the earth about the same axis. If the water were united in one solid mass with the earth, we should, for the moment of impressed forces, merely consider the effect of the sun's and the moon's attraction upon the earth and upon the water. But, as the water is not rigidly connected with the earth, but has a fluctuating motion upon it, and acts upon the earth by a pressure which is modified as well by its elevation as by the circumstances of its motion, it is necessary to take into account the effect of the pressure of the water upon the earth, and the corresponding reaction of the earth upon the water. We must also consider that the same particles of water, in their tidal motion, always oscillate about nearly the same part of the earth.

Principle of the conservation of areas.

(126.) The most general way of considering this is the easiest. The particles of water act upon one another and upon the particles of earth, and the particles of earth act upon one another and upon the particles of water, either by the pressure of contact, or by attraction; and each of these forces produces an equal reaction upon the acting particle. Now there is a well known principle, called that of the *conservation of areas*, which is thus enunciated:—"The sum of the products of the mass of each particle into the area which it describes round a given axis is not altered by the mutual action of the particles." The demonstration of this (which is not given in our Treatise MECHANICS) may be shortly stated as follows. Let x, y be the co-ordinates of a particle m which is acted on by the accelerating forces X, Y; x', y' those of another particle m', which is acted on by the accelerating forces X′, Y′ (z being the axis of rotation); D the distance between these particles; and let F be the force, estimated as a pressure, with which these two particles attract each other. Then,

$$\frac{d^2 x}{dt^2}=\mathrm{X}+\frac{\mathrm{F}}{m}\cdot\frac{x'-x}{\mathrm{D}}$$

$$\frac{d^2 y}{dt^2}=\mathrm{Y}+\frac{\mathrm{F}}{m}\cdot\frac{y'-y}{\mathrm{D}}$$

$$\frac{d^2 x}{dt^2}=\mathrm{X}'+\frac{\mathrm{F}}{m'}\cdot\frac{x-x'}{\mathrm{D}}$$

$$\frac{d^2 y'}{dt^2}=\mathrm{Y}'+\frac{\mathrm{F}}{m'}\cdot\frac{y-y'}{\mathrm{D}}.$$

Therefore

$$m\left(x\frac{d^2 y}{dt^2}-y\frac{d^2 x}{dt^2}\right)=m(x\mathrm{Y}-y\mathrm{X})+\mathrm{F}\,\frac{xy'-yx'}{\mathrm{D}}.$$

But if r is put for the distance of m from the axis, and θ for the angle made by r with the plane of xz, $x = r\cos\theta$, $y = r\sin\theta$, and $x\frac{d^2y}{dt^2} - y\frac{d^2x}{dt^2} = \frac{d}{dt}\left(x\frac{dy}{dt} - y\frac{dx}{dt}\right) = \frac{d}{dt}\left(r^2\frac{d\theta}{dt}\right)$. Put A for the projection, on the plane xy, of double the area described by m round the axis in the unit of time; then $A = r^2\frac{d\theta}{dt}$: and this equation becomes

$$m\frac{dA}{dt} = m(xY - yX) + F.\frac{xy' - yx'}{D}.$$

Similarly for the other particle,

$$m'\frac{dA'}{dt} = m'(x'Y' - y'X') + F.\frac{x'y - y'x}{D}.$$

Adding these,

$$m\frac{dA}{dt} + m'\frac{dA'}{dt} = m(xY - yX) + m'(x'Y' - y'X');$$

or is the same as it would have been if there had been no mutual action of the particles. The same would be found to be true if there had been any number of particles. Then, integrating, we find that $mA + m'A' + \&c.$ is the same as if there had been no mutual action. It is, however, to be remarked, that if the ordinates x, y, x', y', &c. are sensibly altered by that mutual action, the products xY, yX, &c. are altered; and, therefore, in this indirect way the expressions for $m\frac{dA}{dt} + m\frac{dA'}{dt} + \&c.$ may be altered.

(127.) It follows from this, that the sum of the products of the mass of each particle of the earth and sea by the area which it describes round the equatorial axis is unaltered by the fluctuation of the sea (except so far as the surface is raised or depressed by that fluctuation, and the moment of the impressed forces is thereby increased or diminished; but this increase or diminution must be utterly insensible, and we shall give no further attention to it). Now, if the earth and sea were so entirely disconnected that one of them could revolve for any length of time with any velocity, increasing or diminishing in any manner, while the other could revolve with any other velocity changing in any other manner, we could pronounce nothing as to the effect of the fluctuations on precession. But the assumption on which we are to proceed is, that the tidal motion is not great, and is of an oscillatory kind. If, then, there were but a single sea upon the earth, and if in consequence of fluctuation this sea received a considerable velocity in the same direction in which the impressed forces tend to carry the earth, the rotation of the solid earth in that direction round the equatorial axis would thereby be *diminished* (in virtue of the *conservation of areas*). But as soon as that water came to a state of rest, the rotation of the earth round the equatorial axis would acquire the same value as if the water were rigidly connected with the earth; and when the water had a movement in the opposite direction, the earth's velocity of rotation round the equatorial axis would be *increased*. And this would be true whether or not the sea had had in the mean time, from the earth's diurnal revolution, a great motion parallel to z (for z does not enter into the formula), and whether or not the sea had been carried to the opposite side in respect of x or y (for the formula is perfectly general as regards changes of magnitude and sign of x and y). The same applies to any number of seas, of any forms. Thus, though the angular motion round the equatorial axis, and the consequent momentary precession, may be irregular, yet its irregularity will not extend beyond a single complete tidal oscillation; and the whole precession during one tide will be the same as if the water had been fixed.

(128.) The reader will perceive that, although through the greater part of this Section we have not taken into account the density of the water, we have taken it fully into account in these two supplementary propositions. And, in the last of them, we have departed from all hypotheses as to the symmetrical disposition of the water, and have supposed it to be distributed and bounded in any way whatever.

SECTION IV.—THEORY OF WAVES IN CANALS.

(129.) We have already stated (64.) that the Equilibrium-Theory of Tides, though curious in its relation to the history of the science, and valuable for the coincidence of the algebraic form of its results (under certain modifications) with those of more accurate theories, and with the laws deduced from observations, does not deserve the smallest attention as representing the state of the ocean at any time. We have also stated (65.) that Laplace's theory of the movement of the sea, supposing the globe completely covered by water, whose depth is uniform, or follows a very simple geographical law, though based upon sounder principles, has far too little regard to the actual state of the earth to serve for the explanation of the principal phænomena of tides. We now come to a third theory: that of the motion of the tidal waters, supposing them to run in the manner of ordinary waves in canals. It is evident that this theory will not apply to every part of the sea, and therefore it must, to a certain extent, be considered imperfect. Still it will apply strictly to many cases (to rivers without exception; and to arms of the sea where their breadth is smaller than their length, and where the irregularities of the coasts are not very remarkable), and it will apply without sensible modification to other cases of open seas, where the whole may be conceived divided into parallel canals in which the circumstances are nearly similar. For these reasons we are inclined to think that this mode of considering the subject, in the present imperfection of mathematics, deserves special notice among the various Theories of the Tides.

(130.) It is necessary for our present purpose to enter into a pretty general investigation of the Theory of Waves of water; and we shall therefore commence without any obvious reference to the subject of Tides.

(131.) We shall, for convenience, divide this Section into the following parts:

Subsection 1.—General explanation of waves; and general theory of waves, supposing the motion of the particles small.

Subsection 2.—Theory of waves in canals of uniform depth and uniform breadth, whether the waves be short or long, the motion of the particles being supposed small.

Subsection 3.—Theory of long waves in which the elevation of the water bears a sensible proportion to the depth of the canal.

Subsection 4.—Theory of waves when the water is acted on by horizontal and vertical forces, the motions of the particles being small; including also the theory of a single wave, and the theory of waves in canals of variable depth and variable breadth; with the introduction of the ideas of *free-wave* and *forced-wave*.

Subsection 5.—Method of introducing the limits of the canal in general; and application of the doctrine of *free-wave* and *forced-wave*.

Subsection 6.—Theory of waves, as affected by friction.

Subsection 7.—Theory of waves in water of three dimensions, or where the horizontal extent of the surface in two dimensions is taken into account.

Subsection 1.—*General Explanation of Waves, and general Theory of Waves, supposing the motion of the particles small.*

(132.) Without citing the explanations in other essays, it may be desirable here to call the reader's attention to the meaning of the term *wave*, and to the form of the mathematical expression which must be used to represent the motions of the particles of water in wave-motions. The same general ideas attach to the term *wave* or *undulation* in the sciences of Acoustics and Optics: and a clear conception of those ideas may be considered as one of the most important steps in the understanding of many important physical sciences.

A wave in continuous motion does not imply that the water is continuously moving in the same direction.

(133.) In watching the waves of the sea (we allude not to the breaking of the surf, which will be distinctly considered hereafter), the reader may perhaps have imagined that, in each wave, a quantity of water, equal in bulk to that wave, was advancing towards the shore. A very little attention, however, would show that this notion is incorrect. A cork, or a particle of foam, floating on the water, is not carried towards the shore; if watched narrowly, it will be found that it moves towards the shore while the crest of each wave is under it, and from the shore while it is in the hollow of each wave, but these motions are scarcely greater than its vertical motions, and the advance and the regress sensibly balance each other.

It is only the motion of a shape.

(134.) Thus it will appear, as a visible fact, that the continued motion of a wave in one direction is not a continued motion of the water in that direction, but may be described as a continued motion of a *shape*, or of an *arrangement of the particles of the water*. It is necessary now to show that a very small reciprocating motion of each particle of water is sufficient to account for unlimited motion of the *wave* or *shape* continued constantly in one direction.

(135.) In figure 6, suppose that ABCDEFG represents the outline of a succession of waves at one instant of time, *abcdefg* the outline at a second instant; it is required to show how the waves can have advanced from the position ABCDEFG to *abcdefg* by a small oscillating motion of each particle of water.

Explan tion of tion of wave b oscilla motion the pa ticles.

(136.) Draw vertical lines from the surface to the bottom of the water; conceive that all the particles in each line are subject to motion in the direction represented by the small arrows in the figure; that is, that all the particles below the crest of the wave are moving forwards; that all the particles below the hollow of the wave are moving backwards; and that all below the midway-points (A, C, E, G,) are for the moment stationary. And suppose that the velocity of the horizontal motion of the particles in vertical lines intermediate to those drawn in the figure is intermediate to the velocities of the particles in the lines drawn in the figure. This supposition will account for the motion of the wave or *shape*.

(137.) For, take points B_0, B_1 near to B: C_0, C_1 near to C, &c.: draw lines from them to the bottom, and consider the horizontal motion of the particles in those lines. B_0 and B_1 are both between the point of principal backward motion and the point of rest; therefore the particles below B_0 and those below B_1 will be moving backwards, and with nearly the same speed: and therefore the intermediate surface at B will not be sensibly elevated or depressed, inasmuch as the vertical boundaries $B_0\,B_0'$ and $B_1\,B_1'$ of the included column of water will, after a short time, be at the same distance from each other as at present. But the particles in the line $C_0\,C_0'$ are between a point of rest and a point of backward motion, and therefore are moving backwards; those in the line $C_1\,C_1'$ are between a point of rest and a point of forward motion, and therefore are moving forwards; consequently the vertical boundaries, $C_0\,C_0'$, $C_1\,C_1'$, of the included column are separating more widely apart, and therefore the surface at C will drop, and will, after a short time, be found depressed to *c*. In like manner it will be found that in both the lines $D_0\,D_0'$ and $D_1\,D_1'$ the particles are moving forward with nearly the same velocity, and therefore in the intermediate part at D the elevation of the surface is not sensibly altered. But in $E_0\,E_0'$ the particles are moving forward, and in $E_1\,E_1'$ they are moving backward; the horizontal space between these boundaries is therefore diminished, and therefore the surface of the water between them is raised; and it will therefore, after a short time, be found at *e* instead of E. Pursuing this reasoning it will be evident that the continued horizontal motion of the wave or *shape* forwards is entirely accounted for by the rising of some portions of the surface and the falling of others, and that these risings and fallings may be considered as the effect of small horizontal motions of the particles of the water, some forwards and others backwards.

(138.) And as, in the progress of the waves, the same particles are alternately on the crest and in the hollow of the wave, every particle will be alternately moving forwards and backwards, and alternately upwards and downwards; the wave meanwhile will be advancing continually in the same direction.

(139.) The reader must consider the above as merely a general *geometrical* explanation of the motion of a wave by means of oscillating motions of every particle of the water. Whether such motions are consistent with the various forces acting upon water (which forces themselves depend in part upon the motions of the particles) will shortly be a most important subject of inquiry. But from the tenor of this explanation, we may at once collect what must be the form of the mathematical expressions which will be necessary to represent the motions of the particles. We shall call the horizontal ordinate of any particle in its position of rest, measured in the direction of the canal's length from some fixed point, x: and the vertical ordinate of any particle in its position of rest, measured upwards from some horizontal plane (which, when the depth is uniform, may be the bottom of the water) y.

(140.) Now, first, it appears from our explanation that each particle is disturbed in the horizontal as well as in the vertical direction. Consequently, to represent the position of any particle at any time, we must use for co-ordinates

$$x'=x+\mathrm{X}$$

$$y'=y+\mathrm{Y},$$

where both X and Y depend on, or are functions of, x, y, and t (t being used to express the time, as measured from some arbitrary epoch.)

Algebraic characteristic of a wave.

(141.) Secondly. The characteristic of a wave is this: that though, at any one instant, different particles are displaced in different ways; yet, the state of any particle in advance (that is, a particle for which x is large) will be, at some future time, the same as the state of a particle in arrear (that is, a particle for which x is small) is now, provided we wait during a time proportioned to the interval of space between these two particles. In other words: supposing the velocity of the wave to be v, so that in the time t' it will move through $v\,t'$: then the characteristic of a wave is, that the particle whose ordinate is $x+vt'$ will have the same disturbance at the time $t+t'$, which the particle whose ordinate is x has at the time t. Mathematically expressed, putting $\phi(x,t)$ for the disturbance at the time t of a particle whose ordinate was x,

$$\phi(x,t)=\phi(\overline{x+vt'},\ \overline{t+t'}):$$

expanding this latter to the first power of t',

$$\frac{d.\phi(x,t)}{dx}vt'+\frac{d.\phi(x,t)}{dt}t'=0:$$

a well known equation, whose solution is

$$\phi(x,t)=\chi(vt-x),$$

χ being any arbitrary function. As v is not known, it will be equally convenient to put this under the form

$$\chi(nt-mx)$$

where n and m are constants: the function χ being still arbitrary (that is, capable of adaptation to any physical assumption) though not precisely the same as in the former expression. If we suppose the horizontal movements of the particles in different points of the same vertical to be different, we may express that supposition by multiplying this expression by a function of y, which will give

$$\mathrm{X} \text{ or } \phi(x,t)=\mathrm{F}(y)\times\chi(nt-mx).$$

And if we suppose that the horizontal movements of the particles in different points of the same vertical are not simultaneous; for instance, that their times of rest or their times of greatest motion do not all occur at the same instant; we may use the expression

$$\mathrm{X}=\mathrm{F}(y)\times\chi(nt-mx-\mathrm{Q}),$$

where Q depends on y only.

Characteristic when the motion of particles is oscillatory.

(142.) Thirdly. The motion of each particle of water was supposed to be *reciprocating* or *oscillatory*. There is no kind of expression so convenient for representing oscillatory motion as one depending on sines or cosines. And by combination of several terms of that kind, any kind of oscillation may be represented. Thus, the formula

$$\cos(nt-mx)$$

would represent a regular oscillation going through all its changes while nt increased by 2π, or while t increased by $\frac{2\pi}{n}$: but the following formulæ

$$\cos(nt-mx)+a\cos(2nt-m'x)$$

$$\cos(nt-mx)+a.\cos(2nt-m'x)+b.\cos(3nt-m''x)$$

would represent regular oscillations of a different kind, but still going through all their changes while t increased by $\frac{2\pi}{n}$. It will even be seen hereafter that, by proper management of these terms, we may investigate the motions of a *discontinuous* wave, that is where a single wave, and no more, passes along a canal. For these reasons, we shall always suppose the function χ to have the form of a series of sines or cosines of multiples of $nt-mx$. But as each of these terms will be treated separately in the same manner, we shall omit all but the first (for convenience only), and shall therefore assume

$$X=F(y).\cos(nt-mx-Q).$$

The form of Y, as will appear in the investigation, will necessarily follow from that of X.

Characteristic when the form of the wave changes.

(143.) Fourthly. In some very important cases, we shall find it necessary to depart from our original simple suppositions. Circumstances may be conceived, in which, without at all losing the character of a single determinate series of waves, the elevation of each wave alters as it proceeds; and the linear interval between the crest of one wave and the crest of the next wave alters, (the interval of time remaining the same as before,) or the velocity of the wave alters. Thus, in figure 7, the wave, which while at ABC was long and flat, may at IKL become short and steep. This case will be fully represented by introducing a variable coefficient depending on x, and by conceiving that the factor m, or $\frac{n}{v}$, by which the periodic function depends on x, is itself a function of x, and that, instead of a product, an integral is to be used. Thus we shall have

$$X=F(y).G(x).\cos(nt-\textstyle\int_x m).$$

We shall now proceed with that part of the investigation which depends on the properties of fluids.

(144.) In figure 8, let *o*O represent the bottom of a canal of variable depth: *abc* the surface of the water in a state of rest, ABC the surface at a certain instant of time when in wave-motion: and suppose that the very narrow column of water, which when the whole was at rest had the form *oc*, has at this instant the form OC. Suppose the column *oc* divided into a very great number of small parts by horizontal planes, and let *ps* be one of these parts, and PS the corresponding part of the column OC in its displaced state at the instant under consideration. Let the coordinates of the point *o* at the bottom be x and η: the vertical coordinate of the surface *abc* be k: the coordinates of p be x and y: and suppose $pq=h$, $pr=l$. And put X for the horizontal displacement, and Y for the vertical displacement, of the particle whose coordinates are x and y, at the instant under consideration. Let Ξ be the value of X at the bottom, and K the value of Y at the top. Then, considering the disturbance so small that all quantities beyond the first order may be omitted,

The horizontal ordinate of $P=x+X$,

The horizontal ordinate of $Q=x+h+X+\frac{dX}{dx}h$,

therefore the horizontal distance between P and Q $=h\times\left(1+\frac{dX}{dx}\right)$ nearly.

And the vertical ordinate of $P=y+Y$,

The vertical ordinate of $R=y+l+Y+\frac{dY}{dy}l$,

therefore the vertical distance between P and R $=l\times\left(1+\frac{dY}{dy}\right)$ nearly.

Investigation of equation of continuity.

(145.) Now, conceiving that the water, which occupied the volume *ps* without any vacant space, does now occupy the volume PS without any vacant space, or remains *continuous*, it is evident that we must have

$$\text{area } ps=\text{area PS}.$$

But, as in (72.), the area PS, considered as a rhomboid, $=\text{PQ}\times\text{PR}\times\sin\text{RPQ}$,

$=\text{PQ}\times\text{PR}\times$ cosine (inclination of PQ to horizontal line + inclination of PR to vertical)

$=$(PQ × cos incl. PQ to horiz. line) × (PR × cos incl. PR to vertic. line) × (1 − tan incl. PQ . tan incl. PR)

$=$(hor. dist. between P and Q) × (vert. dist. between P and R) × (1 − tan incl. PQ . tan incl. PR).

Now the inclination of PQ to the horizontal line is small; and that of PR to the vertical is small: therefore the product of their tangents is exceedingly small, and may be neglected. Hence we obtain

area PS = (hor. dist. between P and Q) × (vert. dist. between P and R)

$$=h\times\left(1+\frac{dX}{dx}\right)\times l\times\left(1+\frac{dY}{dy}\right)$$

$$=hl\times\left(1+\frac{dX}{dx}+\frac{dY}{dy}\right)\text{ nearly.}$$

Making this equal to area $ps=hl$, we obtain

$$0=\frac{dX}{dx}+\frac{dY}{dy},$$

or

$$Y=-\int_y \frac{dX}{dx}+\text{a function of } x.$$

As there is a fixed boundary to the water at the bottom, we must commence our integration there. Now it is evident that at the bottom the value of Y is $\Xi\times\frac{d\eta}{dx}$, inasmuch as the lowest particles of the water are pushed through the horizontal space Ξ in contact with the sloping bottom whose vertical ordinate is η, and the tangent of whose inclination to the horizon is, therefore, $\frac{d\eta}{dx}$. Thus we have

Equation of continuity.

$$Y=\Xi.\frac{d\eta}{dx}-\int_y \frac{dX}{dx} \text{ (from } y=\eta \text{ to } y).$$

This is the equation of continuity.

(146.) Now let us consider the relation, between the forces which act on the different points of the water, and the motion of the water. Continue the horizontal plane pq to TV, and from T and V draw the vertical lines TW, VX, to the disturbed surface. The points W and X do not coincide with B and C, but in regard to the accuracy of any expression depending merely on the wave-disturbance they may be used indifferently; because WB and XC depend upon the extent of disturbance, and the slope of WB and XC also depend on the extent of disturbance, so that the difference of elevations of W and B, or of X and C, will depend on the square of the disturbance. But the difference of elevations of W and X (which is the difference that we shall shortly use) depends on the extent of disturbance; and, therefore, when the disturbance is made very small, it is a much greater quantity than the difference of elevations of W and B, which depends on the square of the disturbance. And this is entirely independent of the length of the wave. Thus, in a wave whose length from crest to crest is many feet, the whole value of WB may be an inch: by diminishing the violence of the motion, or making the wave flatter, while its length remains the same, WB may be diminished to a tenth of an inch, and then the difference of elevation of W and B will be a hundredth part of what it was before, while that of W and X will be a tenth part of what it was before. Thus, when the motion of the particles is small, instead of using the value of K corresponding to the point W, we may use that which corresponds to the point B: and instead of using the difference between the values of K for W and X, we may use the difference between the values of K corresponding to B and C.

Investigation of the equation of equal pressure.

(147.) Now let p be the pressure at any point in the line PW, estimated by the velocity which that pressure acting on the surface 1 would produce in the volume of water 1, by acting during the time 1. Then p will be a function of x, y, and t. Let g' be the force of gravity, estimated by the velocity which it will produce by its action during the time 1: for reasons which will hereafter appear we shall consider g' as varying from one point of the earth's surface to another, or as being a function of x. Then the pressure at the point whose elevation is y' is p; that at the point whose elevation is $y'+\delta y'$ is $p+\frac{dp}{dy'}\delta y'$: the excess of the upper pressure above the lower is $\frac{dp}{dy'}\delta y'$: and this excess, acting on the column whose length is $\delta y'$, will tend to urge it downwards with an acceleration represented by $\frac{dp}{dy'}$. Adding to this the effect of gravity, we shall have the whole acceleration downwards $=\frac{dp}{dy'}+g'$. Therefore

$$\frac{d^2y'}{dt^2}=-\frac{dp}{dy'}-g'.$$

But $y'=y+Y$, therefore $\frac{d^2y'}{dt^2}=\frac{d^2Y}{dt^2}$ (as y does not depend on t). Consequently

$$\frac{dp}{dy'}=-g'-\frac{d^2Y}{dt^2}, \text{ and } p=\int_{y'}\left(-g'-\frac{d^2Y}{dt^2}\right).$$

Performing the integration from y to $k+K$, ($k+K$ being the value of y' at the surface of the water,) so that the pressure at the surface is zero,

$$p=g'(k+K-y)+\int_{y'}\frac{d^2Y}{dt^2} \text{ (from } y'=y \text{ to } y'=k+K).$$

But, as $\frac{d^2Y}{dt^2}$ is itself a small quantity depending on the motion of the particles, we shall incur no sensible error by integrating with respect to y instead of y', and by taking for superior limit k instead of $k+K$. Thus we obtain for the pressure at T

$$p=+g'(k+K-y)+\int_y \frac{d^2Y}{dt^2}\,(y \text{ to } k).$$

(148.) The particle at V corresponds to a point whose ordinate in the state of rest did not sensibly differ from $x+h$, and the pressure at V is, therefore, $p+\frac{dp}{dx}h$ nearly.

(149.) These pressures have been found from consideration of the motions of the particles of water in a vertical direction, and are therefore vertical pressures. Now the peculiar property of fluids is, that the pressure is equal in all directions, or that the expressions which we have found for the vertical pressures at T and V represent also the horizontal pressures at those points. (On this subject the reader is referred to article 75.) Thus we have

Horizontal pressure at T tending to push TV forwards $=p$,

Horizontal pressure at V tending to push TV backwards $=p+\frac{dp}{dx}h$.

Difference, tending to push TV forwards $=-\frac{dp}{dx}h$.

The length of the column TV on which it acts is nearly h: therefore the pressure tends to urge it forwards with an acceleration represented by $-\frac{dp}{dx}$. If, besides, any force depending on extraneous causes is acting, which would produce an acceleration represented by F, the whole acceleration will be $F-\frac{dp}{dx}$. Thus we have

$$\frac{d^2(x+X)}{dt^2}=F-\frac{dp}{dx}.$$

But x does not depend on t, therefore $\frac{d^2(x+X)}{dt^2}=\frac{d^2X}{dt^2}$. And, putting for p its value, we finally obtain this equation,

Equation of equal pressure.

$$\frac{d^2X}{dt^2}=F+\frac{d}{dx}\left\{-g'(k+K-y)-\int_y \frac{d^2Y}{dt^2}\,(y \text{ to } k)\right\}.$$

This may be called the equation of equal pressure.

This equation, in conjunction with the equation

$$Y=\Xi.\frac{d\eta}{dx}-\int_y \frac{dX}{dx}\,(\eta \text{ to } y),$$

contains the whole theory of the motion of fluids in canals, of uniform breadth, but of uniform or variable depth, the motion being supposed to be entirely longitudinal and vertical.

Equation of equal pressure when gravity is uniform.

(150.) If gravity be considered uniform, and $=g$, the term $\frac{d}{dx}\{-g'(k+K-y)\}$ becomes $\frac{d}{dx}(-gk+gy-gK)$ $=\frac{d}{dx}(-gK)$: and the equation of equal pressure becomes

$$\frac{d^2X}{dt^2}=F+\frac{d}{dx}\left\{-gK-\int_y \frac{d^2Y}{dt^2}\,(y \text{ to } k)\right\}.$$

Equation of continuity when the depth is uniform.

If the depth of the canal be uniform, $\frac{d\eta}{dx}=0$, and the equation of continuity, taking $\eta=0$, or assuming y to be measured from the bottom, becomes

$$Y=-\int_y \frac{dX}{dx}\,(0 \text{ to } y).$$

(151.) In the treatment of these equations, different methods must be used, according to the demands of the problem. If the nature of the motion in the direction of x be assumed; that is, if the expression for X be known, and if it be required to find what force is necessary to maintain the fluid in that state of motion; then we must, from the given expression for X, find the expression for Y by the equation of continuity; and, substituting both in the equation of equal pressure, we shall obtain F. But if F be given, and X and Y be required, we can only eliminate Y by means of the equation of continuity, and then solve the equation for X by methods depending on the form of the resulting equation.

(152.) If there be no motion of the particles, $0=\mathrm{F}-\frac{d}{dx}(g'.\overline{k+\mathrm{K}-y})$; or, if gravity be constant, $0=\mathrm{F}-g\frac{d\mathrm{K}}{dx}$.

Equations limited to oscillatory motion.

(153.) Hitherto we have not, in the investigation, limited ourselves in any way to the case of oscillating motion of the particles: the equations are, in fact, perfectly general as to the kind of longitudinal and vertical motion, and require only that the motion be small in extent. We shall now assume that the motion is oscillating; and, for the reason mentioned in (142.), we shall confine the expression for X or Y to a single term represented by a cosine or sine. Now suppose X to be represented by A cos (nt—B), where A and B are any functions whatever of x and y. (This is the most general form that can be assumed: it does not even imply that the form or magnitude of the waves is uniform, or that the motions of particles, originally in the same vertical column, are constantly in the same direction.) Then $\frac{d^2\mathrm{X}}{dt^2}=-n^2\mathrm{A}\cos(nt-\mathrm{B})=-n^2\mathrm{X}$. And as, in consequence of the equation of continuity, Y will necessarily depend on the sines or the cosines of the same angle $nt-\mathrm{B}$, we shall also have $\frac{d^2\mathrm{Y}}{dt^2}=-n^2\mathrm{Y}$. Thus the equation of equal pressure becomes

$$-n^2\mathrm{X}=\mathrm{F}+\frac{d}{dx}\{-g'(k+\mathrm{K}-y)+n^2\textstyle\int_y\mathrm{Y}\ (y\text{ to }k)\};$$

or, if gravity is considered as uniform,

$$-n^2\mathrm{X}=\mathrm{F}+\frac{d}{dx}\{-g\mathrm{K}+n^2\textstyle\int_y\mathrm{Y}\ (y\text{ to }k)\}.$$

We shall now proceed with some applications of these equations.

(154.) Problem.—To examine whether it is possible that a system of waves, depending upon oscillatory motion of the particles of water, can move along a canal of uniform breadth, but of variable depth: gravity being supposed uniform, and no other force being supposed to act.

Investigation of the possibility of unbroken waves when the depth is variable.

(155.) The equations to be satisfied are

$$\mathrm{Y}=\Xi.\frac{d\eta}{dx}-\int_y\frac{d\mathrm{X}}{dx}(\eta\text{ to }y)$$

$$-n^2\mathrm{X}=\frac{d}{dx}\{-g\mathrm{K}+n^2\textstyle\int_y\mathrm{Y}\ (y\text{ to }k)\}.$$

Differentiating the first with respect to y and to x,

$$\frac{d\mathrm{Y}}{dy}=-\frac{d\mathrm{X}}{dx}$$

$$\frac{d^2\mathrm{Y}}{dy\,dx}=-\frac{d^2\mathrm{X}}{dx^2}.$$

The second equation, observing that the limits of integration of $\int_y\mathrm{Y}$ are independent of x, may be put under this form,

$$-n^2\mathrm{X}=-g.\frac{d\mathrm{K}}{dx}-n^2\int_y\frac{d\mathrm{Y}}{dx}(k\text{ to }y).$$

Differentiating with respect to y,

$$-n^2\frac{d\mathrm{X}}{dy}=-n^2\frac{d\mathrm{Y}}{dx},\quad\text{or}\ \frac{d\mathrm{X}}{dy}=\frac{d\mathrm{Y}}{dx}.$$

Differentiating again with respect to y,

$$\frac{d^2\mathrm{X}}{dy^2}=\frac{d^2\mathrm{Y}}{dx\,dy}.$$

Eliminating $\frac{d^2\mathrm{Y}}{dx\,dy}$ by means of the former equation,

$$\frac{d^2\mathrm{X}}{dy^2}+\frac{d^2\mathrm{X}}{dx^2}=0,$$

the general solution of which equation is

$$\mathrm{X}=\phi(y+x\sqrt{-1})+\psi(y-x\sqrt{-1}),$$

where ϕ and ψ express functions chosen to satisfy any conditions required by the circumstances of the problem.

If, instead of ϕ and ψ, we use two other functions χ and ω, we may put the solution under this form,

$$X=\{\chi(y+x\sqrt{-1})+\chi(y-x\sqrt{-1})\}+\frac{1}{\sqrt{-1}}\{\omega(y+x\sqrt{-1})-\omega(y-x\sqrt{-1})\}$$

Sect. Theor Wave

the whole of which is real, whatever be the form of the functions χ and ω, provided that they contain, in their form, nothing imaginary.

Subs Gene Equa of W

(156.) But the expression just found is the solution of the *derived* equation. We have now to ascertain whether it will satisfy the *original* equations. For convenience we will confine our substitution to a single term (as the result produced by another term will be easily inferred from its result), and will make

$$X=v'(y+x\sqrt{-1}),$$

conceiving v' to be the derived function of some function v. Then

$$\frac{dX}{dx}=\sqrt{-1}.v''(y+x\sqrt{-1})$$

$$\int_y\frac{dX}{dx}=\sqrt{-1}.v'(y+x\sqrt{-1})$$

therefore $-\int_y\frac{dX}{dx}$ from η to y is $\quad\sqrt{-1}\,v'(\eta+x\sqrt{-1})-\sqrt{-1}.v'(y+x\sqrt{-1})$;

Also Ξ, or the value of X when $y=\eta$, $\quad=v'(\eta+x\sqrt{-1})$,

therefore $\quad\Xi\frac{d\eta}{dx}=v'(\eta+x\sqrt{-1})\frac{d\eta}{dx}.$

Hence

$$Y=\Xi\frac{d\eta}{dx}-\int_y\frac{dX}{dx}(\eta\text{ to }y)=v'(\eta+x\sqrt{-1})\left(\frac{d\eta}{dx}+\sqrt{-1}\right)-\sqrt{-1}.v'(y+x\sqrt{-1})$$

$$=\frac{d}{dx}.v(\eta+x\sqrt{-1})-\sqrt{-1}.v'(y+x\sqrt{-1}).$$

And K, or the value of Y when $y=k$, $\quad=\frac{d}{dx}.v(\eta+x\sqrt{-1})-\sqrt{-1}.v'(k+x\sqrt{-1})$;

therefore $\quad g\frac{dK}{dx}=g\frac{d^2}{dx^2}v(\eta+x\sqrt{-1})+g.v''(k+x\sqrt{-1}).$

And $\quad\frac{dY}{dx}=\frac{d^2}{dx^2}v(\eta+x\sqrt{-1})+v''(y+x\sqrt{-1})$;

therefore $\int_y\frac{dY}{dx}(y\text{ to }k)$ is $\quad(k-y)\frac{d^2}{dx^2}v(\eta+x\sqrt{-1})+v'(k+x\sqrt{-1})-v'(y+x\sqrt{-1}).$

Substituting these in the equation $\quad-n^2X=-g\frac{dK}{dx}+n^2\int_y\frac{dY}{dx}(y\text{ to }k)$,

$$-n^2.v'(y+x\sqrt{-1})=-g\frac{d^2}{dx^2}v(\eta+x\sqrt{-1})-gv''(k+x\sqrt{-1})+n^2(k-y)\frac{d^2}{dx^2}v(\eta+x\sqrt{-1})$$
$$+n^2v'(k+x\sqrt{-1})-n^2v'(y+x\sqrt{-1}).$$

Removing the terms which mutually destroy each other, and conceiving the same substitution to be made for a term $v'(y-x\sqrt{-1})$, we shall have this equation,

$$0=(n^2k-n^2y-g)\frac{d^2}{dx^2}\{v(\eta+x\sqrt{-1})+v(\eta-x\sqrt{-1})\}-g\{v''(k+x\sqrt{-1})+v''(k-x\sqrt{-1})\}$$
$$+n^2\{v'(k+x\sqrt{-1})+v'(k-x\sqrt{-1})\}$$

(157.) It is evident, from the form of the multipliers, and the perfect independence of x and y, that this equation implies the existence of the separate equations.

$$0=\frac{d^2}{dx^2}\left\{v(\eta+x\sqrt{-1})+v(\eta-x\sqrt{-1})\right\}$$

$$0=-g\{v''(k+x\sqrt{-1})+v''(k-x\sqrt{-1})\}+n^2\{v'(k+x\sqrt{-1})+v'(k-x\sqrt{-1})\}$$

When the depth is variable, that is, when η is a function of x, it does not appear possible to satisfy the first of these equations by any form of v. It would appear, therefore, that when the depth is variable, it is impossible that there can be a series of waves which consist of oscillatory motion of the particles, and which satisfy the two equations of continuity and of equal pressure.

(158.) The following physical interpretation of this mathematical result appears to be correct, and is worthy of attention. It appears that, if the water is moving in the manner of waves, one at least of the two conditions (continuity and equal pressure) must fail. While the continuity holds, the equal pressure will exist, from the nature of the fluid. Therefore the continuity must cease, or the water must become *broken*. This appears to be the explanation of the broken water which is usually seen upon the edge of a shoal or a ledge of rocks, although the whole is covered, perhaps deeply, by the water. We shall advert again to this subject.

Waves consisting of oscillatory motion not possible when the depth is not uniform.

(159.) When the depth is uniform, or $\eta=0$, there is no difficulty in satisfying the equation. For instance, if $v(\theta)=\varepsilon^{m\theta}-\varepsilon^{-m\theta}$, the expression $v\,(y+x\sqrt{-1})+v\,(y-x\sqrt{-1})$ becomes $2\,(\varepsilon^{my}-\varepsilon^{-my})\,.\cos mx$, which when $y=0$ is always$=0$. Any other form of $v\,(\theta)$ expressed by odd powers only of θ would do equally well.

Subsection 2.—Investigation of the Motion of Waves in a Canal of uniform Depth, the Motions being small.

(160.) We shall assume (as a hypothesis to be proved or disproved by substitution in the equations) that the motion of the waves is uniform, and that all the motions of the particles, horizontal and vertical, are oscillatory; but we shall not, in the first instance, assume that the motions of all the particles in the same vertical line are of the same kind at the same instant. This will be expressed by assuming

$$X=P.\cos\,(nt-mx-Q)$$

where m is constant and P and Q may be functions of y.

Expanding the cosine, and making $P.\cos Q=R$, $P.\sin Q=S$, this becomes

$$X=R.\cos\,(nt-mx)+S.\sin\,(nt-mx).$$

(161.) Now, as we have found (155.), $\dfrac{d^2X}{dy^2}+\dfrac{d^2X}{dx^2}=0$: which in the present instance becomes

$$\left(\frac{d^2R}{dy^2}-m^2R\right)\cos\,(nt-mx)+\left(\frac{d^2S}{dy^2}-m^2S\right)\sin\,(nt-mx)=0.$$

Therefore $$\frac{d^2R}{dy^2}-m^2R=0,\qquad \frac{d^2S}{dy^2}-m^2S=0;$$

whence $$R=C.\varepsilon^{my}+D.\varepsilon^{-my},\qquad S=C'.\varepsilon^{my}+D'.\varepsilon^{-my},$$

and $$X=(C.\varepsilon^{my}+D.\varepsilon^{-my})\cos\,(nt-mx)+(C'.\varepsilon^{my}+D'.\varepsilon^{-my})\sin\,(nt-mx).$$

And as $Y=-\int_y\dfrac{dX}{dx}$ (0 to y), we easily find

$$Y=-(C\varepsilon^{my}-D\varepsilon^{-my}-C+D)\sin\,(nt-mx)+(C'.\varepsilon^{my}-D'.\varepsilon^{-my}-C'+D')\cos\,(nt-mx)$$

$$K=-(C\varepsilon^{mk}-D\varepsilon^{-mk}-C+D)\sin\,(nt-mx)+(C'.\varepsilon^{mk}-D'.\varepsilon^{-mk}-C'+D')\cos\,(nt-mx)$$

$$\frac{dY}{dx}=+m\,(C\varepsilon^{my}-D\varepsilon^{-my}-C+D)\cos\,(nt-mx)+m\,(C'.\varepsilon^{my}-D'.\varepsilon^{-my}-C'+D')\sin\,(nt-mx)$$

$$\int_y\frac{dY}{dx}\,(y\text{ to }k)=$$

$$-\{C\varepsilon^{my}+D\varepsilon^{-my}-C\varepsilon^{mk}-D\varepsilon^{-mk}+m.\overline{y-k}\,.\,\overline{-C+D}\}\cos\,(nt-mx)$$
$$-\{C'.\varepsilon^{my}+D'.\varepsilon^{-my}-C'.\varepsilon^{mk}-D'.\varepsilon^{-mk}+m.\overline{y-k}\,.\,\overline{-C'+D'}\}\sin\,(nt-mx)$$

Substituting in the equation $-n^2X=-g\dfrac{dK}{dx}+n^2\displaystyle\int_y\dfrac{dY}{dx}\,(y\text{ to }k)$

$$-n^2\,(C\varepsilon^{my}+D\varepsilon^{-my})\cos\,(nt-mx)-n^2\,(C'.\varepsilon^{my}+D'.\varepsilon^{-my})\sin\,(nt-mx)=$$
$$-mg\,(C\varepsilon^{mk}-D\varepsilon^{-mk}-C+D)\cos\,(nt-mx)-mg\,(C'.\varepsilon^{mk}-D'\varepsilon^{-mk}-C'+D')\sin\,(nt-mx)$$
$$-n^2\,\{C\varepsilon^{my}+D\varepsilon^{-my}-C\varepsilon^{mk}-D\varepsilon^{-mk}+m.\overline{y-k}.\overline{-C+D}\}\cos\,(nt-mx)$$
$$-n^2\,\{C'.\varepsilon^{my}+D'.\varepsilon^{-my}-C'.\varepsilon^{mk}-D'.\varepsilon^{-mk}+m.\overline{y-k}.\overline{-C'+D'}\}\sin\,(nt-mx)$$

Removing the terms which destroy each other, equating separately the coefficients of cos $(nt-mx)$ and of sin $(nt-mx)$, and observing that y is entirely independent of k, we obtain in the first place

$$-C+D=0 \qquad -C'+D'=0: \qquad \text{or } D=C, \qquad D'=C'.$$

Substituting these values of D and D′ in the other equations, they become

$$-mg\,C\,(\varepsilon^{mk}-\varepsilon^{-mk})+n^2\,C.\,(\varepsilon^{mk}+\varepsilon^{-mk})=0$$
$$-mg\,C'\,(\varepsilon^{mk}-\varepsilon^{-mk})+n^2\,C'\,(\varepsilon^{mk}+\varepsilon^{-mk})=0.$$

These equations leave C and C′ indeterminate; and they agree in giving the following relation between m and n,

$$n^2=mg.\,\frac{\varepsilon^{mk}-\varepsilon^{-mk}}{\varepsilon^{mk}+\varepsilon^{-mk}}.$$

Then, substituting in R and S the values of D and D′,

$$X=(\varepsilon^{my}+\varepsilon^{-my}).\{C\cos(nt-mx)+C'\sin(nt-mx)\};$$

Expressions for displacement of particles in wave-motion when the depth is uniform.

or if $A=\sqrt{C^2+C'^2}$, $\tan B=\frac{C'}{C}$; then $C=A\cos B$, $C'=A\sin B$, and the expression becomes

$$X=A.\,(\varepsilon^{my}+\varepsilon^{-my}).\,\cos(nt-mx-B)$$

where A and B are independent of x and y, and m depends upon n by the equation above. From this we easily find

$$Y=-A.\,(\varepsilon^{my}-\varepsilon^{-my}).\,\sin(nt-mx-B).$$

(162.) From these expressions it appears, as B is constant, that the mathematical results compel us to admit (what we did not at first assume) that the motion of all the particles originally in the same vertical line is, at any instant, of the same kind, although the extent of the motion of the different particles is very different. In future we shall generally omit B from the expression, as the same effect will be produced in the value of the expression by altering the origin of the time as by retaining B.

Explanation of terms.

(163.) It will be convenient to explain here a few terms which will hereafter be occasionally used.

Phase.

(164.) The angle $nt-mx-B$, or $nt-mx$, upon which the expressions for X and Y depend, is called the *phase* of the wave. It is to be considered as an angle, or rather as part of a circle (in the sense in which trigonometrical expressions depend upon an angle or part of a circle) which admits of indefinite increase.

(165.) The expressions for X and Y are not altered in value if we increase or diminish mx by 2π, 4π, 6π, &c.: that is, if we increase or diminish x by $\frac{2\pi}{m}$, $\frac{4\pi}{m}$, $\frac{6\pi}{m}$, &c., while t is unaltered: but the same cannot be asserted of any other value of x. Hence $\frac{2\pi}{m}$ is the value of each of the successive distances at which we find the water in the same state of disturbance, or $\frac{2\pi}{m}$ is the distance between one wave and the next. We shall call this the *length of a wave*, or the *amplitude of a wave*, and shall denote it by the symbol λ.

Length of wave.

(166.) The expressions for X and Y are not altered in value if we increase or diminish nt by 2π, 4π, 6π, &c., that is, if we increase or diminish t by $\frac{2\pi}{n}$, $\frac{4\pi}{n}$, $\frac{6\pi}{n}$, &c., while x is unaltered: but the same cannot be asserted of any other value of t. Hence $\frac{2\pi}{n}$ represents each of the intervals of time at which the water at any given place is successively in the same state of disturbance: we shall call this the *period* of a wave and shall denote it by the symbol τ.

Period of wave.

(167.) We shall now proceed to develope some of the practical interpretations of the equations just found.

(168.) Since X and Y both depend on $nt-mx$, if we put $t+t'$ for t, and $x+x'$ for x, we shall find new values X′ and Y′ depending on $nt-mx+nt'-mx'$; and these will be the same as X and Y if $nt'-mx'$ be zero: that is, at the end of the interval t', we shall find the water in a similar state of displacement, provided we examine it at the distance x' in advance: that is, in the time t' the wave will have travelled through the space x', or the velocity of the wave will be expressed by $\frac{x'}{t'}$; which, by virtue of the equation $nt'-mx'=0$, is the same as $\frac{n}{m}$. Hence

$$\text{Velocity of the wave}=\frac{n}{m}.$$

But we have found $n^2 = gm . \frac{\varepsilon^{mk} - \varepsilon^{-mk}}{\varepsilon^{mk} + \varepsilon^{-mk}}$: hence the velocity$= \sqrt{\frac{n^2}{m^2}} = \sqrt{\left\{\frac{g}{m} . \frac{\varepsilon^{mk} - \varepsilon^{-mk}}{\varepsilon^{mk} + \varepsilon^{-mk}}\right\}}$. This expression is not constant, but depends on m and k. From this it appears—

Inferences with regard to the velocity of waves.

1st. In water of given depth, the velocity of waves of all kinds is not the same, but depends upon m, or upon $\frac{2\pi}{m}$, or upon λ the length of the wave. (In this respect the waves of water are analogous to those of light, but are not analogous to those of sound.)

2nd. It follows immediately that, in water of given depth, the velocity of waves depends upon the interval of time at which they follow each other.

3rd. If the distance between the crests of the waves $\left(\lambda \text{ or } \frac{2\pi}{m}\right)$ is given, the velocity varies with the depth of the water.

4th. If the interval of time between successive waves $\left(\tau \text{ or } \frac{2\pi}{n}\right)$ is given, the velocity varies with the depth of the water.

(169.) The circumstances of waves of different lengths will easily be reduced to numerical calculation, if for n we put $\frac{2\pi}{\tau}$, and for m we put $\frac{2\pi}{\lambda}$; the equation between n and m is thus brought to the following form:

$$\tau^2 = \frac{2\pi\lambda}{g} . \frac{\varepsilon^{\frac{4\pi k}{\lambda}} + 1}{\varepsilon^{\frac{4\pi k}{\lambda}} - 1};$$

where it is to be remarked that $\varepsilon^{\frac{4\pi k}{\lambda}}$ is the number whose common logarithm is $\frac{4\pi k}{\lambda} \times 0{\cdot}434294$. If the time is expressed in seconds, and the space in feet, g (or the velocity which gravity communicates to a free body in one second), expressed in the same manner, is 32·16. From these data the following table is computed:

Table of the periods of waves.

TABLE I.

Depth of water, in feet.	Length of the wave, in feet.								
	1	10	100	1000	10,000	100,000	1000,000	10,000,000	100,000,000
	Corresponding period of wave, in seconds.								
1	0·442	1·873	17·645	176·33	1763·3	17633	176330	1763300	17633000
10	0·442	1·398	5·923	55·800	557·62	5576·2	55762	557620	5576200
100	0·442	1·398	4·420	18·730	176·45	1763·3	17633	176330	1763300
1000	0·442	1·398	4·420	13·978	59·230	558·00	5576·2	55762	557620
10,000	0·442	1·398	4·420	13·978	44·201	187·30	1764·5	17633	176330
100,000	0·442	1·398	4·420	13·978	44·201	139·78	592·30	5580	55762
1000,000	0·442	1·398	4·420	13·978	44·201	139·78	442·01	1873	17645

(170.) From these numbers the velocities are easily computed by dividing the length of the wave by the period. The following table contains the results:—

Table of the velocities of waves.

TABLE II.

Depth of water, in feet.	Length of the wave, in feet.									
	1	10	100	1000	10,000	100,000	1000,000	10,000,000	100,000,000	Infinite.
	Corresponding velocity of wave per second, in feet.

1000,000	2·2624	7·1543	22·624	71·543	226·24	715·43	2262·4	5339·0	5667·2	5671·0

The velocity of short waves does not depend on the depth.

The velocity of long waves depends only on the depth.

(171.) From these numbers it appears that,

1st. When the length of the wave is not greater than the depth of the water, the velocity of the wave depends (sensibly) only on its length, and is proportional to the square root of its length.

2nd. When the length of the wave is not less than a thousand times the depth of the water, the velocity of the wave depends (sensibly) only on the depth, and is proportional to the square root of the depth. It is, in fact, the same as the velocity which a free body would acquire by falling from rest, under the action of gravity, through a height equal to half the depth of the water.

3rd. For intermediate proportions of the length of the wave and the depth of the water, the velocity of the wave can be found only by means of the general equation.

(172.) The values in the extreme cases will easily be found by expansion of the general formula. Thus, when λ is small, or $\frac{k}{\lambda}$ large, $\varepsilon^{\frac{4\pi k}{\lambda}}$ is very large: $\frac{\varepsilon^{\frac{4\pi k}{\lambda}}+1}{\varepsilon^{\frac{4\pi k}{\lambda}}-1}$ does not sensibly differ from unity, and $\tau^2=\frac{2\pi\lambda}{g}$: whence the velocity $=\frac{\lambda}{\tau}=\sqrt{\frac{g\lambda}{2\pi}}$. When λ is large, or $\frac{k}{\lambda}$ small, $\varepsilon^{\frac{4\pi k}{\lambda}}=1+\frac{4\pi k}{\lambda}$ nearly, and $\tau^2=\frac{\lambda^2}{gk}$; whence the velocity $=\frac{\lambda}{\tau}=\sqrt{gk}$.

(173.) There is one numerical value of τ which, in reference to future applications, deserves special consideration—it is that corresponding to the wave originally produced by the action of the Sun and Moon. This wave may with propriety be called the tide-wave. But for clearness we may remark (although anticipating another part of this Section), that there are two distinct classes of waves bearing the name *tide-wave*. One of them is produced by the immediate action of the forces of the Sun and Moon, and its highest or its lowest point is always at a determinate distance from that place in the canal at which the disturbing forces vanish; the velocity, therefore, of this wave does not depend at all upon the depth of the water. This we shall call the *forced tide-wave*. Coexistent with this there may be, and generally is, a wave in which the period τ is the same, but in which λ is different, and the velocity consequently different; produced originally by the action of the Sun and Moon, but not affected by their action in regard to its velocity of propagation: this kind of tide-wave is the only one which is sensible in narrow seas and rivers. This we shall call the *free tide-wave*. Our present computations belong to the *free* tide-wave only.

(174.) The interval of time (τ) for the semidiurnal tide-wave is not constant; but it may be considered as 12 hours 24 minutes, or 44,640 seconds. Now we have found, Table II., that with a depth of water of 100,000 feet, or 20 miles nearly, a wave of any length exceeding 100,000,000 feet will travel with a velocity sensibly independent of its length; and that even if its length be only 10,000,000 feet, the velocity will not differ from that of a longer wave by $\frac{1}{1500}$ part. The former wave, by Table I., would have the period 55,762 seconds; the latter would have the period 5580 seconds. It is clear that the period of the tide-wave is sufficient to justify us in assuming the velocity of the *free* tide-wave as equal to that which belongs properly to a wave of indefinite length in water of the same depth. On this principle the following table is computed:—

Table for the semidiurnal free tide-wave.

TABLE III.

Depth of water, in feet.	Velocity of free tide-wave per second, in feet.	Length of free tide-wave, in miles.	Space described by free tide-wave in one hour, in miles.	Depth of water, in feet.	Velocity of free tide-wave per second, in feet.	Length of free tide-wave, in miles.	Space described by free tide-wave in one hour, in miles.

(175.) The diurnal tide-wave, and others connected with the tides, of which we shall have occasion to speak, so far as they are *free* tide-waves, may all be considered as moving with the same velocity. The table will, therefore, apply to them, excepting only the column of the *length of the tide-wave*, the numbers in which must be doubled for the diurnal tide-wave.

(176.) We shall now proceed to examine the circumstances of the motion of each particle of water in wave-motion. And, first, we shall consider the values of the extreme extent of motion of each particle.

Formulæ for extreme motion of individual particles.

(177.) We have found (161.) that the horizontal displacement X of any particle, whose height above the bottom is y, is represented by $A(\varepsilon^{my}+\varepsilon^{-my})\cos(nt-mx-B)$. The extreme values of this quantity are $-A(\varepsilon^{my}+\varepsilon^{-my})$ when $nt-mx-B$ is an odd multiple of 180°, and $+A(\varepsilon^{my}+\varepsilon^{-my})$ when $nt-mx-B$ is an even multiple of 180°. And (161.) the vertical displacement Y of the same particle is represented by $-A(\varepsilon^{my}-\varepsilon^{-my})\sin(nt-mx-B)$; the extreme values of which are $-A(\varepsilon^{my}-\varepsilon^{-my})$ when $nt-mx-B=90°+$ an even multiple of 180°, and $+A(\varepsilon^{my}-\varepsilon^{-my})$ when $nt-mx-B=90°+$ an odd multiple of 180°. Hence $A(\varepsilon^{my}+\varepsilon^{-my})$ and $A(\varepsilon^{my}-\varepsilon^{-my})$ may be considered as representing the greatest extent of horizontal and vertical motions; or, omitting A (as our object is only to show the proportion of the various motions), and putting $\frac{2\pi}{\lambda}$ for m, the horizontal and vertical motions will be represented respectively by $\varepsilon^{\frac{2\pi y}{\lambda}}+\varepsilon^{-\frac{2\pi y}{\lambda}}$ and $\varepsilon^{\frac{2\pi y}{\lambda}}-\varepsilon^{-\frac{2\pi y}{\lambda}}$. At the bottom, where $y=0$, the extreme horizontal motion will be represented by $\varepsilon^{0}+\varepsilon^{0}=2$. By means of these formulæ the following table is computed :—

Table of proportional extent of horizontal and vertical motions.

TABLE IV.

Greatest extent of the horizontal and vertical displacements of the particles at different depths, for different proportions of the length of the wave to the whole depth: the greatest horizontal displacement of the particles at the bottom being represented by 2.

In this table, by 1(27287 figures) is meant the figure 1 followed by 27287 significant figures before the decimal point; and similarly 2(24558 figures) is intended to express the figure 2 followed by 24558 figures before the decimal point; and so for the others.

(178.) From inspection of this table the following points are evident:

When the wave is short, the motion is not sensible except near the surface.

1st. When the depth is great in comparison with the length of the wave (as in the case of ordinary waves in the open sea), the motion of the water at any great depth below the surface is wholly insignificant in comparison with that at the surface. The following rule may be convenient. As the depth below the surface proceeds in arithmetical progression, the motion diminishes in geometrical progression; and at a depth equal to the length of the wave the motion is diminished to $\frac{1}{535 \cdot 4}$ of that at the surface. This rule will be demonstrated by remarking that when $\frac{k}{\lambda}$ is large and therefore $\frac{y}{\lambda}$ is large (the depths below the surface not being extremely great) $\varepsilon^{mk}+\varepsilon^{-mk}$, or $\varepsilon^{\frac{2\pi}{\lambda}}+\varepsilon^{-\frac{2\pi k}{\lambda}}$, and $\varepsilon^{my}+\varepsilon^{-my}$, or $\varepsilon^{\frac{2\pi y}{\lambda}}+\varepsilon^{-\frac{2\pi y}{\lambda}}$, will, as to sense, be reduced to their first terms $\varepsilon^{\frac{2\pi k}{\lambda}}$ and $\varepsilon^{\frac{2\pi y}{\lambda}}$: and therefore the motion at the depth $k-y$ will $=$ motion at surface $\times \frac{\varepsilon^{\frac{2\pi y}{\lambda}}}{\varepsilon^{\frac{2\pi k}{\lambda}}} =$ motion at surface $\times \varepsilon^{-\frac{2\pi}{\lambda}(k-y)}$, or the motion diminishes in geometrical progression, as the depth $k-y$ increases in arithmetical progression. And if $k-y=\lambda$, the motion at the depth $\lambda=$motion at surface $\times \varepsilon^{-2\pi}=$ motion at surface $\times \frac{1}{535 \cdot 4}$.

The horizontal and vertical motions are equal.

(179.) 2d. On the same supposition, the greatest horizontal motion of any particle is equal to its greatest vertical motion: except for those particles very near to the bottom, where the whole motion is insensible.

When the wave is long, the horizontal motion is nearly the same at all depths.

(180.) 3d. When the length of the wave is great in comparison with the depth of the water, (as in the case of tide-waves,) the horizontal motion is sensibly the same from the surface to the bottom, and the vertical motion for different particles varies in the same proportion as their height above the bottom.

The vertical motion is much less than the horizontal motion.

(181.) 4th. On the same supposition the vertical motion of the superficial particles is very much less than their horizontal motion. The proportion of the vertical motion to the horizontal motion is $\frac{\varepsilon^{\frac{2\pi k}{\lambda}}-\varepsilon^{-\frac{2\pi k}{\lambda}}}{\varepsilon^{\frac{2\pi k}{\lambda}}+\varepsilon^{-\frac{2\pi k}{\lambda}}}$: and when $\frac{2\pi k}{\lambda}$ is small, $\varepsilon^{\frac{2\pi k}{\lambda}}-\varepsilon^{-\frac{2\pi k}{\lambda}}$ is nearly equal to $\frac{4\pi k}{\lambda}$, and $\varepsilon^{\frac{2\pi k}{\lambda}}+\varepsilon^{-\frac{2\pi k}{\lambda}}$ is nearly equal to 2: and thus the proportion of the vertical motion of the superficial particles to the horizontal motion is $\frac{4\pi k}{2\lambda}$ $=6 \cdot 2832 \times \frac{k}{\lambda}$.

When the waves are short, each particle at the surface moves uniformly in a circle.

(182.) We shall now examine the curve described by any individual particle. And first, the motion of a particle at the surface in ordinary small waves. We have seen that, in this case, the horizontal displacement $X = A . \varepsilon^{\frac{2\pi k}{\lambda}} . \cos(nt - mx - B)$ $\left\{\text{neglecting the insignificant term } \varepsilon^{-\frac{2\pi k}{\lambda}}\right\}$, which we will call $C . \cos(nt - mx - B)$. In like manner, the vertical displacement $Y = -A . \varepsilon^{\frac{2\pi k}{\lambda}} . \sin(nt - mx - B) = -C . \sin(nt - mx - B.)$ Therefore $\sqrt{X^2 + Y^2}$, or the particle's whole distance from the point whose co-ordinates are x and y (which do not vary with the time) is $= C$. That is, any particle is, at any instant whatever, somewhere in the circumference of a circle, whose centre is the fixed point defined by the co-ordinates x and y, and whose radius is C or $A . \varepsilon^{\frac{2\pi k}{\lambda}}$. Let θ be the angle made with the vertical by the radius joining the particle and the point whose ordinates are x, y; considered positive when the particle is *above* that point, and *advanced before* it. Then $\tan\theta = \frac{X}{Y} = -\frac{C . \cos(nt - mx - B)}{C . \sin(nt - mx - B)} = -\cot(nt - mx - B) = \tan(nt - mx - B + 90°)$, or $\theta = nt - mx - B + 90°$. As the time t increases uniformly, the angle θ increases uniformly. Consequently the particle revolves uniformly in the circle of which we have spoken; moving forwards when at the highest part of the circle, and backwards when at the lowest part. The same applies to particles below the surface, except those nearly in contact with the bottom.

In all other cases, each particle moves in an ellipse.

(183.) In all other cases, and especially when the length of the wave is great in proportion to the depth of the water, or $\frac{k}{\lambda}$ is small, the coefficients entering into the expressions (which are the same as the greatest motions, whose proportions are given by the numbers in Table IV.) are very different. Representing X by $C . \cos\overline{nt - mx - B}$ and Y by $-c . \sin\overline{nt - mx - B}$, we shall have $\frac{X^2}{C^2} + \frac{Y^2}{c^2} = 1$: the equation to an ellipse whose semiaxes are C and c. The particle therefore will always be found in the circumference of an ellipse whose centre is the point of which the co-ordinates are x, y. In the case of the tide-wave, this ellipse is extremely flat.

The water at the top of the wave moves most rapidly forward.

(184.) But in the tide-wave, and every other wave, which travels along a channel in the manner which we have supposed in this subsection, this law is universal: that the water is travelling forward with its greatest speed at the time of high water, or at the top of the wave. This follows clearly enough from the theorems that we have laid down (that in small waves every particle moves uniformly in a circle, and therefore each particle has its most rapid motion forwards when it is highest: and that in long waves the motions in the two ordinates are expressed by the same law with different coefficients): but it is so important that this should be clearly understood, that we think it necessary expressly to call the reader's attention to it. It will be easily shown by remarking that the horizontal velocity or $\frac{dX}{dt} = -n C . \sin\overline{nt - mx - B}$, and therefore the horizontal velocity forwards is in a constant proportion to Y the elevation of the water above its mean place. Thus when the water is highest, the velocity forward is greatest: when the water is at its mean height (whether before high water or after high water), Y is 0 and the water's velocity is 0, or it is still water: when the water is at its greatest depression, or Y has its greatest negative value, the water is running backwards with its greatest velocity. We shall consider this as the standard case in the theory of waves; and shall occasionally refer to it in noting the deviations from these laws which occur in particular circumstances.

That in the hollow of the wave moves most rapidly backwards.

(185.) Reverting now to the general equations of (150.) for shallow waves, supposing $F = 0$, namely, $Y = -\int_y \frac{dX}{dx}$ (0 to y): $\frac{d^2X}{dt^2} = \frac{d}{dx}\left\{-gK - \int_y \frac{d^2Y}{dt^2} (y \text{ to } k)\right\}$ we may make the following remarks.

First: having found that this equation is satisfied by a function of $+nt$, as $A(\varepsilon^{my} + \varepsilon^{-my}) . \cos(nt - mx)$, we can at once assert that it will be satisfied by the same function of $-nt$, or $A(\varepsilon^{my} + \varepsilon^{-my}) \cos(-nt - mx)$, or

$$A(\varepsilon^{my} + \varepsilon^{-my}) \cos(nt + mx).$$

Opposite waves.

For the only way in which the multiplier n affects the substitution of these quantities in the equation is by its influence in the second differential coefficients $\frac{d^2X}{dt^2}$ and $\frac{d^2Y}{dt^2}$: and these, by differentiation, obtain the same factor whether $+n$ or $-n$ be the multiplier of t. Thus, if $X = A(\varepsilon^{my} + \varepsilon^{-my}) \cos(nt - mx)$, $\frac{d^2X}{dt^2} = -n^2 X$: if $X = A(\varepsilon^{my} + \varepsilon^{-my}) \cos(-nt - mx)$, $\frac{d^2X}{dt^2}$ still $= -n^2 X$. Now an expression depending on $\cos(-nt - mx)$ or $\cos(nt + mx)$ will imply a wave, in the same manner as one depending on $\cos(nt - mx)$, but with this difference: that whereas in the latter case the wave moves in the direction of x, on the contrary, in the former case, the wave moves in the opposite direction, but with the same speed. This will be seen from the same reasoning as in (168.).

Combination of several waves.

(186.) Secondly: Having found any number of functions X′, X″, X‴, &c., with their corresponding functions Y′, Y″, Y‴, &c., K′, K″, K‴, &c., each of which satisfies the equations

$$\mathrm{Y}'=-\int_y \frac{d\mathrm{X}'}{dx},\quad \frac{d^2\mathrm{X}'}{dt^2}=\frac{d}{dx}\left\{-g\mathrm{K}'-\int_y \frac{d^2\mathrm{Y}'}{dt^2}\,(y \text{ to } k)\right\}, \text{\&c.}$$

Subsect. Motion of Waves in Canal of uniform Depth.

we see at once that the sum X′+X″+X‴+ &c., will satisfy the same equation. For upon adding together all the separate equations formed from X′, X″, X‴, &c. we produce the very same equation which would be formed by substituting the whole quantity X′+X″+X‴+, &c. Now each of the functions X′, X″, &c., with its related functions Y′, K′, Y″, K″, &c, represents a wave or system of waves; and our theorem therefore amounts to this: "If there are any number of systems of shallow waves which can exist separately on water, these waves can all exist together upon the water: the elevations being added at the places where they coincide, or the depression of one being subtracted from the elevation of another where the place of depression of one wave corresponds to the place of elevation of another, &c."

Combination of equal opposite waves.

(187.) One instance of this coexistence of waves may be mentioned as a matter of interest. Suppose two waves, equal in period, and equal in magnitude, to move in opposite directions upon a canal. In one of these, the expression for X′ will be

$$\mathrm{A}.(\varepsilon^{my}+\varepsilon^{-my})\cos(nt-mx+\mathrm{B});$$

in the other, the expression for X″ will be

$$\mathrm{A}.(\varepsilon^{my}+\varepsilon^{-my})\cos(nt+mx+\mathrm{B}').$$

The sum of these gives for the compounded wave X=X′+X″=

$$2\mathrm{A}.(\varepsilon^{my}+\varepsilon^{-my}).\cos\left(nt+\frac{\mathrm{B}+\mathrm{B}'}{2}\right).\cos\left(mx+\frac{\mathrm{B}'-\mathrm{B}}{2}\right).$$

And the corresponding value of $\mathrm{Y}=-\int_y \frac{d\mathrm{X}}{dx}=$

$$2\mathrm{A}.(\varepsilon^{my}-\varepsilon^{-my}).\cos\left(nt+\frac{\mathrm{B}+\mathrm{B}'}{2}\right).\sin\left(mx+\frac{\mathrm{B}'-\mathrm{B}}{2}\right),$$

from which K or the elevation of the surface =

$$2\mathrm{A}.(\varepsilon^{mk}-\varepsilon^{-mk}).\cos\left(nt+\frac{\mathrm{B}+\mathrm{B}'}{2}\right).\sin\left(mx+\frac{\mathrm{B}'-\mathrm{B}}{}\right).$$

From inspection of these expressions we may see that

Produces a stationary wave.

(188.) First, as neither X nor Y depends upon such a quantity as $pt-qx$, there is no appearance whatever of a progressive wave.

Each particle moves in a straight line.

(189.) Secondly; the displacement of any particle in the direction of x depends upon $\cos\left(nt+\frac{\mathrm{B}+\mathrm{B}'}{2}\right)$, (the factor $\cos\left(mx+\frac{\mathrm{B}'-\mathrm{B}}{2}\right)$ being constant for that particle,) and the displacement of the same particle in the direction of y depends also upon $\cos\left(nt+\frac{\mathrm{B}+\mathrm{B}'}{2}\right)$. Therefore, for any particle, the horizontal and vertical displacements are always in the same proportion, or each particle moves in a straight line.

(190.) Thirdly; at the places where $\cos\left(mx+\frac{\mathrm{B}'-\mathrm{B}}{2}\right)=0$, or where $mx+\frac{\mathrm{B}'-\mathrm{B}}{2}=\frac{\pi}{2}$, or $\frac{3\pi}{2}$, or $\frac{5\pi}{2}$, &c., there is no horizontal motion whatever, but there is great vertical motion.

(191.) Fourthly; at the places where $\sin\left(mx+\frac{\mathrm{B}'-\mathrm{B}}{2}\right)=0$, or where $mx+\frac{\mathrm{B}'-\mathrm{B}}{2}=0$, or π, or 2π, &c., there is no vertical motion whatever, but there is great horizontal motion.

Subsection 3.—Theory of Long Waves, in which the Elevation of the Water bears a sensible proportion to the depth of the Canal.

(192.) Hitherto we have considered the displacements of the particles to be so small that the squares and higher powers of those displacements might be neglected. In the following problem we shall take into account the higher orders of the displacements.

Problem.—To investigate the motion of a very long wave, as the tide-wave, in a canal whose depth is so small that the range of elevation and depression of the surface bears a considerable proportion to the whole depth.

Limitations permitted when the wave is very long.

(193.) We have seen, (180.) and (181.), that, for the tide-wave, the horizontal motion of the particles at different depths in the same vertical line is sensibly the same, and that the vertical motion is extremely small in comparison with the horizontal motion. We shall, therefore, assume that the horizontal motion is uniform for all particles in the same vertical; or that particles which are once in a vertical line remain in a vertical line. And we shall assume that, in estimating the pressure at any point, the height of water above that point is all that needs to be considered: the part represented in the former equations by $\frac{d^2Y}{dt^2}$ being insignificant on account of the smallness of the vertical motion. These assumptions are similar to those in (68.).

(194.) Let x be the horizontal ordinate corresponding to one vertical line of particles in their state of rest: $x+h$ that corresponding to another vertical line of particles; k the depth of the water in a state of rest. In the state of wave-motion, let the first-mentioned vertical line be displaced at the time t through the horizontal space X, so that its horizontal ordinate is $x+X$ (x being independent of t); and let V or $k+K$ be the corresponding depth of the water. Then, the horizontal ordinate which was x has now become $x+X$; that which was $x+h$ has now become $x+h+X+\frac{dX}{dx}h$ nearly: therefore the intermediate horizontal space which was h has now become $h\left(1+\frac{dX}{dx}\right)$. And the vertical elevation which was k has now become $k+K$ or V. Consequently, the volume which was expressed by $h\times k$ is now expressed by $h\left(1+\frac{dX}{dx}\right)\times V$. These expressions must be equal: therefore we have $h\times k=h\left(1+\frac{dX}{dx}\right)\times V$, or

$$V=\frac{k}{1+\frac{dX}{dx}}.$$

This is the equation of continuity for this case.

Equation of continuity, supposing the displacement to be large.

(195.) Now if we consider the pressure upon any particle whose coordinates are $x+X$ and y, as produced by the elevation of the water above it, we shall find it to be represented by the weight of a column of water whose length is $V-y$. In like manner, the pressure upon the particle whose ordinates are $x+h'+X+\frac{dX}{dx}h'$ and y, is represented by the weight of a column of water whose length is $V+\frac{dV}{dx}h'-y$. And as the pressures are equal in all directions, the horizontal pressures on the included horizontal column whose length is $h'\left(1+\frac{dX}{dx}\right)$, are the weights of columns of water, one represented by $V-y$, tending to push it forwards, and one represented by $V+\frac{dV}{dx}h'-y$, tending to push it backwards. Or, the pressure tending to push forwards the column $h'\left(1+\frac{dX}{dx}\right)$ is the weight of a column $\frac{-dV}{dx}h'$; and, therefore, the acceleration produced in the direction of x is $-g\frac{dV}{dx}\cdot\frac{1}{1+\frac{dX}{dx}}$; or $\frac{d^2(x+X)}{dt^2}=-g\frac{dV}{dx}\cdot\frac{1}{1+\frac{dX}{dx}}$. Observing that x is independent of t, and putting for V its value found above, we obtain the equation

$$\frac{d^2X}{dt^2}=gk\,\frac{\frac{d^2X}{dx^2}}{\left(1+\frac{dX}{dx}\right)^2},$$

in which equation $\left(\text{as the variations of V are not to be neglected, and as those variations depend on }\frac{dX}{dx}\right)$ we must not neglect $\frac{dX}{dx}$, although we may consider it small.

Equation of equal pressure.

(196.) This equation may be solved to any degree of approximation by successive substitution. Expanding the fraction, and (for convenience) putting v^2 for gk, the equation may be thus expressed:

$$\frac{d^2X}{dt^2}-v^2.\frac{d^2X}{dx^2}=v^2.\frac{d^2X}{dx^2}\times\left\{-3\frac{dX}{dx}+6\left(\frac{dX}{dx}\right)^2-\&c.\right\}.$$

First we may obtain an approximate value for X by neglecting all the terms on the second side of the equation; then, substituting that value in the first term on the second side, we shall have a more approximate value; and so on.

Solution to first approximation.

(197.) First approximation; $\frac{d^2X}{dt^2}-v^2\frac{d^2X}{dx^2}=0$. To solve this equation let $vt-x=u$, $vt+x=w$; and consider X as a function of u and w. Then $\frac{dX}{dt}=\frac{dX}{du}.\frac{du}{dt}+\frac{dX}{dw}.\frac{dw}{dt}=v\left(\frac{dX}{du}+\frac{dX}{dw}\right)$. Call this X′. Then $\frac{d^2X}{dt^2}=\frac{dX'}{dt}=v\left(\frac{dX'}{du}+\frac{dX'}{dw}\right)=v^2\left(\frac{d^2X}{du^2}+2\frac{d^2X}{du\,dw}+\frac{d^2X}{dw^2}\right)$. Also $\frac{dX}{dx}=\frac{dX}{du}.\frac{du}{dx}+\frac{dX}{dw}.\frac{dw}{dx}=-\frac{dX}{du}+\frac{dX}{dw}$. Call this X″. Then $\frac{d^2X}{dx^2}=\frac{dX''}{dx}=-\frac{dX''}{du}+\frac{dX''}{dw}=\frac{d^2X}{du^2}-2\frac{d^2X}{du\,dw}+\frac{d^2X}{dw^2}$. Substituting these in the equation, we have $4v^2.\frac{d^2X}{du\,dw}=0$, or $\frac{d^2X}{du\,dw}=0$. Integrating successively with regard to u and w, and remarking that the arbitrary constant at each integration may be an arbitrary function of the other variable, $\frac{dX}{dw}=\psi'(w)$ $X=\phi(u)+\psi(w)$. Restoring the expressions for u and w, $X=\phi(vt-x)+\psi(vt+x)$, where ϕ and ψ may be any functions whatever. The second term represents a wave rolling backwards, but as we do not at present consider such a wave, we shall make that term $=0$. The first expresses that we may assume any law whatever, provided that $vt-x$ is the subject of it; but in the Theory of Tides we must assume that, in the mouth of the channel connected with the open sea, the disturbance depends upon $\cos(nt+A)$, n and A being independent of the time: and, therefore, we must assume the form of X here to be

$$a\cos(mvt-mx),$$

where $mv=n$. For convenience, we omit to add a constant to the arc $mvt-mx$, as the same effect may be produced by altering the epoch from which t is measured. The assumption of this form for X will not prevent us from adding to it a small term of the form $a^2.\cos(2mvt-2mx)$, or $a^2.\sin(2mvt-2mx)$, if we should find it necessary, as those terms also satisfy the equation $\frac{d^2X}{dt^2}-v^2\frac{d^2X}{dx^2}=0$.

Solution to second approximation.

(198.) Second approximation. With the value $X=a.\cos(mvt-mx)$, we have $\frac{dX}{dx}=ma.\sin(mvt-mx)$, $\frac{d^2X}{dx^2}=-m^2a.\cos(mvt-mx)$; and substituting these values in the first term on the second side of the equation,

$$\frac{d^2X}{dt^2}-v^2\frac{d^2X}{dx^2}=\frac{3}{2}a^2v^2m^3.\sin(2mvt-2mx),$$

or

$$4v^2\frac{d^2X}{du\,dw}=\frac{3}{2}a^2v^2m^3.\sin 2mu,$$

or

$$\frac{d^2X}{du\,dw}=\frac{3}{8}a^2m^3.\sin 2mu.$$

Integrating with respect to u,

$$\frac{dX}{dw}=\psi'(w)-\frac{3}{16}a^2m^2.\cos 2mu.$$

Integrating again with respect to w,

$$X=\phi(u)+\psi(w)-\frac{3}{16}a^2m^2.w.\cos 2mu;$$

or

$$X=\phi(vt-x)+\psi(vt+x)-\frac{3}{16}a^2m^2.(vt+x).\cos(2mvt-2mx).$$

The arbitrary functions must be so chosen that the result of this solution may be consistent, to the first order of the small quantity a, with the first approximate solution; and may also enable us to satisfy the tidal condition at the mouth of the river. For this purpose the term $vt.\cos(2mvt-2mx)$ must be destroyed; because its existence would imply that the rise and fall of the water at the river's mouth are constantly increasing from tide to tide. We shall, therefore, take for $\phi(vt-x)+\psi(vt+x)$ the following quantity, in which every term is a function of $vt-x$:

$$a\cos(mvt-mx)+\frac{3}{16}a^2m^2(vt-x).\cos(2mvt-2mx)+ca^2.\cos(2mvt-2mx)$$
$$+c'a^2.\sin(2mvt-2mx),$$

which gives for X

$$a.\cos(mvt-mx)-\frac{3}{8}a^2m^2.x.\cos(2mvt-2mx)$$
$$+\ ca^2.\cos(2mvt-2mx)$$
$$+\ c'a^2.\sin(2mvt-2mx)\,;$$

where c and c' may be hereafter chosen so as to satisfy the condition of communicating with the tide of the open sea.

(199.) Taking the expression found for X, we obtain

$$\frac{dX}{dx}=am.\sin(mvt-mx)-\frac{3}{4}a^2m^2.x.\sin(2mvt-2mx)$$
$$+\ 2a^2m\,c.\sin(2mvt-2mx)$$
$$-a^2\left(\frac{3}{8}m^2+2mc'\right)\cos(2mvt-2mx)\,;$$

and, substituting this in the expression $V=\dfrac{k}{1+\dfrac{dX}{dx}}$, we find

$$V=k\left\{\begin{array}{l}1-am\sin(mvt-mx)+a^2\dfrac{m^2}{2}\\ \qquad+\dfrac{3}{4}a^2m^2.x.\sin(2mvt-2mx)\\ \qquad-\ 2a^2mc.\sin(2mvt-2mx)\\ \qquad+a^2\left(-\dfrac{m^2}{2}+\dfrac{3m^2}{8}+2mc'\right)\cos(2mvt-2mx)\end{array}\right\};$$

This, however, is the expression for the height of the water at the present place of those particles whose horizontal ordinate was originally $=x$. If we wish to find the height of the water at the place whose ordinate, measured on the bank of the canal, is x', we must consider that the original ordinate of the particles now there was x, where $x+X=x'$, or $x=x'-X=x'-X'$ nearly $=x'-a.\cos(mvt-mx')$ nearly; and this quantity must be substituted for x in the expression for V. In the term multiplied by a, instead of $\sin(mvt-mx)$, we shall have

$$\sin\{mvt-mx'+ma.\cos(mvt-mx')\}=\sin(mvt-mx')+\frac{ma}{2}+\frac{ma}{2}\cos(2mvt-2mx')\text{ nearly.}$$

The terms multiplied by a^2 require no alteration, as the alteration would introduce terms depending on a^3, to which order we have not proceeded in our approximation. Thus we find for the elevation of the water at the point whose ordinate is x',

$$V=k\left\{\begin{array}{l}1-am\sin(mvt-mx')+\dfrac{3}{4}a^2m^2x'.\sin(2mvt-2mx')\\ \qquad-\ 2a^2mc.\sin(2mvt-2mx')\\ \qquad+a^2\left(-\dfrac{m^2}{2}-\dfrac{m^2}{2}+\dfrac{3m^2}{8}+2mc'\right)\cos(2mvt-2mx')\end{array}\right\}.$$

(200.) Now suppose x' to be measured from the point where the canal communicates with the open sea. The expression for the elevation of the water at that point will depend upon $\sin nt$ or $\sin mvt$, (by the laws of the tides which we shall hereafter investigate,) but not upon $\sin 2mvt$ or $\cos 2mvt$: and, therefore, when $x'=0$, the terms depending on $\sin(2mvt-2mx')$ and $\cos(2mvt-2mx')$ must vanish. We must, therefore, assume

$$c=0,\quad -\frac{m^2}{2}-\frac{m^2}{2}+\frac{3m^2}{8}+2mc'=0.$$

Thus we find at length,

$$V=k\left\{1-am.\sin(mvt-mx')+\frac{3}{4}a^2m^2.\,x'.\,\sin(2mvt-2mx')\right\};$$

or, putting b for am,

Expression for tidal elevation in the river.

$$V=k\left\{1-b\,.\,\sin(mvt-mx')+\frac{3}{4}b^2.\,mx'.\,\sin(2mvt-2mx')\right\}:$$

and the elevation of the water above its mean height is expressed by

$$K = -bk.\sin(mvt - mx') + \frac{3}{4}b^2.k.mx'.\sin(2mvt - 2mx').$$

Peculiarity of the form of the expression.

The first term of this expression is similar to those which we have found for the elevation when the displacement of the particles is small in comparison with the depth of the water. The second is entirely different, inasmuch as it contains the multiplier x' on the outside of the periodical function: it may be conceived to represent a wave whose magnitude continually increases as it travels along the canal.

(201.) To represent to the eye the form of the wave produced by the combination of the two terms, we have constructed the curve in figure 9. The horizontal line represents the level line of the mean height of water: the elevation or depression of the curve represents (on an enormously exaggerated scale) the elevation or depression above the mean height, given by the expression above. The value of x' is supposed to increase from the left to the right: on which supposition the quantity $mvt - mx'$, representing the phase of the wave, diminishes from the left to the right (mvt being constant).

(202.) To exhibit to the eye the law of the ascent and descent of the surface of the water at different points of the canal, the figures 10, 11, 12, and 13 are constructed. The first of these is intended for the point where the canal communicates with the sea: the others for points successively more and more distant from the sea. The horizontal line is used as a measure of time, or rather of the phase $mvt - mx'$: in which, for each station, x' is constant: the elevation or depression of the corresponding point of the curve represents the corresponding elevation or depression of the water above its mean height, as given by the expression above.

An inspection of these diagrams will suggest the following remarks:—

Peculiarity in the form of the wave.

(203.) When the wave leaves the open sea, its front slope and its rear slope are equal in length, and similar in form. But as it advances in the canal, its front slope becomes short and steep, and its rear slope becomes long and gentle. In advancing still further, this remarkable change takes place in the rear slope: it is not so steep in the middle as in the upper and the lower parts; at length it becomes horizontal at the middle; and, finally, slopes the opposite way, forming in fact two waves (figure 9).

(204.) At the station near the sea, (see figure 10,) the time occupied by the rise of the water is equal to the time occupied by the descent: at a station more removed from the sea (figure 11) the rise occupies a shorter time than the descent: the rise is steady and rapid throughout, but the descent begins rapid, then becomes more gentle, then becomes rapid again: at stations still farther from the sea, (figures 12 and 13,) the descent, after having begun rapid, is absolutely checked, or is even changed for a rise, to which another rapid descent succeeds: in this case there will be at that station two unequal tides corresponding to one tide at the mouth of the canal.

(205.) The greatest elevation and depression of the water are not much altered from one station to another.

Investigation of the duration of rise and fall of the water.

(206.) We may investigate the duration of the rise and fall in the following manner. The elevation of the water above its mean height, or $-bk\left\{\sin(mvt - mx') - \cos(mvt - mx').\frac{3}{2}bmx'.\sin(mvt - mx')\right\}$, may be put under the form $-bk\sin\left\{mvt - mx' - \frac{3}{2}bmx'.\sin(mvt - mx')\right\}$, considering the second term as small in comparison with the first. The phase of low water will be represented by giving to the sine its greatest positive value, or by making $mvt - mx' - \frac{3}{2}bmx'.\sin(mvt - mx') = \frac{\pi}{2}$. The first approximation (neglecting the second term) gives $mvt - mx' = \frac{\pi}{2}$, and $\sin(mvt - mx') = 1$. Substituting this in the second term, $mvt - mx' - \frac{3}{2}bmx' = \frac{\pi}{2}$: therefore

$$\text{at low water,} \quad t = \frac{1}{mv}\left\{\frac{\pi}{2} + mx' + \frac{3}{2}bmx'\right\}.$$

The next low water will be found by making $mvt - mx' - \frac{3}{2}bmx'.\sin(mvt - mx') = \frac{5\pi}{2}$; the next by making it $= \frac{9\pi}{2}$, &c.; and the corresponding values of t are $\frac{1}{mv}\left\{\frac{5\pi}{2} + mx' + \frac{3}{2}bmx'\right\}$, $\frac{1}{mv}\left\{\frac{9\pi}{2} + mx' + \frac{3}{2}bmx'\right\}$, &c. The phase of high water will be represented by giving to the sine its greatest negative value, or by making $mvt - mx' - \frac{3}{2}bmx'.\sin(mvt - mx') = \frac{3\pi}{2}$. The first approximation gives $mvt - mx' = \frac{3\pi}{2}$, $\sin mvt - mx = -1$. Substituting this in the second term, $mvt - mx' + \frac{3}{2}bmx' = \frac{3\pi}{2}$; therefore

$$\text{at high water,} \quad t = \frac{1}{mv}\left\{\frac{3\pi}{2} + mx' - \frac{3}{2}bmx'\right\}.$$

The successive high waters will be obtained by putting $\frac{7\pi}{2}$, $\frac{11\pi}{2}$, &c., in place of $\frac{3\pi}{2}$. Thus we have

At low water $t=\frac{1}{mv}\left\{\frac{\pi}{2}+mx'+\frac{3}{2}bmx'\right\}$

At the next high water $t=\frac{1}{mv}\left\{\frac{3\pi}{2}+mx'-\frac{3}{2}bmx'\right\}$

At the next low water $t=\frac{1}{mv}\left\{\frac{5\pi}{2}+mx'+\frac{3}{2}bmx'\right\}$

At the next high water $t=\frac{1}{mv}\left\{\frac{7\pi}{2}+mx'-\frac{3}{2}bmx'\right\}$

&c.

Interval from low water to high water $=\frac{1}{mv}\{\pi-3bmx'\}$

Interval from high water to low water $=\frac{1}{mv}\{\pi+3bmx'\}$

Excess of the latter above the former $=\frac{1}{mv}6bmx'=6b\frac{x'}{v}$.

As $v=\frac{n}{m}$, this is $6b\frac{mx'}{n}$.

Rise of the water occupies less time than its fall.

(207.) The fraction $\frac{x'}{v}$ is the time occupied by the tide-wave in passing from the open sea to the station under consideration. Thus we find,

Excess of the time of water falling above the time of water rising $=6b\times$ time occupied by the tide-wave in passing from the open sea to the station under consideration.

$$\text{Where}\quad b=\frac{\text{rise of tide above the mean state}}{\text{mean depth of water}}.$$

Thus in any part of the canal far from the sea, the times of high water and of low water, and the interval between them, will on different days depend on the extent through which the surface of the water oscillates up and down, or upon the magnitude of the whole rise of tide. And in places on the canal at different distances from the sea, the inequality of the times of water rising and water falling will, on the same day, depend upon the distance of the places from the sea.

(208.) Since the high water occurs, in the place whose distance from the sea is x', at the time $\frac{1}{mv}\left\{\frac{3\pi}{2}+mx'-\frac{3}{2}bmx'\right\}$, it will occur, in the place whose distance is $x'+x_{,}$, at the time

$$\frac{1}{mv}\left\{\frac{3\pi}{2}+m.\overline{x'+x_{,}}-\frac{3}{2}bm.\overline{x'+x_{,}}\right\},$$

and therefore the time occupied by the phase of high water in describing the space $x_{,}$ will be $\frac{1}{mv}\left\{mx_{,}-\frac{3}{2}bmx_{,}\right\}$ $=\frac{x_{,}}{v}\left(1-\frac{3b}{2}\right)=\frac{x_{,}}{v\left(1+\frac{3b}{2}\right)}$ nearly; therefore the phase of high water has travelled along the canal with the velocity $v\left(1+\frac{3b}{2}\right)=\sqrt{gk}\times\left(1+\frac{3b}{2}\right)=\sqrt{\{gk(1+3b)\}}$ nearly. The velocity with which a shallow wave of great length would travel along the surface of water, whose depth $=$ depth here at high water, would, by (172.), be $\sqrt{g\times\text{depth at high water}}=\sqrt{g\times k(1+b)}$. Consequently, the phase of high water travels along the canal with a velocity greater than that of a shallow wave on water of the same depth as the high water. In like manner, the phase of low water travels along the canal with the velocity $\sqrt{\{gk(1-3b)\}}$ nearly, which is less than that of a long shallow wave on water of the same depth as the low water. The following theorem will be easily remembered. If D_2 be the depth at low water, D_3 that at high water, and if D_1, D_2, D_3, D_4, are in arithmetical progression; then the phase of low water travels with the velocity due to the depth D_1, and the phase of high water with the velocity due to the depth D_4.

Simple rule for the velocity of the phases of high water and low water.

(209.) The actual velocity of the particles of the water, or the velocity of the tide-stream, is represented by $\frac{dX}{dt}$. Observing that $X=a.\cos(mvt-mx)-\frac{3}{8}a^2m^2x.\cos(2mvt-2mx)+\frac{5}{16}ma^2.\sin(2mvt-2mx)$, we have

$$\frac{dX}{dt}=amv\left\{-\sin(mvt-mx)+\frac{3}{4}am^2x.\sin(2mvt-2mx)+\frac{5}{8}ma.\cos(2mvt-2mx)\right\}.$$

This is the velocity of the particles whose original ordinate was x: if for x, as in (199.), we put $x'-a\cos(mvt-mx')$, the expression for the velocity of the particles of water which are passing the place whose ordinate measured on the canal-bank is x', will become

$$amv\left\{-\sin(mvt-mx')-\frac{ma}{2}+\frac{ma}{8}\cos(2mvt-2mx')+\frac{3}{4}am^2x'\sin(2mvt-2mx')\right\}.$$

At high water, $mvt-mx'=\frac{3\pi}{2}-\frac{3}{2}bmx'$, $\sin(mvt-mx')=-1$ nearly, $2mvt-2mx'=3\pi$ nearly, $\sin(2mvt-2mx')=0$, $\cos(2mvt-2mx')=-1$, and the expression for the velocity is

$$amv\left\{1-\frac{ma}{2}-\frac{ma}{8}\right\}=bv\left\{1-\frac{5b}{8}\right\}.$$

At low water, $mvt-mx'=\frac{\pi}{2}+\frac{3}{2}bmx'$, $\sin(mvt-mx')=1$, $\sin(2mvt-2mx')=0$, $\cos(2mvt-2mx')=-1$, and

Velocity of ebb-stream greater than that of flow-stream.

the expression for the velocity is $amv\left\{-1-\frac{ma}{2}-\frac{ma}{8}\right\}=$

$$-amv\left\{1+\frac{ma}{2}+\frac{ma}{8}\right\}=-bv\left\{1+\frac{5b}{8}\right\}.$$

These are respectively the same (very nearly) as the greatest velocities of the water up and down the canal: hence the greatest velocity of the tide-stream downwards exceeds the greatest velocity of the tide-stream upwards.

(210.) If we wish to proceed with a third approximation to the value of X, we must use the value already found, namely,

$$X=a\cos\overline{mvt-mx}+\frac{5ma^2}{16}\sin\overline{2mvt-2mx}-\frac{3m^2a^2}{8}x\cos\overline{2mvt-2mx};$$

in which the two last terms are to be regarded as small quantities of the second order. We must then substitute this (having due regard to the orders of quantities) in the right-hand side of the equation,

$$4v^2.\frac{d^2X}{du\,dw}=\frac{d^2X}{dt^2}-v^2\frac{d^2X}{dx^2}=v^2\frac{d^2X}{dx^2}\times\left\{-3\frac{dX}{dx}+6\left(\frac{dX}{dx}\right)^2\right\};$$

in which the right-hand side of the equation is to be expressed in terms of u and w; and, solving it, we obtain a value of X, to which (as before) an arbitrary term $\phi(vt-x)$ is to be attached. This arbitrary term can only be of the third order, inasmuch as the last approximation comprehended every term of the second order. From this expression for X, that for V is obtained by substitution in the equation

$$V=k\left(1-\frac{dX}{dx}+\left(\frac{dX}{dx}\right)^2-\left(\frac{dX}{dx}\right)^3\right).$$

Then, to adapt our expression for the elevation to a fixed point on the canal-bank, we must solve the equation $x+X=x'$, including terms of the second order: this gives

$$x=x'-a.\cos\overline{mvt-mx'}+\frac{3}{16}ma^2.\sin\overline{2mvt-2mx'}+\frac{3}{8}m^2a^2x'.\cos\overline{2mvt-2mx'}.$$

This must be substituted in every part of the expression for V; and the arbitrary function $\phi(vt-x)$ must be so determined as to make the expression $=k\left(1-ma.\sin\overline{mvt-mx'}\right)$ at the mouth of the canal, or when $x'=0$. The expression finally obtained is this; putting b for ma,

Solution to third approximation.

$$V=k\left\{1-b.\sin\overline{mvt-mx'}+\left(\frac{3}{4}b^2.\sin\overline{2mvt-2mx'}+\frac{33}{32}b^3.\cos\overline{mvt-mx'}-\frac{21}{32}b^3.\cos\overline{3mvt-3mx'}\right)mx'\right.$$
$$\left.+\left(\frac{9}{32}b^3.\sin\overline{mvt-mx'}-\frac{27}{32}b^3.\sin\overline{3mvt-3mx'}\right)m^2x'^2\right\}.$$

In figures (14) and (15) we have represented the course of the waves up a channel on two suppositions: the first supposing $b=\frac{1}{3}$, the second supposing $b=\frac{1}{6}$. We shall leave to the reader the task of discussing the results of this approximation, or of proceeding with further approximations. That which we have obtained will be found very important in the explanation of some peculiar cases of tides.

(211.) On account of the great importance of this problem in applications to the tides, we shall examine another modification of it.

Problem.—To investigate the motion of the tide-wave under the same circumstances, when the water of the canal is supposed also to have a current-flow (independent of fluctuations of tide) towards the sea.

Investigation when there is a current-flow in the river.

(212.) The investigation of the equation of the last problem includes this case, and the differential equation, therefore, will be the same, namely,

$$\frac{d^2X}{dt^2}-v^2\frac{d^2X}{dx^2}=v^2\frac{d^2X}{dx^2}\times\left\{-3\frac{dX}{dx}+6\left(\frac{dX}{dx}\right)^2-\&c.\right\}.$$

For a first approximation, $\frac{d^2X}{dt^2}-v^2\frac{d^2X}{dx^2}=0$; the solution of which is $X=\phi(vt-x)+\psi(vt+x)$. Now it will not be sufficient to take $X=a\cos(mvt-mx)$, because this formula will not express the current-flow: but that circumstance will be expressed by the following assumption:—

Solution to first approximation.

$$X=a\cos(mvt-mx)-\frac{e}{2v}(vt+x)-\frac{e}{2v}(vt-x),$$

or

$$X=a\cos(mvt-mx)-et;$$

where e represents the mean velocity of the current-flow towards the sea.

Solution to second approximation.

(213.) For the second approximation we find the same equation as before (198.), and the general solution will be the same as that of (198.), namely,

$$X=\phi(vt-x)+\psi(vt+x)-\frac{3}{16}a^2m^2(vt+x)\cos(2mvt-2mx).$$

But for the arbitrary functions we cannot adopt the same form as in (198.): first, because, as we have already seen, the principal term of X must have the form $a\cos(mvt-mx)-et$: secondly, because, as in (199.), the term $x.\cos(2mvt-2mx)$ will introduce a term $x.\sin(2mvt-2mx)$ into the expression for V; and, as x is the original co-ordinate of the particles, and as these particles (from the flow of the current) will at length come to the mouth of the canal or to the sea, it would follow that in the sea, after the lapse of a certain time, we shall have an oscillation expressed by $\sin(2mvt-2mx)$, which is inadmissible. The latter fault, it is easily seen, will be remedied by introducing the proper multiple of $t.\cos(2mvt-2mx)$. This can be done by means of the arbitrary functions, since $f\times(vt-x)\times\cos(2mvt-2mx)$ is a function of $vt-x$. Adding, also, the arbitrary terms in the solution of (198.), we have

$$\begin{aligned}X=a\cos(mvt-mx)-et-\frac{3}{8}a^2m^2.x.\cos(2mvt-2mx)&\\+ca^2.\cos(2mvt-2mx)&\\+c'a^2.\sin(2mvt-2mx)&\\+f\times(vt-x)\times\cos(2mvt-2mx).&\end{aligned}$$

(214.) From this expression we obtain the following value of $\frac{dX}{dx}$:

$$\begin{aligned}am.\sin(mvt-mx)+\left\{2ca^2m+2fmvt-\left(2fm+\frac{3}{4}a^2m^3\right)x\right\}\sin(2mvt-2mx)&\\-\left\{2c'a^2m+f+\frac{3}{8}a^2m^2\right\}\cos(2mvt-2mx);&\end{aligned}$$

and substituting this in the expression $V=\frac{k}{1+\frac{dX}{dx}}$, we find

$$V=k\left\{\begin{aligned}&1-am\sin(mvt-mx)+\frac{a^2m^2}{2}\\&\qquad-\left\{2ca^2m+2fmvt-\left(2fm+\frac{3}{4}a^2m^3\right)x\right\}\sin(2mvt-2mx)\\&\qquad+\left\{2c'a^2m+f+\frac{3}{8}a^2m^2-\frac{a^2m^2}{2}\right\}\cos(2mvt-2mx).\end{aligned}\right\}$$

But this expression gives the height of the water at the place of those particles whose original ordinate was x. If we wish to find the height of the water at the place whose ordinate, measured along the bank of the canal, is x', we must ascertain the value of the original ordinate x of the particles whose ordinate at the instant in question is x', and must substitute that value of x in the expression. The first step, then, is to make $x+X=x'$. Now X, by the expressions obtained, $=a\cos(mvt-mx)-et$ nearly: and the equation is

$$x+a.\cos(mvt-mx)-et=x'.$$

The first approximate solution is $x-et=x'$, whence $mx=mx'+met$. Substituting this in the small term, the equation becomes

$$x+a.\cos\left(\overline{mv-me}.t-mx'\right)-et=x',$$

or

$$x=x'+et-a.\cos\left(\overline{mv-me}.t-mx'\right).$$

This degree of approximation is sufficient. Substituting this expression for x in the second term of the formula for V, and substituting $x'+et$ for x in the remaining terms of the formula for V, we find

$$V=k\left\{\begin{array}{l}1-am.\sin\left(\overline{v-e}.mt-mx'\right)+\left\{-2ca^2m+\left(-2fm.\overline{v-e}+\frac{3}{4}a^2m^3e\right)t+\left(2fm+\frac{3}{4}a^2m^3\right)x'\right\}\sin\left(2.\overline{v-e}.mt-2mx'\right)\\ \qquad\qquad+\left\{2c'a^2m+f-\frac{5}{8}a^2m^2\right\}\cos\left(2.\overline{v-e}.mt-2mx'\right).\end{array}\right\}$$

(215.) At the sea $x'=0$. Now we assume that at the sea the oscillation follows the simple law of $-kam.\sin nt$, or $-kam.\sin\left(\overline{v-e}.mt\right)$. Equating to zero the terms which remain in addition to that term when $x'=0$, we find: $-2ca^2m=0$; $-2fm.\overline{v-e}+\frac{3}{4}a^2m^3e=0$, or $f=\frac{3}{8}a^2m^2.\frac{e}{v-e}$; $2c'a^2m+f-\frac{5}{8}a^2m^2=0$.

Expression for tidal elevation.

Substituting the value of f, we now find

$$V=k\left\{1-am.\sin\left(\overline{v-e}\,mt-mx'\right)+\frac{3}{4}a^2m^3\frac{v}{v-e}.x'.\sin\left(2.\overline{v-e}.mt-2mx'\right)\right\};$$

or, putting $am=b$, the expression for the elevation of the water above its mean height is,

$$K=-bk.\sin\left(\overline{v-e}.mt-mx'\right)+\frac{3}{4}b^2k.\frac{v}{v-e}.mx'.\sin\left(2.\overline{v-e}.mt-2mx'\right).$$

(216.) We might proceed in the discussion of this expression and of that for X in the same manner as in (201.) &c. The only point, however, to which we shall attend here is the times of high water and low water. The expression just found may be put under the form

Investigation of the duration of rise and fall of the water.

$$-bk\left\{\sin\left(\overline{v-e}.mt-mx'\right)-\cos\left(\overline{v-e}.mt-mx'\right)\frac{3}{2}b.\frac{v}{v-e}mx'.\sin\left(\overline{v-e}.mt-mx'\right)\right\}$$

$$\text{or}\quad -bk\sin\left\{\overline{v-e}.mt-mx'-\frac{3}{2}b.\frac{v}{v-e}mx'.\sin\left(\overline{v-e}.mt-mx'\right)\right\}.$$

For low water we must give to the sine its greatest positive value, or must make the arc $=\frac{\pi}{2}$, or $\frac{5\pi}{2}$, or $\frac{9\pi}{2}$, &c. Adopting $\frac{\pi}{2}$, we have

$$\overline{v-e}.mt-mx'-\frac{3}{2}b.\frac{v}{v-e}.mx'.\sin\left(\overline{v-e}.mt-mx'\right)=\frac{\pi}{2}.$$

A first approximation is $\overline{v-e}.mt-mx'=\frac{\pi}{2}$, $\sin\left(\overline{v-e}.mt-mx'\right)=1$. Substituting in the second term,

$$\overline{v-e}.mt-mx'-\frac{3}{2}b.\frac{v}{v-e}.mx'=\frac{\pi}{2};$$

from which

$$t=\frac{1}{(v-e)m}\left\{\frac{\pi}{2}+mx'+\frac{3}{2}b.\frac{v}{v-e}.mx'\right\}.$$

Rise of tide occupies less time than the fall.

Proceeding in the same manner for high water, and taking different multiples of $\frac{\pi}{2}$, we find the following times.

At low water $$t=\frac{1}{(v-e)m}\left\{\frac{\pi}{2}+mx'+\frac{3}{2}b.\frac{v}{v-e}.mx'\right\}.$$

At the next high water $$t=\frac{1}{(v-e)m}\left\{\frac{3\pi}{2}+mx'-\frac{3}{2}b.\frac{v}{v-e}mx'\right\}.$$

At the next low water $$t=\frac{1}{(v-e)m}\left\{\frac{5\pi}{2}+mx'+\frac{3}{2}b.\frac{v}{v-e}mx'\right\}.$$

At the next high water $$t=\frac{1}{(v-e)m}\left\{\frac{7\pi}{2}+mx'-\frac{3}{2}b.\frac{v}{v-e}mx'\right\}.$$

&c.

Interval from low water to high water $$=\frac{1}{(v-e)m}\left\{\pi-3b\frac{v}{v-e}mx'\right\}$$

Interval from high water to low water $$=\frac{1}{(v-e)m}\left\{\pi+3b\frac{v}{v-e}mx'\right\}$$

Excess of the latter above the former $$=6bx'\frac{v}{(v-e)^2}.$$

As $v-e=\frac{n}{m}$, this is $$6b.\frac{m^2}{n^2}\left(\frac{n}{m}+e\right)x'=6bx'\left(\frac{m}{n}+e\frac{m^2}{n^2}\right).$$

This excess is greater than the excess when there is no current, in the proportion of $1+\frac{em}{n}$ to 1.

(217.) The preceding investigations suppose that the depth of the canal is uniform in its cross section. In the case of a wave of great length, as the tide-wave, we may, however, apply a satisfactory investigation to the motion of the wave along a canal of uniform section of any form.

Problem.—The section of the canal is defined by the equation $z=\phi(y)$, z being a horizontal co-ordinate: to find the equations for the motion of a long wave.

Investigation for long waves in a canal whose section is invariable but of any form.

(218.) Let $u=\psi(y)$ be the area of the section up to the height y, so that $\frac{du}{dy}=z$: let X be the horizontal displacement, in the direction of the canal's length, of the particles whose co-ordinate measured along the canal was x; V the present elevation of that part of the water. Then, as in (194.), the horizontal space which was h has now become $h\left(1+\frac{dX}{dx}\right)$, and the area of section which was $\psi(k)$ is now $\psi(V)$, and therefore the volume which was expressed by $h.\psi(k)$ is now expressed by $h\left(1+\frac{dX}{dx}\right)\psi(V)$. Making these equal,

$$\psi(V)=\frac{\psi(k)}{1+\frac{dX}{dx}}.$$

This is the equation of continuity.

(219.) The pressure tending to push forward the water included between the two particles whose horizontal co-ordinates were x and $x+h'$, and whose horizontal co-ordinates are now $x+X$ and $x+X+\left(1+\frac{dX}{dx}\right)h'$, will, as in (195.) be the difference of the pressures caused by two vertical columns whose heights are $V-y$ and $V+\frac{dV}{dx}h'-y$ respectively. Hence, as in (195.), we find

$$\frac{d^2X}{dt^2}=-g.\frac{dV}{dx}.\frac{1}{1+\frac{dX}{dx}}.$$

To eliminate $\frac{dV}{dx}$, we must differentiate the equation of continuity found above, from which we obtain

$$\psi'(V).\frac{dV}{dx}=\frac{-\psi(k)}{\left(1+\frac{dX}{dx}\right)^2}.\frac{d^2X}{dx^2};$$

substituting from this, we have

$$\frac{d^2X}{dt^2}=\frac{g\psi(k)}{\psi'(V)}.\frac{\frac{d^2X}{dx^2}}{\left(1+\frac{dX}{dx}\right)^3},$$

an equation which may be solved by successive substitution.

(220.) The first approximation will be made by considering V in the factor as equal to k, and neglecting

Solution to first approximation.

$\frac{dX}{dx}$. This gives $\frac{d^2X}{dt^2}=\frac{g\,\psi(k)}{\psi'(k)}\cdot\frac{d^2X}{dx^2}$. Let $k'=\frac{\psi(k)}{\psi'(k)}$, $v'^2=gk'$: then $\frac{d^2X}{dt^2}=v'^2\frac{d^2X}{dx^2}$; of which the solution is $X=\chi(v't-x)+\omega(v't+x)$. This expression denotes that the waves travel with the same velocity v' or $\sqrt{gk'}$, as if the depth of the canal were uniform and equal to $\frac{\psi(k)}{\psi'(k)}$ or $\frac{\psi(k)}{\phi(k)}$. For instance, if the section of the canal were a triangle, $\phi(y)=z=ay$: $\psi(y)=\int_y\phi(y)=\frac{ay^2}{2}$: therefore $\frac{\psi(k)}{\phi(k)}=\frac{\frac{ak^2}{2}}{ak}=\frac{k}{2}$, and the velocity would be that due to a canal of uniform depth equal to half the greatest depth of the triangular canal. If the section were a parabola, $\phi(y)=z=\sqrt{ay}$: $\psi(y)=\frac{2}{3}\sqrt{ay^3}$: $\frac{\psi(k)}{\phi(k)}=\frac{2}{3}\cdot\frac{\sqrt{ak^3}}{\sqrt{ak}}=\frac{2k}{3}$, and the velocity would be that due to a canal of uniform depth equal to two-thirds of the greatest depth of the parabolic canal.

Equation to second approximation.

(221.) For a second approximation, we must expand the equation $\psi(V)=\frac{\psi(k)}{1+\frac{dX}{dx}}$ to the first power of small quantities: this gives $\psi(k)+\psi'(k).(V-k)=\psi(k)-\psi(k)\frac{dX}{dx}$,

whence
$$V-k=\frac{-\psi(k)}{\psi'(k)}\cdot\frac{dX}{dx},$$

and $\psi'(V)$, or $\psi'(k+V-k)=\psi'(k)+\psi''(k).(V-k)=\psi'(k)-\frac{\psi(k).\psi''(k)}{\psi'(k)}\cdot\frac{dX}{dx}$:

therefore
$$\frac{g\psi(k)}{\psi'(V)}=\frac{g\psi(k)}{\psi'(k)}\cdot\left\{1+\frac{\psi(k).\psi''(k)}{\{\psi'(k)\}^2}\cdot\frac{dX}{dx}\right\};$$

and the equation becomes
$$\frac{d^2X}{dt^2}=\frac{g\psi(k)}{\psi'(k)}\cdot\left\{1-\frac{3\{\psi'(k)\}^2-\psi(k).\psi''(k)}{\{\psi'(k)\}^2}\cdot\frac{dX}{dx}\right\}\cdot\frac{d^2X}{dx^2},$$

which is to be solved in the same manner as in (198.), &c.

Limitations to the application of this solution.

(222.) The preceding solution, it is plain, depends on the assumption that the horizontal motion in the direction of z is insignificant in comparison with that in the direction of x. And this consideration points out the limitations within which the solution will apply. It will certainly apply when the sides of the canal at and near the surface of the water are so steep (say, for instance, inclined at an angle of 45° to the vertical) that the motion in the direction of z does not much exceed the vertical motion. It will certainly not apply when the shore is so flat that the motion in the direction of z greatly exceeds the vertical motion and is at all comparable with the motion in the direction of x.

Addition of solutions does not apply here.

(223.) Before closing this subsection, we must call the reader's attention to the circumstance that the addition of solutions, treated of in (186.), and which holds in all cases of waves where the motion of the particles is extremely small, does not hold here. For, if we have two functions X′ and X″, each of which separately satisfies one of the equations,

$$\frac{d^2X'}{dt^2}-v^2\frac{d^2X'}{dx^2}=v^2\frac{d^2X'}{dx^2}\times\left\{-3\frac{dX'}{dx}+,\ \&c.\right\}$$
$$\frac{d^2X''}{dt^2}-v^2\frac{d^2X''}{dx^2}=v^2\frac{d^2X''}{dx^2}\times\left\{-3\frac{dX''}{dx}+,\ \&c.\right\}$$

the sum of these functions will not satisfy the similar equation,

$$\frac{d^2(X'+X'')}{dt^2}-v^2\frac{d^2(X'+X'')}{dx^2}=v^2\frac{d^2(X'+X'')}{dx^2}\times\left\{-3\frac{d(X'+X'')}{dx}+,\ \&c.\right\}$$

as will be evident on adding together the two equations.

Subsection 4.—Theory of Waves when the Water is under the action of Horizontal and Vertical Forces.

(224.) The general equations applicable to water under the action of forces (149.) are

$$Y=\Xi.\frac{d\eta}{dx}-\int_y\frac{dX}{dx}\ (\eta\text{ to }y)$$

Tides and Waves.

$$\frac{d^2X}{dt^2}=F+\frac{d}{dx}\left\{-g'(k+K-y)-\int_y \frac{d^2Y}{dt^2}\,(y \text{ to } k)\right\},$$

General equations when there is external force.

where F is the extraneous force acting in an horizontal direction, and g' is gravity increased by the extraneous force acting in the vertical direction. If there be no extraneous vertical force, the second equation becomes

$$\frac{d^2X}{dt^2}=F+\frac{d}{dx}\left\{-gK-\int_y \frac{d^2Y}{dt^2}\,(y \text{ to } k)\right\}.$$

Before entering upon the legitimate objects of this subsection, we will apply these equations to the solution of two or three problems which would, at first sight, seem to be unconnected with them.

(225.) Hitherto we have assumed in every part of our investigation that there is upon the surface of the water an unlimited succession of waves. We shall now proceed to consider the case of a single wave.

Problem.—To ascertain the conditions under which it is possible that a single wave can travel along a canal.

Investigation for motion of a solitary wave.

(226.) By a moving wave, we mean in all cases (till we shall make new suppositions) a displacement of the particles, of such a nature that, upon examining the state of particles which are at a greater distance in the direction of x, and increasing the time by a quantity proportionate to that increase of distance, the displacement of the new particles at that later time will be found the same as the displacement of the old particles at the earlier time. It follows, therefore, that in all cases, whether there be a single wave or an indefinite succession of waves, the displacement must be represented by a function of $vt-x$. Yet any ordinary function of $vt-x$ will not fulfil our object, inasmuch as any ordinary function, though it may make the displacement $=0$ for particular values of $vt-x$, will not make the displacement $=0$ for all the values of $vt-x$ corresponding to the values of x preceding and following that part of the surface at which alone the wave is supposed to have a real existence at any instant of time t. We must adopt for our purpose a *discontinuous* function; that is (putting, for convenience, $vt-x=z$), we must suppose that for all values of z up to a certain limit, the value of X is 0; that from that limiting value of z up to another certain limit, the value of X will be expressed by a certain function of z, whose form is given: that from that second limiting value to a third, the value of X will be expressed by another certain function of z: and so on: and that for values of z exceeding that value which corresponds to the termination of the wave, the value of X will be constantly 0, or equal to some assigned quantity. This supposition corresponds exactly to the supposition that the surface of the water is perfectly level up to a certain point, and that then there exists a wave whose outline is determined by uniting portions of different curves, and that after that the water is again level. There is no objection whatever to our making such a supposition, provided that it be so framed as to satisfy the conditions which are evidently implied in forming our equations for the wave-motion.

Discontinuous function may be used for a single wave.

(227.) To simplify our language, we will suppose that only one function of z (which we will call the *wave-function*) is adopted to express the value of X between the values $z=0$, $z=a$: that for values of z less than 0, X is always $=0$: and that for values of z greater than a, X is always $=b$. (This will denote that the particles of water are, as it were, carried through the space b by the passage of the wave and then deposited.) Upon examining the equations (224.) it will be seen that Y depends on $\frac{dX}{dx}$, and (as the integration is with regard to y only) will be a multiple of $\frac{dX}{dx}$: that therefore $\frac{d^2Y}{dt^2}$, and its integral with respect to y which occurs in the second equation, will be a multiple of $\frac{d^3X}{dx\,dt^2}$: and, considering X as a function of $vt-x$, it is easily seen that $\frac{d^3X}{dx\,dt^2}=-v^2\frac{d^3X}{dz^3}$: and therefore its differential coefficient depends on $\frac{d^4X}{dz^4}$. Consequently our equations involve all the differential coefficients of X with regard to z, to the fourth inclusive. We will now examine the restrictions under which this number of differential coefficients places our assumptions for the form of X: they depend intimately on the way in which we conceive the differential coefficients to be formed.

(228.) In physical investigations there is but one definition of the differential coefficient which can be applied, namely, *the limiting value of the quotient formed by dividing the increment of the function by the increment of the independent variable.* If the reader will turn to the investigations of (144.), &c., he will see that this principle is adopted throughout; in estimating the sides of the small parallelogram by which the equation of continuity is formed; in estimating the pressure depending on the vertical column of fluid; and in estimating the motion which it will produce in the horizontal column of fluid. Taking this definition, then, it is clear, in the first place, that algebraic continuity in the form of the function is unnecessary: but, in the second place, it is clear that at these values of z where different forms of the function unite, there must be no *sudden* change in the value of X: for, if there were a sudden change, then at that point the value of $\frac{dX}{dz}$ (in consequence of the mode of forming the differential coefficient just described) would be infinite. In fact $\frac{dX}{dz}$ would be the limiting

The differential coefficients to a certain order must vanish at the extremities of the wave.

value of $\frac{\delta X}{\delta z}$, where δX had a finite value even when δz was indefiuitely small: this would lead to suppositions of infinite forces, &c., such as were not contemplated at all in our investigation. There must, therefore, be no sudden change in the values of X at the beginning and the end of our wave-function. In like manner there must be no sudden change in the value of $\frac{dX}{dz}$ at the beginning and end of the wave-function, as such sudden change would make the values of $\frac{d^2X}{dz^2}$ infinite. In like manner there must be no sudden change in the values of $\frac{d^2X}{dz^2}$ and $\frac{d^3X}{dz^3}$. Then, as the equations of (224.) hold equally for still water, and for water in wave-motion, and as there is to be no sudden change in the values of the first and second and third differential coefficients, it follows also that there must be no sudden change in the value of the fourth. If, however, we are willing to suppose the sudden introduction of a finite force at a particular point of the wave, we may dispense with the last condition.

Forms of function which satisfy these conditions.

(229.) Now for the still water which precedes and follows the wave, all the differential coefficients are 0. Hence we must have,

At the beginning of the wave-function, or when $z=0$,

$$X=0, \quad \frac{dX}{dz}=0, \quad \frac{d^2X}{dz^2}=0, \quad \frac{d^3X}{dz^3}=0, \quad \frac{d^4X}{dz^4}=0.$$

At the end of the wave-function, or when $z=a$,

$$X \text{ must } =b, \quad \frac{dX}{dz}=0, \quad \frac{d^2X}{dz^2}=0, \quad \frac{d^3X}{dz^3}=0, \quad \frac{d^4X}{dz^4}=0.$$

The higher orders of differential coefficients may have any values whatever.

(230.) There is no difficulty in finding forms for X which will satisfy these conditions. For instance, if we take

$$X=\frac{630\,b}{a^9}\left\{\frac{1}{5}a^4z^5-\frac{2}{3}a^3z^6+\frac{6}{7}a^2z^7-\frac{1}{2}az^8+\frac{1}{9}z^9\right\};$$

then, on making $z=0$, X will $=0$: and, on making $z=a$, X will $=b$. The value of $\frac{dX}{dz}$ is $\frac{630\,b}{a^9}\cdot z^4.(a-z)^4$; and this quantity, and its three next differential coefficients, vanish when $z=0$ or $z=a$.

(231.) Similarly, if we had chosen to assume that for values of z greater than a, X should $=0$, that condition, with all the others, would be satisfied by the assumption for the wave-function $X=c.z^5.(a-z)^5$.

(232.) It may, however, be more convenient to assume a form depending on sines and cosines. Thus, suppose the condition to be that all particles resume, after the passing of the wave, the same place which they had before its approach, or that X shall $=0$ for all values of $z<0$, and for all $>a$. It is easily seen that the condition that X, $\frac{dX}{dz}$, $\frac{d^2X}{dz^2}$, $\frac{d^3X}{dz^3}$, $\frac{d^4X}{dz^4}$ shall $=0$ for $z=0$ and $z=a$, will be satisfied by the assumption $X=\sin^5\frac{\pi z}{a}$; or by any higher power of the sine; or by $\sin^5\frac{\pi z}{a}$ increased by any number of such quantities as $\sin^5\frac{c\pi(z+e)}{a}$, where c may be any number (whole or fractional) greater than 1, and where the argument $\frac{c\pi(z+e)}{a}$ may be carried through as many whole multiples of π as we please, provided that the first value of z be >0, and the last $<a$. (This amounts to the same as supposing that any number of short waves, possessing the characteristic property in regard to the differential coefficients at their beginnings and ends, are piled upon the longer wave.) But if the condition is to be, that the particles are to be removed to the distance b and left there, it will be satisfied by the assumption $X=\frac{8b}{3a}\int_z \sin^4\frac{\pi z}{a}=\frac{2b}{3\pi}\left\{\frac{3}{2}\cdot\frac{\pi z}{a}-\sin\frac{2\pi z}{a}+\frac{1}{8}\sin\frac{4\pi z}{a}\right\}$. For this makes $X=0$ when $z=0$, and $X=b$ when $z=a$; and it makes $\frac{dX}{dz}=0$, $\frac{d^2X}{dz^2}=0$, $\frac{d^3X}{dz^3}=0$, $\frac{d^4X}{dz^4}=0$, for $z=0$ and $z=a$. A higher power of the sine might have been taken; and the function might have been increased by any number of the supplementary functions mentioned above. Thus a single wave of any degree of complexity might be produced., We shall, however, for simplicity, confine ourselves to the simple form

$$X=\frac{8b}{3a}\int_z \sin^4\frac{\pi z}{a}.$$

(233.) But we have not yet examined whether these forms of wave are consistent in all respects with the equations of wave-motion. For this purpose we must substitute the assumed value of X in the equations

$$Y = -\int_y \frac{dX}{dx}(0 \text{ to } y)$$

$$\frac{d^2X}{dt^2} = F + \frac{d}{dx}\left\{-gK - \int_y \frac{d^2Y}{dt^2}(y \text{ to } k)\right\};$$

and thereby ascertain whether any force F is necessary to maintain the particles of water in the assumed state of movement. Now taking the last assumption, and putting $vt-x$ for z; and putting $\phi''(y)$ for the factor depending on y, $\left(\text{it being understood that at the surface, or when } y=k,\ \phi''(k)=\frac{2b}{3\pi}\right)$, where $\phi''(y)$ is conceived to be the second derived function of some function $\phi(y)$, we have

$$X = \phi''(y).\left\{\frac{3\pi}{2a}(vt-x) - \sin\frac{2\pi}{a}(vt-x) + \frac{1}{8}\sin\frac{4\pi}{a}(vt-x)\right\}$$

$$-\frac{dX}{dx} = \phi''(y).\left\{\frac{3\pi}{2a} - \frac{2\pi}{a}.\cos\frac{2\pi}{a}(vt-x) + \frac{\pi}{2a}\cos\frac{4\pi}{a}(vt-x)\right\}$$

$$Y = \{\phi'(y)-\phi'(0)\}.\left\{\frac{3\pi}{2a} - \frac{2\pi}{a}.\cos\frac{2\pi}{a}(vt-x) + \frac{\pi}{2a}\cos\frac{4\pi}{a}(vt-x)\right\}$$

$$K = \{\phi'(k)-\phi'(0)\}.\left\{\frac{3\pi}{2a} - \frac{2\pi}{a}.\cos\frac{2\pi}{a}(vt-x) + \frac{\pi}{2a}\cos\frac{4\pi}{a}(vt-x)\right\}$$

$$\frac{d^2Y}{dt^2} = \{\phi'(y)-\phi'(0)\}.\left\{\frac{8\pi^3}{a^3}v^2.\cos\frac{2\pi}{a}(vt-x) - \frac{8\pi^3}{a^3}v^2.\cos\frac{4\pi}{a}(vt-x)\right\}$$

$$-\int_y \frac{d^2Y}{dt^2}(y \text{ to } k) = \left\{\phi(y)-\phi(k)-\overline{y-k}.\phi'(0)\right\}.\left\{\frac{8\pi^3}{a^3}v^2.\cos\frac{2\pi}{a}(vt-x) - \frac{8\pi^3}{a^3}v^2.\cos\frac{4\pi}{a}(vt-x)\right\}$$

$$\frac{d}{dx}\left\{-gK - \int_y \frac{d^2Y}{dt^2}(y \text{ to } k)\right\} = \left\{\frac{4\pi^2 g}{a^2}.\overline{\phi'(k)-\phi'(0)} + \frac{16\pi^4 v^2}{a^4}.\overline{\phi(y)-\varphi(k)-(y-k).\phi'(0)}\right\}\sin\frac{2\pi}{a}(vt-x)$$

$$+\left\{-\frac{2\pi^2 g}{a^2}.\overline{\phi'(k)-\phi'(0)} - \frac{32\pi^4 v^2}{a^4}\overline{\phi(y)-\phi(k)-(y-k).\phi'(0)}\right\}\sin\frac{4\pi}{a}(vt-x)$$

$$-\frac{d^2X}{dt^2} = -\phi''(y).\frac{4\pi^2v^2}{a^2}\sin\frac{2\pi}{a}(vt-x) + \phi''(y).\frac{2\pi^2v^2}{a^2}\sin\frac{4\pi}{a}(vt-x).$$

Expression for force which is necessary to maintain this wave.

The sum of the two last expressions, with sign changed, is the value of F, the horizontal force which must be applied to maintain this state of undulation.

(234.) It is evident that the value of F cannot generally be $=0$, since the different parts of the coefficients of $\sin\frac{2\pi}{a}(vt-x)$ and $\sin\frac{4\pi}{a}(vt-x)$ are not in the same proportion, and therefore those coefficients cannot vanish together. Therefore, in general, this discontinuous wave cannot exist without the application of force. But if the wave be long, so that the terms divided by a^4 may be neglected in comparison with those divided by a^2, F will $=0$ if $-\frac{2\pi^2 g}{a^2}\overline{\phi'(k)-\phi'(0)} + \frac{2\pi^2 v^2}{a^2}\phi''(y) = 0$. This implies that $\phi''(y)$ is constant and $=\frac{2b}{3\pi}$; therefore, $\phi'(y) = \frac{2b}{3\pi}y$, and $\phi'(k)-\phi'(0) = \frac{2b}{3\pi}k$; and the equation becomes $-\frac{2\pi^2 g}{a^2}k + \frac{2\pi^2 v^2}{a^2} = 0$, or $v^2 = gk$. The same thing would have been found to be true if the wave-function had consisted of any number of sines. Thus it appears, that a single discontinuous wave of any degree of complexity may travel on water without any force to maintain it, provided, in the first place, that it satisfies the conditions laid down with regard to the differential coefficients at its terminations, and in the next place, that the wave is so long that a succession of simple waves, each of that length, would travel sensibly with the velocity due to waves of infinite length.

When the wave is very long, no force is necessary.

(235.) If the single wave is moderately long, a small force will maintain it as a discontinuous wave: but if it be short, the force must be (in proportion to the various pressures acting on the water) considerable. In fact, each of the different terms in the wave-function represents a wave of different length; and, when the waves are short, each of these would tend to travel on with its own peculiar velocity, which velocities are very different for the different waves. But when the waves are long, the peculiar velocities are very nearly the same for the different waves.

In a subsequent article (410.), we shall give the theory of a single wave, acted on by any force, and travelling with a velocity different from that mentioned above.

(236.) We may proceed in the same manner for the discussion of the motion of a single wave of considerable depth and of great length, observing that the equation for that case is $\frac{d^2 X}{dt^2} = F + gk . \frac{\frac{d^2 X}{dx^2}}{\left(1 + \frac{dX}{dx}\right)^2}$.

(237.) Hitherto we have supposed the depth in every part of the canal to be the same. We shall now suppose that the depth is different at different points of the canal; the variation, however, being supposed to be gradual. We have already seen (157.), that the equations cannot be satisfied in this case: and our investigation, therefore, cannot be quite so satisfactory in its character as the investigations undertaken where the equations can be satisfied. Still we conceive that the following will be found sufficiently certain and accurate to enable us to judge with confidence of the effect of the variation of depth upon the general circumstances of the waves.

Depth of canal variable.

Problem.—The depth being supposed variable: to find what alteration takes place in the magnitude, length, and velocity of the waves, in passing from one part of the canal to another.

(238.) In our former investigations, in which the horizontal bottom of the canal was taken as the axis of x, we found that the horizontal disturbance X might be represented by a collection of terms, each of which is of the form $A . (\varepsilon^{my} + \varepsilon^{-my}) \cos (nt - mx)$, where m and n are connected by the equation $n^2 = mg . \frac{\varepsilon^{mk} - \varepsilon^{-mk}}{\varepsilon^{mk} + \varepsilon^{-mk}}$. If, instead of taking the bottom of the canal, we had taken some other horizontal line for the axis of x, and if the ordinate of the bottom of the canal had then been η, the expression for X would have been $A (\varepsilon^{m(y-\eta)} + \varepsilon^{m(\eta-y)}) \cos (nt - mx)$; and the equation connecting m and n would have been $n^2 = mg . \frac{\varepsilon^{m(k-\eta)} - \varepsilon^{m(\eta-k)}}{\varepsilon^{m(k-\eta)} + \varepsilon^{m(\eta-k)}}$. In this case, η is constant.

Assumption on which a plausible solution may be found.

Suppose now that in our canal of slowly varying depth there are, at different parts, portions of sensible length, whose depth is uniform through those lengths; then, through each of these lengths, the expression for X and the equation between n and m will have the same form as those above. It seems, then, not unreasonable to conjecture that the same form may apply to the parts of variable depth, or the parts where η is a function of x, and where, consequently, m will be a function of x, (for n, upon which the *period* of the waves depends, must be invariable through the whole extent of the disturbed water.) A must also be a function of x, whose form is yet to be determined. In regard to the term mx under the cosine, a necessity for change will be obvious. In a canal of uniform depth, mx represents the decrease of phase due to the space x, and, therefore, mh would represent the decrease of phase due to the small space h: if, then, (going upon the principle already announced,) we make the phase decrease for each small part of the canal of variable depth in the same manner as if that depth were continued uniform, we must not use mx for the decrease of the phase, but $\int_x m$. Let this integral $= M$: then our supposition will be

$$X = A . (\varepsilon^{m(y-\eta)} + \varepsilon^{m(\eta-y)}) \cos (nt - M)$$

$$n^2 = mg . \frac{\varepsilon^{m(k-\eta)} - \varepsilon^{m.(\eta-k)}}{\varepsilon^{m(k-\eta)} + \varepsilon^{m(\eta-k)}};$$

where η is a given function of x, m in consequence is implicitly a given function of x, $\frac{dM}{dx} = m$, and A is an unknown function of x, whose form is to be determined so as to satisfy as nearly as possible the equations of waves.

(239.) The equation of continuity is

$$Y = \mathfrak{X} . \frac{d\eta}{dx} - \int_y \frac{dX}{dx} \text{ (from } \eta \text{ to } y).$$

Now
$$\frac{dX}{dx} = \frac{dA}{dx} (\varepsilon^{m(y-\eta)} + \varepsilon^{m(\eta-y)}) \cos \overline{nt - M} + A \frac{dm}{dx} . (y - \eta)(\varepsilon^{m(y-\eta)} - \varepsilon^{m(\eta-y)}) \cos \overline{nt - M}$$
$$- Am \frac{d\eta}{dx} (\varepsilon^{m(y-\eta)} - \varepsilon^{m(\eta-y)}) \cos \overline{nt - M} + Am (\varepsilon^{m(y-\eta)} + \varepsilon^{m(\eta-y)}) \sin \overline{nt - M}.$$

Therefore $- \int_y \frac{dX}{dx}$ from η to y, or $+ \int_y \frac{dX}{dx}$ from y to η, is

$$- \frac{dA}{dx} \frac{1}{m} . (\varepsilon^{m(y-\eta)} - \varepsilon^{m(\eta-y)}) \cos \overline{nt - M} - A \frac{1}{m} . \frac{dm}{dx} . (y - \eta) (\varepsilon^{m(y-\eta)} + \varepsilon^{m(\eta-y)}) \cos \overline{nt - M}$$

$$+\mathrm{A}.\frac{1}{m^2}.\frac{dm}{dx}\left(\varepsilon^{m(y-\eta)}-\varepsilon^{m(\eta-y)}\right)\cos\overline{nt-\mathrm{M}}+\mathrm{A}\frac{d\eta}{dx}\left(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)}\right)\cos\overline{nt-\mathrm{M}}$$

$$-\mathrm{A}\left(\varepsilon^{m(y-\eta)}-\varepsilon^{m(\eta-y)}\right).\sin\overline{nt-\mathrm{M}}-2\mathrm{A}\frac{d\eta}{dx}\cos\overline{nt-\mathrm{M}}.$$

And
$$\Xi.\frac{d\eta}{dx}=2\mathrm{A}\frac{d\eta}{dx}.\cos\overline{nt-\mathrm{M}}.$$

Therefore
$$\mathrm{Y}=-\frac{d\mathrm{A}}{dx}.\frac{1}{m}\left(\varepsilon^{m(y-\eta)}-\varepsilon^{m(\eta-y)}\right).\cos\overline{nt-\mathrm{M}}-\mathrm{A}.\frac{1}{m}.\frac{dm}{dx}(y-\eta)\left(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)}\right)\cos\overline{nt-\mathrm{M}}$$

$$+\mathrm{A}\frac{1}{m^2}.\frac{dm}{dx}.\left(\varepsilon^{m(y-\eta)}-\varepsilon^{m(\eta-y)}\right).\cos\overline{nt-\mathrm{M}}+\mathrm{A}.\frac{d\eta}{dx}\left(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)}\right)\cos\overline{nt-\mathrm{M}}$$

$$-\mathrm{A}\left(\varepsilon^{m(y-\eta)}-\varepsilon^{m(\eta-y)}\right).\sin\overline{nt-\mathrm{M}};$$

or
$$\mathrm{Y}=-\frac{d}{dx}\left\{\frac{\mathrm{A}}{m}\left(\varepsilon^{m(y-\eta)}-\varepsilon^{m(\eta-y)}\right)\cos\overline{nt-\mathrm{M}}\right\}.$$

(240.) The equation of equal pressure is

$$\mathrm{F}=\frac{d^2\mathrm{X}}{dt^2}+\frac{d}{dx}\left\{g\mathrm{K}+\int_y\frac{d^2\mathrm{Y}}{dt^2}(y\text{ to }k)\right\}.$$

Now it is well known that, as x, y, and t, are independent of each other, the differentiation expressed by $\frac{d^2\mathrm{Y}}{dt^2}$ may be performed upon the quantity under the sign $\frac{d}{dx}$; and the integration with regard to y may also be performed on the quantity under the sign $\frac{d}{dx}$, provided that (as is the case here) the limits of the integral are independent of x. Thus we have

$$\frac{d^2\mathrm{Y}}{dt^2}=\frac{d}{dx}\left\{\frac{n^2\mathrm{A}}{m}\left(\varepsilon^{m(y-\eta)}-\varepsilon^{m(\eta-y)}\right)\cos\overline{nt-\mathrm{M}}\right\}$$

$$\int_y\frac{d^2\mathrm{Y}}{dt^2}(\text{generally})=\frac{d}{dx}\left\{\frac{n^2\mathrm{A}}{m^2}\left(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)}\right)\cos\overline{nt-\mathrm{M}}\right\}$$

$$\int_y\frac{d^2\mathrm{Y}}{dt^2}(y\text{ to }k)=-\frac{d}{dx}\left\{\frac{n^2\mathrm{A}}{m^2}\left(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)}\right)\cos\overline{nt-\mathrm{M}}\right\}$$
$$+\frac{d}{dx}\left\{\frac{n^2\mathrm{A}}{m^2}\left(\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)}\right)\cos\overline{nt-\mathrm{M}}\right\}.$$

And
$$g\mathrm{K}=-\frac{d}{dx}\left\{\frac{g\mathrm{A}}{m}\left(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)}\right)\cos\overline{nt-\mathrm{M}}\right\}.$$

In adding these together, it will be observed, that the two last lines destroy each other, by virtue of the equation $n^2=mg\frac{\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)}}{\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)}}$. And as $\frac{d^2\mathrm{X}}{dt^2}=-n^2\mathrm{A}\left(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)}\right)\cos\overline{nt-\mathrm{M}}$, the expression for F becomes

$$\mathrm{F}=-n^2\mathrm{A}\left(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)}\right)\cos\overline{nt-\mathrm{M}}-\frac{d^2}{dx^2}\left\{\frac{n^2\mathrm{A}}{m^2}\left(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)}\right)\cos\overline{nt-\mathrm{M}}\right\}.$$

Expression for force necessary to maintain this motion.

(241.) To facilitate the differentiation of the last term, we will remark, that the alteration of depth is supposed to be gradual, so that $\frac{d\eta}{dx}$ is small, and therefore $\frac{dm}{dx}$ and $\frac{d\mathrm{A}}{dx}$ which depend on it are small, and therefore their powers and products and the second differential coefficients will be extremely small, and may be neglected. If then for the moment we make $\frac{n^2\mathrm{A}}{m^2}\left(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)}\right)=\mathrm{P}$, in differentiating $\mathrm{P}.\cos\overline{nt-\mathrm{M}}$ we may omit $\frac{d^2\mathrm{P}}{dx^2}$. Thus we have

$$\frac{d}{dx}(\mathrm{P}.\cos\overline{nt-\mathrm{M}})=\frac{d\mathrm{P}}{dx}.\cos\overline{nt-\mathrm{M}}+\mathrm{P}.m.\sin\overline{nt-\mathrm{M}}$$

$$-\frac{d^2}{dx^2}(\mathrm{P}.\cos\overline{nt-\mathrm{M}})=-\left(2\frac{d\mathrm{P}}{dx}m+\mathrm{P}\frac{dm}{dx}\right)\sin\overline{nt-\mathrm{M}}+m^2\mathrm{P}.\cos\overline{nt-\mathrm{M}}.$$

Add to this the first term $=-m^2\mathrm{P}.\cos\overline{nt-\mathrm{M}}$

and the expression for F becomes $-\left(2\frac{d\mathrm{P}}{dx}m+\mathrm{P}\frac{dm}{dx}\right)\sin\overline{nt-\mathrm{M}}$

$$=-2m^{\frac{1}{2}}.\frac{d}{dx}(\mathrm{P}m^{\frac{1}{2}}).\sin\overline{nt-\mathrm{M}}$$

$$=-2n^2.m^{\frac{1}{2}}.\frac{d}{dx}\{\mathrm{A}.m^{-\frac{5}{2}}(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)})\}.\sin\overline{nt-\mathrm{M}}.$$

Expanding the differential coefficient, we should have one term multiplied by A and another by $\frac{d\mathrm{A}}{dx}$; and by proper determination of $\frac{1}{\mathrm{A}}.\frac{d\mathrm{A}}{dx}$ we should be able to make the expression for $\mathrm{F}=0$ for any one value of y; but it is not possible to make it $=0$ for all values of y; and thus it appears that some force, though perhaps extremely small, is necessary to maintain the sort of undulation which we have supposed.

Whole force, from the bottom to the surface, assumed to be 0.

(242.) Among the different conditions on which we may fix for the determination of $\frac{d\mathrm{A}}{dx}$, the following appears the most reasonable; that upon the whole, from the bottom to the surface of the water, the horizontal force necessary to maintain the assumed wave-motion shall be 0, or that $\int_y\mathrm{F}$ shall $=0$. We cannot here perform the integration under the differential sign, because the limits of the integration will be η and k, the former of which is a function of x. Expanding the differential therefore, we find F=

$$\left\{\begin{array}{l}-2n^2\frac{d\mathrm{A}}{dx}.\frac{1}{m}.(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)})-2n^2\mathrm{A}\frac{1}{m}.\frac{dm}{dx}(y-\eta)(\varepsilon^{m(y-\eta)}-\varepsilon^{m(\eta-y)})\\+3n^2\mathrm{A}.\frac{1}{m^2}.\frac{dm}{dx}(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)})+2n^2\mathrm{A}\frac{d\eta}{dx}(\varepsilon^{m(y-\eta)}-\varepsilon^{m(\eta-y)})\end{array}\right\}\sin\overline{nt-\mathrm{M}}.$$

For $\int_y\mathrm{F}$, the general integral is

$$\left\{\begin{array}{l}-2n^2\frac{d\mathrm{A}}{dx}.\frac{1}{m^2}.(\varepsilon^{m(y-\eta)}-\varepsilon^{m(\eta-y)})-2n^2\mathrm{A}\frac{1}{m^2}.\frac{dm}{dx}(y-\eta)(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)})\\+5n^2\mathrm{A}.\frac{1}{m^3}.\frac{dm}{dx}.(\varepsilon^{m(y-\eta)}-\varepsilon^{m(\eta-y)})+2n^2\mathrm{A}\frac{1}{m}.\frac{d\eta}{dx}(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)})\end{array}\right\}\sin\overline{nt-\mathrm{M}},$$

which from $y=\eta$ to $y=k$ is

$$\left\{\begin{array}{l}-2n^2\frac{d\mathrm{A}}{dx}.\frac{1}{m^2}.(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})-2n^2\mathrm{A}.\frac{1}{m^2}.\frac{dm}{dx}(k-\eta)(\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)})\\+5n^2\mathrm{A}.\frac{1}{m^3}.\frac{dm}{dx}(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})+2n^2\mathrm{A}.\frac{1}{m}.\frac{d\eta}{dx}(\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)})-4n^2\mathrm{A}.\frac{1}{m}.\frac{d\eta}{dx}\end{array}\right\}\sin\overline{nt-\mathrm{M}}$$

$$=-2n^2m^{\frac{1}{2}}\left\{\frac{d\mathrm{A}}{dx}.m^{-\frac{5}{2}}.(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})+\mathrm{A}\frac{d}{dx}\{m^{-\frac{5}{2}}.(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})\}+2\mathrm{A}.m^{-\frac{3}{2}}.\frac{d\eta}{dx}\right\}\sin\overline{nt-\mathrm{M}}.$$

Making this $=0$, we find

$$\frac{1}{\mathrm{A}}.\frac{d\mathrm{A}}{dx}=\frac{-\frac{d}{dx}\{m^{-\frac{5}{2}}.(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})\}-2m^{-\frac{3}{2}}.\frac{d\eta}{dx}}{m^{-\frac{5}{2}}(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})}$$

whence

$$\mathrm{A}=\frac{\mathrm{C}m^{\frac{5}{2}}}{\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)}}\times\varepsilon^{\mathrm{Q}},$$

where

$$\frac{d\mathrm{Q}}{dx}=\frac{-2m\frac{d\eta}{dx}}{\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)}}.$$

Coefficient of horizontal motion.

(243.) The coefficient of horizontal displacement of particles at the surface is

$$\mathrm{A}(\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)})=\mathrm{C}.m^{\frac{5}{2}}.\frac{\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)}}{\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)}}.\varepsilon^{\mathrm{Q}}=\mathrm{C}.m^{\frac{5}{2}}.\frac{mg}{n^2}.\varepsilon^{\mathrm{Q}}=\frac{\mathrm{C}g}{n^2}m^{\frac{7}{2}}.\varepsilon^{\mathrm{Q}}.$$

(244.) The expression for the vertical displacement of particles at the surface, or K, consists of a large term and a small one, which may be represented by $B.\sin\overline{nt-M}+b.\cos\overline{nt-M}$. Making $\frac{b}{B}=\tan\alpha$, this expression $=\sqrt{B^2+b^2}.\sin\overline{nt-M+\alpha}$; but as b is small, $\sqrt{B^2+b^2}$ will not differ sensibly from B. The coefficient therefore of vertical displacement $=B$

Coefficient of vertical motion.

$$=A\,(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})=C.m^{\frac{5}{2}}.\varepsilon^{Q}.$$

(245.) In order then fully to understand the changes in the magnitude of the waves, we have now only to estimate the exponential ε^{Q}. It does not appear that the requisite integration for the exponent can be effected, unless a value be assigned for η in terms of x. But the following limiting values will give a good idea of its general value.

Value of coefficient for short waves.

(246.) 1st. When the waves are short in proportion to the depth (as in common waves, or in the ordinary swell of the sea), m or $\frac{2\pi}{\lambda}$ is large; therefore $\varepsilon^{m(k-\eta)}$ is very large, and $\dfrac{m\frac{d\eta}{dx}}{\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)}}$ is insignificantly small: therefore its integral $=0$; and the exponential term $=\varepsilon^{0}=1$. Thus we have this theorem. When the water is deep in proportion to the length of the waves, the coefficient of horizontal displacement varies as $m^{\frac{3}{2}}$ or inversely as $\lambda^{\frac{3}{2}}$; and the coefficient of vertical displacement varies as $m^{\frac{5}{2}}$ or inversely as $\lambda^{\frac{5}{2}}$. This theorem is not much in error if the depth be even as small as half the length of a wave.

Value of coefficient for long waves.

(247.) 2nd. When the waves are long in proportion to the depth (as in the tide-wave), m is small, and $\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)}=2m\,(k-\eta)$ nearly; therefore the exponent $=-2\int\dfrac{m\frac{d\eta}{dx}}{2m(k-\eta)}=-\int\dfrac{\frac{d\eta}{dx}}{k-\eta}=\log\,(k-\eta)$; and the exponential term $=\varepsilon^{\log(k-\eta)}=k-\eta$. But when m is small, the equation $m=\frac{n^2}{g}.\dfrac{\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)}}{\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)}}$ becomes $m=\frac{n^2}{g}.\frac{2}{2m(k-\eta)}$; therefore $m=\frac{n}{\sqrt{g}}.\frac{1}{(k-\eta)^{\frac{1}{2}}}$; $m^{\frac{3}{2}}=\frac{n^{\frac{3}{2}}}{g^{\frac{3}{4}}}.\frac{1}{(k-\eta)^{\frac{3}{4}}}$; $m^{\frac{5}{2}}=\frac{n^{\frac{5}{2}}}{g^{\frac{5}{4}}}.\frac{1}{(k-\eta)^{\frac{5}{4}}}$. Substituting these in the expressions for A and B we have this theorem. When the water is shallow in proportion to the length of the waves, the coefficient of horizontal displacement varies as $\overline{\text{the depth}}|^{-\frac{3}{4}}$ or as $m^{\frac{3}{2}}$, or inversely as $\lambda^{\frac{3}{2}}$; and the coefficient of vertical displacement varies as $\overline{\text{the depth}}|^{-\frac{1}{4}}$, or as $m^{\frac{1}{2}}$, or inversely as $\lambda^{\frac{1}{2}}$.

(248.) It may be worth while to examine into the value of F at the surface. We have already found for F the expression $-2n^2m^{\frac{1}{2}}.\frac{d}{dx}\{Am^{-\frac{3}{2}}(\varepsilon^{m(y-\eta)}+\varepsilon^{m(\eta-y)})\}.\sin\overline{nt-M}$; and putting k for y, the value of F at the surface is $-2n^2m^{\frac{1}{2}}.\frac{d}{dx}\{Am^{-\frac{3}{2}}(\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)})\}.\sin\overline{nt-M}$; which, on substituting for $A(\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)})$ the value already found, becomes

$$-2Cgm^{\frac{1}{2}}\frac{d}{dx}\{m^2.\varepsilon^{Q}\}\sin\overline{nt-M}.$$

$$=4Cgm^{\frac{3}{2}}.\varepsilon^{Q}\times\left\{\frac{m^2\frac{d\eta}{dx}}{\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)}}-\frac{dm}{dx}\right\}.\sin\overline{nt-M}.$$

The sign of the coefficient of $\sin\overline{nt-M}$ will depend entirely on the sign of the quantity within the large brackets; the external multiplier being essentially positive when C is positive; that is, when A is positive. Now suppose the wave to be moderately long, or m to be moderately small. On differentiating the equation

$$\log n^2=\log mg+\log\,(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})-\log\,(\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)})$$

and then expanding the exponentials to the third power of $m(k-\eta)$, we find

$$\frac{dm}{dx}=\frac{m\frac{d\eta}{dx}}{2(k-\eta)+\frac{2}{3}m^2(k-\eta)^3}.$$

Force necessary at the surface, to maintain the motion.

Expanding the exponentials in the term $\dfrac{m^2\dfrac{d\eta}{dx}}{\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)}}$ in the same manner, we find for the quantity within the large brackets

$$\frac{m\dfrac{d\eta}{dx}}{2(k-\eta)+\dfrac{1}{3}m^2(k-\eta)^3}-\frac{m\dfrac{d\eta}{dx}}{2(k-\eta)+\dfrac{2}{3}m^2(k-\eta)^3};$$

which, supposing the canal to become more shallow as the wave advances, that is, supposing $\dfrac{d\eta}{dx}$ to be positive, is evidently a very small positive quantity. The expression for F at the surface may therefore be represented by $+\text{E}.\sin\overline{nt-\text{M}}$. Now the elevation of the water, or K, has for its principal term $-\text{A}(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})\sin\overline{nt-\text{M}}$; consequently at the crest of a wave, or where K is greatest and positive, $\sin\overline{nt-\text{M}}=-1$; therefore at the crest of the wave, $\text{F}=-\text{E}$. That is, the force, which must act at the crest of the wave to maintain the particles in the state of wave-motion, must be in the direction opposite to that in which the wave is advancing; or, supposing no such force to act, the particles at the crest of the wave will spring forwards from the wave, or will *break* towards the shallow side. This seems to be a complete explanation of the breaking of waves over the edge of a sunk shoal.

Breaking of waves over sunk shoals, &c. explained.

Cause of the surf.

(249.) The breaking of the surf upon a beach is not, perhaps, entirely to be ascribed to the cause which we have assigned for breakers over sunk banks; although that cause undoubtedly produces a great part of the effect. The excessive extent of disturbance of the particles of the water is probably one of the principal causes. As $k-\eta$ is diminished, m is increased or λ diminished; that is, on the water becoming shallower, the waves become shorter. And as we have seen, the elevation of the high parts and the depression of the low parts become greater, so that the general character of the waves is becoming steeper. Moreover, as the height of the wave bears a large proportion to the depth of the water, the front of the wave becomes, from that cause, very steep (203.). At the crest of the wave (nearly) $\sin\overline{nt-\text{M}}$ as we have found $=-1$, or $nt-\text{M}=\dfrac{3\pi}{2}$; therefore at the crest of the wave, X, which depends on $\cos\overline{nt-\text{M}}$, is 0; in front of the crest, M is greater, $nt-\text{M}$ is less than $\dfrac{3\pi}{2}$, and X therefore is negative, or the particles are thrown backwards towards the crest, and therefore (in addition to the cause already assigned) on account of the rapidly increasing coefficient of X as the breadth diminishes, the steepness of the front of the wave rapidly increases. At the same time, the particles on the crest are themselves moving in the direction of the wave-motion, and with a velocity which becomes greater and greater (for the particles which happen to be on the crest) as the wave approaches the shore. It is evident that the limit to these circumstances is, that the front of the wave becomes as steep as a wall, while the uppermost particles are moving towards the shore and the lowermost from the shore; that the former, therefore, will tumble over the latter; and this is the motion of surf.

Investigation when the breadth is not uniform.

(250.) Hitherto we have supposed the breadth of the canal uniform; or, rather, we have taken no account whatever of its breadth. We will now suppose the breadth of a narrow canal to be variable.

Problem.—To investigate the circumstances of the change of wave-motion in a narrow canal of uniform depth whose breadth at different points is different.

(251.) Let β, the breadth of the canal, be considered a function of x. It is easily seen that the equation of continuity must now be altered. For in figure 8, the small parallelogram ps is carried forward to the position PS, where the breadth of the canal is different; namely, is $\beta+\dfrac{d\beta}{dx}\text{X}$ instead of β: and, therefore, instead of making $hl=h\times\left(1+\dfrac{d\text{X}}{dx}\right)\times l\times\left(1+\dfrac{d\text{Y}}{dy}\right)$, as in (145.), we must make

$$\beta\times hl=\beta\left(1+\frac{1}{\beta}\cdot\frac{d\beta}{dx}\text{X}\right)\times h\left(1+\frac{d\text{X}}{dx}\right)\times l\left(1+\frac{d\text{Y}}{dy}\right):$$

from which we find

$$0=\frac{1}{\beta}\cdot\frac{d\beta}{dx}\text{X}+\frac{d\text{X}}{dx}+\frac{d\text{Y}}{dy};$$

and, integrating with respect to y,

$$\text{Y}=-\int_y\left(\frac{d\text{X}}{dx}+\frac{\text{X}}{\beta}\cdot\frac{d\beta}{dx}\right)\text{ (from 0 to } y\text{)}.$$

The equation of equal pressure remains as before; namely,

$$\frac{d^2X}{dt^2}=F+\frac{d}{dx}\left\{-gK-\int_y \frac{d^2Y}{dt^2}\,(y \text{ to } k)\right\}.$$

(252.) We shall now proceed as in the case of variable depth, assuming that the expression for the wave-displacement may be represented by the same formula as if the breadth were uniform, with proper alteration of the constants. The assumption, however, is much simpler than where the depth is variable, inasmuch as we have no reason for assuming the expression for the phase to be different (the velocity of the wave, as depending on the depth, being everywhere the same). Thus, then, we have for X, $A(\varepsilon^{my}+\varepsilon^{-my})\cos\overline{nt-mx}$, where A is a function of x, and m is constant, connected with n by the equation $n^2=gm.\dfrac{\varepsilon^{mk}-\varepsilon^{-mk}}{\varepsilon^{mk}+\varepsilon^{-mk}}$.

(253.) The expression $\dfrac{dX}{dx}+\dfrac{X}{\beta}.\dfrac{d\beta}{dx}$ becomes

$$(\varepsilon^{my}+\varepsilon^{-my})\left\{\frac{dA}{dx}.\cos\overline{nt-mx}+mA.\sin\overline{nt-mx}+\frac{A}{\beta}.\frac{d\beta}{dx}.\cos\overline{nt-mx}\right\};$$

from which we obtain for Y,

$$-(\varepsilon^{my}-\varepsilon^{-my})\left\{\frac{1}{m}.\frac{dA}{dx}.\cos\overline{nt-mx}+A.\sin\overline{nt-mx}+\frac{1}{m}.\frac{A}{\beta}.\frac{d\beta}{dx}.\cos\overline{nt-mx}\right\};$$

therefore $$\frac{d^2Y}{dt^2}=(\varepsilon^{my}-\varepsilon^{-my})\left\{\frac{n^2}{m}.\frac{dA}{dx}.\cos\overline{nt-mx}+n^2A.\sin\overline{nt-mx}+\frac{n^2}{m}.\frac{A}{\beta}.\frac{d\beta}{dx}.\cos\overline{nt-mx}\right\},$$

and $$-\int_y\frac{d^2Y}{dt^2}\,(y \text{ to } k)=(\varepsilon^{my}+\varepsilon^{-my}-\varepsilon^{mk}-\varepsilon^{-mk})\left\{\frac{n^2}{m^2}.\frac{dA}{dx}.\cos\overline{nt-mx}+\frac{n^2}{m}A.\sin\overline{nt-mx}+\frac{n^2}{m^2}.\frac{A}{\beta}.\frac{d\beta}{dx}.\cos\overline{nt-mx}\right\}.$$

Also $$-gK=(\varepsilon^{mk}-\varepsilon^{-mk})\left\{\frac{g}{m}.\frac{dA}{dx}.\cos\overline{nt-mx}+gA.\sin\overline{nt-mx}+\frac{g}{m}.\frac{A}{\beta}.\frac{d\beta}{dx}.\cos\overline{nt-mx}\right\}.$$

Therefore, by virtue of the equation $n^2(\varepsilon^{mk}+\varepsilon^{-mk})=gm(\varepsilon^{mk}-\varepsilon^{-mk})$,

$$-gK-\int_y\frac{d^2Y}{dt^2}\,(y \text{ to } k)=(\varepsilon^{my}+\varepsilon^{-my})\left\{\frac{n^2}{m^2}.\frac{dA}{dx}.\cos\overline{nt-mx}+\frac{n^2}{m}A.\sin\overline{nt-mx}+\frac{n^2}{m^2}.\frac{A}{\beta}.\frac{d\beta}{dx}.\cos\overline{nt-mx}\right\}.$$

(254.) In differentiating this quantity with regard to x, we shall suppose the breadth to vary slowly, and shall, therefore, as in the similar differentiation of the last Problem, reject all products of differential coefficients, and all differential coefficients of the second order. Thus we obtain

$$\frac{d}{dx}\left\{-gK-\int_y\frac{d^2Y}{dt^2}\,(y \text{ to } k)\right\}=$$

$$(\varepsilon^{my}+\varepsilon^{-my})\left\{\frac{2n^2}{m}.\frac{dA}{dx}.\sin\overline{nt-mx}n^2-A.\cos\overline{nt-mx}+\frac{n^2}{m}.\frac{A}{\beta}.\frac{d\beta}{dx}.\sin\overline{nt-mx}\right\}.$$

Also $$\frac{d^2X}{dt^2}=(\varepsilon^{my}+\varepsilon^{-my})\,(-n^2A.\cos\overline{nt-mx}).$$

Subtracting the former from the latter,

$$F=-(\varepsilon^{my}+\varepsilon^{-my})\left\{\frac{2n^2}{m}.\frac{dA}{dx}+\frac{n^2}{m}.\frac{A}{\beta}.\frac{d\beta}{dx}\right\}\sin\overline{nt-mx}.$$

Coefficients of horizontal and vertical motion.

This expression vanishes, or no force is necessary to maintain the wave-motion, if $2\dfrac{dA}{dx}+\dfrac{A}{\beta}.\dfrac{d\beta}{dx}=0$, or if $\dfrac{2}{A}.\dfrac{dA}{dx}+\dfrac{1}{\beta}.\dfrac{d\beta}{dx}=0$, or if $\log(A^2\beta)=\log C^2$, or $A=\dfrac{C}{\sqrt{\beta}}$. That is, the coefficient of horizontal motion will be inversely as the square root of the breadth of the canal. The coefficient of vertical motion (in the same manner as in (244.)), will not sensibly differ from $-A(\varepsilon^{my}-\varepsilon^{-my})$, or, at the surface, $-A(\varepsilon^{mk}-\varepsilon^{-mk})$: and thus the height of the waves will be inversely as the square root of the breadth of the canal.

(255.) We might, without difficulty, have combined the investigations of the two last Problems; and we should have found the expression for the variation of the coefficient of either motion in a canal where both breadth and depth vary, to be represented by the product of those found separately in the two Problems.

(256.) Before quitting these important investigations, we shall make one remark. When waves travel along a canal of uniform breadth and depth, the motion of every particle, as we have seen (182.) and (183.), is in a circle, or an ellipse whose major axis is horizontal: if in a circle, its motion in that circle is uniform; if in an ellipse, the horizontal motion is, at any instant of time, in the same proportion to the whole horizontal motion as in a circle, and the vertical motion is also in the same proportion to the whole vertical motion as in a circle.

And (184.) the greatest horizontal motion forwards occurs when a particle is at the top of a wave: the greatest horizontal motion backwards occurs when a particle is at the bottom of a wave; and the horizontal motion is 0 when a particle is at its mean elevation. These assertions are not true if the depth or breadth is variable. Thus, in the case of variable depth; the horizontal displacement at the surface $=X=A(\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)})\cos\overline{nt-M}$: the horizontal motion $=-nA(\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)})\sin\overline{nt-M}$: this is greatest when $nt-M=\frac{3\pi}{2}$, $\sin\overline{nt-M}=-1$, $\cos\overline{nt-M}=0$; substituting these values in the expression for K, it becomes $A(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})$, which is not the greatest value of K; for the expression for K is of the form $B\sin\overline{nt-M}+b\cos\overline{nt-M}$, the greatest value of which is $\sqrt{B^2+b^2}$, where $B=A(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})$. The horizontal motion is 0 when $\sin\overline{nt-M}=0$; which (if we take the case of still water following the high water, implying that t has been increased above the value which made $\sin\overline{nt-M}=-1$) gives $nt-M=0$, $\cos nt-M=1$; and the corresponding value of K is

$$-\frac{dA}{dx}\cdot\frac{1}{m}(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})-A\frac{1}{m}\cdot\frac{dm}{dx}(k-\eta)(\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)})+A\frac{1}{m^2}\cdot\frac{dm}{dx}(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})+A\frac{d\eta}{dx}(\varepsilon^{m(k-\eta)}+\varepsilon^{m(\eta-k)})$$

$$=-\frac{d}{dx}\left\{\frac{A}{m}(\varepsilon^{m(k-\eta)}-\varepsilon^{m(\eta-k)})\right\}$$

$$=-\frac{d}{dx}\cdot\frac{\text{coefficient of vertical displacement}}{m}.$$

In the case of short waves in deep water, we have found the coefficient of vertical displacement to vary as $m^{\frac{3}{2}}$; therefore this value of K varies as $-\frac{d}{dx}m^{\frac{1}{2}}$: as the depth diminishes, m increases, and this value of K is negative. But in the case of long waves in shallow water (as the tide-wave), the coefficient of vertical displacement varies as $m^{\frac{1}{2}}$; therefore this value of K varies as $-\frac{d}{dx}\cdot\frac{1}{m^{\frac{1}{2}}}$: as the depth diminishes, m increases, and K is therefore positive. That is, in the case of long waves in shallow water, where the depth diminishes, the water is sensibly elevated above its mean height when the flow ceases; and in like manner it is sensibly depressed below its mean height when the ebb ceases.

Cessation of flow occurs earlier than if the depth and breadth were uniform.

(257.) In the case of variable width; the horizontal displacement at the surface $=A(\varepsilon^{mk}+\varepsilon^{-mk})\cos\overline{nt-mx}$; the horizontal motion $=-nA(\varepsilon^{mk}+\varepsilon^{-mk})\sin\overline{nt-mx}$: this is 0, for the still water following the high water, when $\sin\overline{nt-mx}=0$, $\cos\overline{nt-mx}=1$; the corresponding value of K is

$$-(\varepsilon^{mk}-\varepsilon^{-mk})\left\{\frac{1}{m}\cdot\frac{dA}{dx}+\frac{1}{m}\cdot\frac{A}{\beta}\cdot\frac{d\beta}{dx}\right\}=-\frac{1}{m\beta}(\varepsilon^{mk}-\varepsilon^{-mk})\frac{d}{dx}(A\beta).$$

But we have found $A=\frac{C}{\beta^{\frac{1}{2}}}$, therefore $A\beta=C\beta^{\frac{1}{2}}$; and therefore $K=-\frac{1}{m\beta}(\varepsilon^{mk}-\varepsilon^{-mk})\frac{d}{dx}(C\beta^{\frac{1}{2}})$ If the breadth diminishes as x increases, the differential coefficient $\frac{d}{dx}(C\beta^{\frac{1}{2}})$ is negative, and therefore the value of K is positive. That is, where the breadth diminishes, the water is sensibly elevated above its mean height when the flow ceases; and in like manner, the water is sensibly depressed below its mean height when the ebb ceases.

(258.) When (as usually happens) both these causes unite, that is when the channel along which the tide-wave is propagated becomes at the same time shallower and narrower, it may happen that the height of the water above its mean level is considerable when the flow ceases.

Investigation for a canal whose section is of any form and varies in any degree, when the wave is very long.

(259.) The change in the circumstances of the wave produced by the variation of the section of the channel in form as well as in breadth and in depth, when the wave is supposed to be very long, may be found more simply in the following manner.

(260.) Let the equation to the section, as in (218.), be $z=\phi(y,x)$, x being introduced into the function because the form and dimensions vary with x; and $u=\int_y z=\psi(y,x)$. For the same reason as in (238.), suppose X to be represented by $A\cos\overline{nt-M}$, where $M=\int_x m$. Now we have found in (220.) that the function expressing a single wave on a uniform canal whose section is defined by the equation $u=\psi(y,x)$, is $X=\chi(v't-x)=\chi\left(t\sqrt{\frac{g\psi(k)}{\phi(k)}}-x\right)=\chi_{,}\left(nt-nx\sqrt{\frac{\phi(k)}{g\psi(k)}}\right)$. Comparing this with our usual form for X in a uniform canal, namely, $A\cos\overline{nt-mx}$, it appears that $m=n\sqrt{\dfrac{\phi(k)}{g\psi(k)}}$, and therefore in the variable canal

$$M=n\int_x\sqrt{\frac{\phi(k,x)}{g\psi(k,x)}}.$$

(261.) Now the fluid, which when at rest was included between two vertical planes whose co-ordinates were x and $x+h$, is now included between two vertical planes whose co-ordinates are $x+X$ and $x+X+h+\dfrac{dX}{dx}h$ nearly; and the area of the vertical section, which was $\psi(k,x)$, is now $\psi(V,x+X)$, or $\psi(k+\overline{V-k},x+X)$, or $\left(\text{observing that } \dfrac{d\,.\,\psi(k,x)}{dk}=\phi(k,x)\right)$ $\psi(k,x)+\phi(k,x).\overline{V-k}+\dfrac{d\,.\,\psi(k,x)}{dx}X$. Thus the equation of continuity becomes

$$h\times\psi(k,x)=h\left(1+\frac{dX}{dx}\right)\times\left\{\psi(k,x)+\phi(k,x).\overline{V-k}+\frac{d.\psi(k,x)}{dx}X\right\},$$

or

$$0=\frac{dX}{dx}.\psi(k,x)+\phi(k,x).\overline{V-k}+\frac{d.\psi(k,x)}{dx}X;$$

whence

$$V-k=-\frac{1}{\phi(k,x)}\frac{d}{dx}\Big(X.\psi(k,x)\Big).$$

(262.) The equation of pressure will be as before, $\dfrac{d^2X}{dt^2}=-g\dfrac{dV}{dx}.\dfrac{1}{1+\dfrac{dX}{dx}}=-g\dfrac{dV}{dx}$ nearly. Substituting for V, this becomes

$$\frac{d^2X}{dt^2}=g\frac{d}{dx}\left\{\frac{1}{\phi(k,x)}\frac{d}{dx}\Big(X.\psi(k,x)\Big)\right\}.$$

Performing the interior differentiation on the assumption $X=A\cos\overline{nt-M}$, where A is a function of x, and $\dfrac{dM}{dx}=n\sqrt{\dfrac{\phi(k,x)}{g\psi(k,x)}}$, this becomes

$$\frac{d^2X}{dt^2},\text{ or }-n^2A.\cos\overline{nt-M}=g\frac{d}{dx}\left\{\frac{1}{\phi(k,x)}\frac{d}{dx}\Big(A.\psi(k,x)\Big)\cos\overline{nt-M}+nA\sqrt{\frac{\psi(k,x)}{g\phi(k,x)}}\sin\overline{nt-M}\right\}.$$

Performing the second differentiation, with the limitation that, as $\phi(k,x)$ and $\psi(k,x)$ vary very slowly, their second differentials and squares of first differentials may be rejected,

$$-n^2A.\cos\overline{nt-M}=n\sqrt{g}.\left\{\frac{1}{\sqrt{\phi(k,x).\psi(k,x)}}\frac{d}{dx}\Big(A.\psi(k,x)\Big)+\frac{d}{dx}\left\{\frac{A.\psi(k,x)}{\sqrt{\phi(k,x).\psi(k,x)}}\right\}\right\}\text{sih}\,\overline{nt-M}$$
$$-n^2A.\cos\overline{nt-M}.$$

Let $A\psi(k,x)=\nu$, $\sqrt{\phi(k,x).\psi(k,x)}=\mu$: then this equation reduces itself to

$$\frac{1}{\mu}.\frac{d\nu}{dx}+\frac{d}{dx}\left\{\frac{\nu}{\mu}\right\}=0,$$

or

$$\frac{2}{\mu}.\frac{d\nu}{dx}-\frac{\nu}{\mu^2}.\frac{d\mu}{dx}=0,$$

or

$$\frac{2}{\nu}.\frac{d\nu}{dx}-\frac{1}{\mu}.\frac{d\mu}{dx}=0,$$

the integral of which is $\dfrac{\nu^2}{\mu}=C^2$, or $A^2.\{\psi(k,x)\}^{\frac{3}{2}}.\{\phi(k,x)\}^{-\frac{1}{2}}=C^2$,

or

$$A=C.\{\psi(k,x)\}^{-\frac{3}{4}}.\{\phi(k,x)\}^{\frac{1}{4}}.$$

This is the coefficient of horizontal displacement of the particles.

Coefficient of horizontal motion.

(263.) For the vertical displacement,

$$K=V-k=-\frac{1}{\phi(k,x)}\frac{d}{dx}\Big(X.\psi(k,x)\Big)=-\frac{1}{\phi(k,x)}.\frac{d}{dx}\Big(A.\psi(k,x).\cos\overline{nt-M}\Big)$$
$$=-\frac{1}{\phi(k,x)}\left\{\frac{d}{dx}\Big(A.\psi(k,x)\Big).\cos\overline{nt-M}+A.\psi(k,x).\sin\overline{nt-M}\,.\,n\sqrt{\frac{\phi(k,x)}{g\psi(k,x)}}\right\},$$

in which the first term may be neglected as much smaller than the second. Thus

Tides and Waves.

$$\mathrm{K}=-\frac{n}{\sqrt{g}}.\mathrm{A}\sqrt{\frac{\psi\,(k,x)}{\phi\,(k,x)}}.\ \sin\overline{nt-\mathrm{M}}.$$

Coefficient of vertical motion.

Putting for A its value found above, we have for the coefficient of vertical displacement

$$-\frac{n}{\sqrt{g}}\mathrm{C}\,.\{\psi\,(k,x)\}^{-\frac{1}{4}}\,.\,\{\phi\,(k,x)\}^{-\frac{1}{4}}.$$

(264.) For instance: if the section of the canal be everywhere a rectangle, $\phi\,(k,x)=$ breadth, and $\psi\,(k,x)=$ breadth × depth: which gives for the coefficient of vertical displacement

$$-\frac{n}{\sqrt{g}}\mathrm{C}.\{\text{breadth}\}^{-\frac{1}{2}}.\{\text{depth}\}^{-\frac{1}{4}},$$

a result which agrees with those found for long waves in shallow water in (247.) and (254.).

(265.) The two following problems regarding the motion of variable waves on a sea of uniform depth are interesting, as applying to some most important phænomena.

Elevations increase from wave to wave.

Problem.—The amplitude of each successive wave in a long series is the same, but the elevations of the waves increase progressively from wave to wave, the same elevation always corresponding to the same place: to find the forces which must act on the particles of water to maintain this state of undulation.

(266.) Here the value of Y at the surface, or K, must have a factor of $\sin\overline{nt-mx}$, which itself depends upon x. We may therefore suppose X to have such a factor: in other respects the form assumed for X may be the same as in the case of uniform waves. Let therefore

$$\mathrm{X}=(\varepsilon^{my}+\varepsilon^{-my})\,.\,\phi\,(x).\ \cos\overline{nt-mx}:$$

where n and m are connected by the equation $n^2=mg\dfrac{\varepsilon^{mk}-\varepsilon^{-mk}}{\varepsilon^{mk}+\varepsilon^{-mk}}$. Then

$$\frac{d\mathrm{Y}}{dy}=-\frac{d\mathrm{X}}{dx}=-(\varepsilon^{my}+\varepsilon^{-my})\,\frac{d}{dx}\Big(\phi\,(x)\cos\overline{nt-mx}\Big);$$

integrating from 0 to y,

$$\mathrm{Y}=\frac{1}{m}\,(-\varepsilon^{my}+\varepsilon^{-my})\,\frac{d}{dx}\Big(\phi\,(x).\ \cos\overline{nt-mx}\Big);$$

$$\mathrm{K}=\frac{1}{m}\,(-\varepsilon^{mk}+\varepsilon^{-mk})\,\frac{d}{dx}\Big(\phi\,(x).\cos\overline{nt-mx}\Big):$$

$$\frac{d^2\mathrm{Y}}{dt^2}=\frac{n^2}{m}(\varepsilon^{my}-\varepsilon^{-my})\,\frac{d}{dx}\Big(\phi\,(x).\cos\overline{nt-mx}\Big)$$

$$\int_y\frac{d^2\mathrm{Y}}{dt^2}\,(y\text{ to }k)=\frac{n^2}{m^2}\,(\varepsilon^{mk}+\varepsilon^{-mk}-\varepsilon^{my}-\varepsilon^{-my})\,\frac{d}{dx}\Big(\phi\,(x).\ \cos\overline{nt-mx}\Big):$$

therefore $$g\mathrm{K}+\int_y\frac{d^2\mathrm{Y}}{dt^2}(y\text{ to }k)=-\frac{n^2}{m^2}\,(\varepsilon^{my}+\varepsilon^{-my})\,\frac{d}{dx}\Big(\phi\,(x).\ \cos\overline{nt-mx}\Big):$$

the terms $\dfrac{g}{m}\,(-\varepsilon^{mk}+\varepsilon^{-mk})+\dfrac{n^2}{m^2}\,(\varepsilon^{mk}+\varepsilon^{-mk})$ destroying one another by virtue of the equation between n and m.

Also $$\frac{d^2\mathrm{X}}{dt^2}=-n^2\,(\varepsilon^{my}+\varepsilon^{-my}).\phi\,(x)\cos\overline{nt-mx}.$$

Hence F or $\dfrac{d^2\mathrm{X}}{dt^2}+\dfrac{d}{dx}\Big\{g\mathrm{K}+\displaystyle\int_y\dfrac{d^2\mathrm{Y}}{dt^2}\,(y\text{ to }k)\Big\}$ becomes

$$-n^2(\varepsilon^{my}+\varepsilon^{-my}).\Big\{\phi\,(x).\ \cos\overline{nt-mx}+\frac{1}{m^2}.\frac{d^2}{dx^2}\Big(\phi\,(x).\ \cos\overline{nt-mx}\Big)\Big\}.$$

Performing the differentiation, this becomes

$$-n^2\,(\varepsilon^{my}+\varepsilon^{-my}).\Big\{\frac{2}{m}.\ \phi'\,(x)\ .\ \sin\overline{nt-mx}+\frac{1}{m^2}.\phi''\,(x)\ .\ \cos\overline{nt-mx}\Big\}.$$

Force necessary to maintain this motion.

If $\phi\,(x)=\mathrm{C}x+\mathrm{D}$, this expression for F becomes $-\dfrac{2\mathrm{C}n^2}{m}\,(\varepsilon^{my}+\varepsilon^{-my}).\ \sin\overline{nt-mx}$. Now when the force is small, or the coefficient C small, the expression for Y will not sensibly differ from $-(\varepsilon^{my}-\varepsilon^{-my}).(\mathrm{C}x+\mathrm{D}).\sin\overline{nt-mx}$. The term ε^{-my} is very small in comparison with ε^{my}, except very near the bottom. The result therefore is this: the force which, acting horizontally upon the particles of water, will maintain such a series of waves as we have supposed, must, for each particle, be nearly proportional to the elevation of that particle above its mean place: the proportion varying slowly, however, from one particle to another. Or we may state it thus: the force must be proportional to the horizontal velocity of each particle, and in the same direction as its motion.

(267.) Now we have nearly such a force in the action of the wind upon the waves. For the part of the wave which is principally or solely exposed to the action of the wind is its upper part. Thus the highest parts alone, or those near the crest of the wave, are urged forward: the lowest parts, or those in the hollow of the wave, either are not urged forward, or (more probably) by the eddies of the wind are actually urged backwards. Moreover, the action of the wind does not sensibly extend to a great depth below the surface: and in this respect it may be considered as fairly represented by ε^{my}. Thus then we have a mathematical explanation of the circumstance that the action of the wind will maintain the motion of a series of waves, whose elevation beginning at the windward shore is 0, and goes on increasing successively from wave to wave, without remarkable alteration from time to time (when they have once attained a certain magnitude). And as the proportion of the force of the wind, in regard to depth, is in pretty good agreement with that required by the theory for continuous unbroken waves, the theory explains the circumstance that, when the waves have attained this certain magnitude, their heads will scarcely be broken by the action of the wind.

The force of the wind corresponds closely with this expression.

(268.) It may, however, be remarked that, in the open sea, the waves of large amplitude only are so much increased as to attract much attention. The reason appears to be that, when the action of the wind has in some degree increased all, the long waves protect the short ones from the continuance of its action upon them. And thus the long waves are conspicuous upon an open sea, not because the short waves are changed into long ones, but because the long ones only are conspicuously increased from the windward shore to the open sea.

In the open sea, the long waves only become important.

(269.) Problem.—The amplitudes of all the waves are equal, and the elevations are all equal at the same time, but increase constantly from time to time: to find the forces which must act on the particles of water to maintain this state of undulation.

The waves increase from time to time.

(270.) Here we shall assume

$$X = (\varepsilon^{my} + \varepsilon^{-my}) \cdot \psi(t) \cdot \cos \overline{nt - mx}.$$

Then

$$\frac{dY}{dy} = -\frac{dX}{dx} = -m\,(\varepsilon^{my} + \varepsilon^{-my}) \cdot \psi(t) \cdot \sin \overline{nt - mx}:$$

integrating from 0 to y,

$$Y = (-\varepsilon^{my} + \varepsilon^{-my}) \cdot \psi(t) \cdot \sin \overline{nt - mx}:$$

$$\frac{d^2Y}{dt^2} = (-\varepsilon^{my} + \varepsilon^{-my}) \frac{d^2}{dt^2}\left(\psi(t) \cdot \sin \overline{nt - mx}\right):$$

$$\int_y \frac{d^2Y}{dt^2}(y \text{ to } k) = \frac{1}{m}\,(-\varepsilon^{mk} - \varepsilon^{-mk} + \varepsilon^{my} + \varepsilon^{-my}) \frac{d^2}{dt^2}\left(\psi(t) \cdot \sin \overline{nt - mx}\right):$$

$$K = (-\varepsilon^{mk} + \varepsilon^{-mk}) \cdot \psi(t) \cdot \sin \overline{nt - mx}:$$

therefore

$$\frac{d}{dx}\left\{gK + \int_y \frac{d^2Y}{dt^2}(y \text{ to } k)\right\} =$$

$$\frac{d}{dx}\left\{g\,(-\varepsilon^{mk} + \varepsilon^{-mk}) \cdot \psi(t) \cdot \sin \overline{nt - mx} + \frac{1}{m}\,(-\varepsilon^{mk} - \varepsilon^{-mk} + \varepsilon^{my} + \varepsilon^{-my}) \frac{d^2}{dt^2}\left(\psi(t) \cdot \sin \overline{nt - mx}\right)\right\}$$

$$= gm\,(\varepsilon^{mk} - \varepsilon^{-mk}) \cdot \psi(t) \cdot \cos \overline{nt - mx} + (\varepsilon^{mk} + \varepsilon^{-mk} - \varepsilon^{my} - \varepsilon^{-my}) \cdot \frac{d^2}{dt^2}\left(\psi(t) \cdot \cos \overline{nt - mx}\right).$$

Also

$$\frac{d^2X}{dt^2} = (\varepsilon^{my} + \varepsilon^{-my}) \frac{d^2}{dt^2}\left(\psi(t) \cdot \cos \overline{nt - mx}\right).$$

Hence the expression for F or $\frac{d^2X}{dt^2} + \frac{d}{dx} \left. gK + \int_y \frac{d^2Y}{dt^2}(y \text{ to } k)\right\}$ becomes

$$gm\,(\varepsilon^{mk} - \varepsilon^{-mk}) \cdot \psi(t) \cdot \cos \overline{nt - mx} + (\varepsilon^{mk} + \varepsilon^{-mk}) \frac{d^2}{dt^2}\left(\psi(t) \cdot \cos \overline{nt - mx}\right).$$

Performing the differentiation, and observing that $gm\,(\varepsilon^{mk} - \varepsilon^{-mk}) - n^2\,(\varepsilon^{mk} + \varepsilon^{-mk}) = 0$, we have

$$F = (\varepsilon^{mk} + \varepsilon^{-mk})\,\{\psi''(t) \cdot \cos \overline{nt - mx} - 2n \cdot \psi'(\ ) \cdot \sin \overline{nt - mx}\}.$$

Force necessary to maintain this motion.

If $\psi(t) = Ct + D$, we must have

$$F = -2nC\,(\varepsilon^{mk} + \varepsilon^{-mk}) \cdot \sin \overline{nt - mx}.$$

That is: the elevations of the waves will be increased uniformly, provided a horizontal force acts upon every particle, which is equal for all the particles in the same vertical column, and which urges forward those particles that are above their mean places and urges backward those that are below their mean places, according to the law of the sine of the phase.

(271.) Now the action of the wind produces a force strongly resembling this, but not so nearly as before. For the force (as in the former case) does act to urge forward those parts which are above their mean place, and in some degree to urge backwards those which are below their mean place. But it is not nearly equal for the particles at different elevations in the same vertical column: being effective only near the top and insensible for other parts. Hence it appears that there is too much horizontal force at the top of the waves for continuous undulation: and this excess of force is in the direction in which the wave is going, and therefore tends to

The force of the wind nearly represents this force, but not exactly.

push the top of the wave too rapidly. To this cause, as we conceive, is to be ascribed the breaking of the crests of the waves, which always takes place when the wind is raising the sea.

We may proceed in the same manner if $\mathrm{X}=(\varepsilon^{my}+\varepsilon^{-my})\,(\mathrm{A}+\mathrm{B}x+\mathrm{C}t)\cos\overline{ni-mx}$.

Manner in which the wind acts to raise the waves. Limitation to the height of the waves raised by a wind of given force on a sea of given extent.

(272.) The effect of continued action of wind upon the sea may be conceived to show itself in the following manner. It is to be understood that, either from preceding disturbances, or from the trifling irregularities in the action of the wind while the water is smooth, there are very shallow undulations upon the water. When the wind begins to act, it will at first only increase the height of the waves in every part (271.), and during this time the heads of the waves will be broken. But after a time the waves, beginning with the windward shore, will be (for a short distance at least) so much increased, that the power of the wind will merely maintain them in that state without any increase (267.), but for all the sea in advance the wind will still be raising the waves. But as the waves successively attain that height which corresponds, according to the result of (266.), with the height which the wind can just maintain, those waves will no longer be increased, but the waves in advance will still be increased. Thus a wind of given intensity, however long it blows, can only raise the waves at a given point to a certain height: which height, however, will depend upon the distance of that point from the windward shore.

Motion of water under the action of forces similar to the tidal forces.

(273.) We shall now consider the motion of water in a canal of uniform breadth and depth under the action of a given force. The difficulties connected with a general solution of this problem would, in the present state of mathematics, be found insuperable; we shall therefore confine ourselves to a law of force which applies perfectly to the problem of tides.

(274.) Problem.—The water in a canal of uniform breadth and depth is acted on by a horizontal force represented at every point by $\mathrm{H}.\sin\overline{it-mx}$ and by a vertical force represented by $\mathrm{G}.\cos\overline{it-mx}$: to find the nature of the wave which will be produced.

(275.) The equations to be used are those of (224.), supposing the depth uniform or $\eta=0$. They become

$$\mathrm{Y}=-\int_y\frac{d\mathrm{X}}{dx}\,(0\text{ to }y)$$

$$\frac{d^2\mathrm{X}}{dt^2}=\mathrm{H}.\sin\overline{it-mx}+\frac{d}{dx}\left\{-(g+\mathrm{G}.\cos\overline{it-mx})\,(k-y+\mathrm{K})-\int_y\frac{d^2\mathrm{Y}}{dt^2}\,(y\text{ to }k)\right\}.$$

The forces are supposed to be small, and the term $\frac{d}{dx}\,(g.\overline{k-y})$ is evidently $=0$. These considerations reduce the second equation to this form:

$$\frac{d^2\mathrm{X}}{dt^2}=\mathrm{H}.\sin\overline{it-mx}+\frac{d}{dx}\left\{-g\mathrm{K}-\overline{k-y}.\mathrm{G}.\cos\overline{it-mx}-\int_y\frac{d^2\mathrm{Y}}{dt^2}\,(y\text{ to }k)\right\}.$$

Now the least trial would show that the expression for X must depend on $\sin\overline{it-mx}$. Assume therefore

$$\mathrm{X}=\phi''(y).\sin\overline{it-mx};$$

$\phi''(y)$ being a function of y whose form is yet to be determined, and which is conceived as the second derived function from some function $\phi(y)$. Then

$$\frac{d\mathrm{X}}{dx}=-m\phi''(y)\cos\overline{it-mx};\qquad-\int_y\frac{d\mathrm{X}}{dx}=m\phi'(y)\cos\overline{it-mx};$$

from which

$$\mathrm{Y}=m\Big(\phi'(y)-\phi'(0)\Big)\cos\overline{it-mx}.$$

Therefore

$$\frac{d^2\mathrm{Y}}{dt^2}=-i^2m\Big(\phi'(y)-\phi'(0)\Big)\cos\overline{it-mx};$$

$$-\int_y\frac{d^2\mathrm{Y}}{dt^2}\,(y\text{ to }k)=+i^2m\Big(\phi(k)-\phi(y)-\phi'(0).\overline{k-y}\Big)\cos\overline{it-mx};$$

$$-g\mathrm{K}=-gm\Big(\phi'(k)-\phi'(0)\Big)\cos\overline{it-mx}.$$

Adding to these terms $-\overline{k-y}.\mathrm{G}.\cos\overline{it-mx}$, differentiating with regard to x, and putting for $\frac{d^2\mathrm{X}}{dt^2}$ its value $-i^2.\phi''(y).\sin\overline{it-mx}$, our second equation becomes

$$\begin{aligned}-i^2.\phi''(y).\sin\overline{it-mx}=\mathrm{H}.\sin\overline{it-mx}&\\-gm^2.\Big(\phi'(k)-\phi'(0)\Big).\sin\overline{it-mx}&\\-m(k-y).\mathrm{G}.\sin\overline{it-mx}&\\+i^2m^2\Big(\phi(k)-\phi(y)-\phi'(0).\overline{k-y}\Big)\sin\overline{it-mx}.&\end{aligned}$$

(276.) Equating to 0 the terms depending on y, we have

$$-i^2.\phi''(y)=-i^2m^2\phi(y);\ 0=-m(k-y)\,\mathrm{G}-i^2m^2\phi'(0).\overline{k-y}.$$

Sect. IV. Theory of Waves.

bsec. 4. en the er is er the on of izontal Verti- Forces.

The first gives $\phi(y)=A.\varepsilon^{my}+B.\varepsilon^{-my}$. From this we obtain $\phi'(y)=mA.\varepsilon^{my}-mB.\varepsilon^{-my}$; $\phi''(y)=m^2A.\varepsilon^{my}+m^2B.\varepsilon^{-my}$. The second equation gives $G+i^2m\phi'(0)=0$, or $G+i^2m^2A-i^2m^2B=0$, or $B-A=\frac{G}{i^2m^2}$; whence $B=A+\frac{G}{i^2m^2}$; $\phi(y)=A(\varepsilon^{my}+\varepsilon^{-my})+\frac{G}{i^2m^2}\varepsilon^{-my}$; $\phi'(y)=mA(\varepsilon^{my}-\varepsilon^{-my})-\frac{G}{i^2m}\varepsilon^{-my}$. Substituting in those parts of the equation which have not been already destroyed,

$$0=H-gm^2\left(mA(\varepsilon^{mk}-\varepsilon^{-mk})-\frac{G}{i^2m}\varepsilon^{-mk}+\frac{G}{i^2m}\right)+i^2m^2\left(A(\varepsilon^{mk}+\varepsilon^{-mk})+\frac{G}{i^2m^2}\varepsilon^{-mk}\right)$$

or

$$A\{-gm^3(\varepsilon^{mk}-\varepsilon^{-mk})+i^2m^2(\varepsilon^{mk}+\varepsilon^{-mk})\}=-H-G\left\{\frac{gm}{i^2}\varepsilon^{-mk}-\frac{gm}{i^2}+\varepsilon^{-mk}\right\}$$

whence

$$A=\frac{-H+\frac{gm}{i^2}G-\left(1+\frac{gm}{i^2}\right)G\varepsilon^{-mk}}{i^2m^2(\varepsilon^{mk}+\varepsilon^{-mk})-gm^3(\varepsilon^{mk}-\varepsilon^{-mk})}$$

$$B=A+\frac{G}{i^2m^2}=\frac{-H+\frac{gm}{i^2}G+\left(1-\frac{gm}{i^2}\right)G\varepsilon^{mk}}{i^2m^2(\varepsilon^{mk}+\varepsilon^{-mk})-gm^3(\varepsilon^{mk}-\varepsilon^{-mk})}$$

$$\phi''(y)=\frac{-H+\frac{gm}{i^2}G-\left(\frac{gm}{i^2}+1\right)G.\varepsilon^{-mk}}{i^2(\varepsilon^{mk}+\varepsilon^{-mk})-gm(\varepsilon^{mk}-\varepsilon^{-mk})}\varepsilon^{my}+\frac{-H+\frac{gm}{i^2}G-\left(\frac{gm}{i^2}-1\right)G\varepsilon^{mk}}{i^2(\varepsilon^{mk}+\varepsilon^{-mk})-gm(\varepsilon^{mk}-\varepsilon^{-mk})}\varepsilon^{-my}$$

$$m\phi'(y)=\frac{-H+\frac{gm}{i^2}G-\left(\frac{gm}{i^2}+1\right)G.\varepsilon^{-mk}}{i^2(\varepsilon^{mk}+\varepsilon^{-mk})-gm(\varepsilon^{mk}-\varepsilon^{-mk})}\varepsilon^{my}-\frac{-H+\frac{gm}{i^2}G-\left(\frac{gm}{i^2}-1\right)G\varepsilon^{mk}}{i^2(\varepsilon^{mk}+\varepsilon^{-mk})-gm(\varepsilon^{mk}-\varepsilon^{-mk})}\varepsilon^{-my}.$$

(277.) With these expressions forming the values of X and Y at the surface, we obtain the following:

Horizontal and vertical motions of the particles at the surface.

$$\text{X at the surface}=\frac{-H(\varepsilon^{mk}+\varepsilon^{-mk})+G.\frac{gm}{i^2}(\varepsilon^{mk}-2+\varepsilon^{-mk})}{i^2(\varepsilon^{mk}+\varepsilon^{-mk})-gm(\varepsilon^{mk}-\varepsilon^{-mk})}\sin\overline{it-mx}$$

$$\text{Y at the surface, or K}=\frac{-H(\varepsilon^{mk}-\varepsilon^{-mk})+G(\varepsilon^{mk}-2+\varepsilon^{-mk})}{i^2(\varepsilon^{mk}+\varepsilon^{-mk})-gm(\varepsilon^{mk}-\varepsilon^{-mk})}\cos\overline{it-mx}.$$

Upon these expressions we may make the following remarks:

Distinction between *forced* wave and *free* wave.

(278.) 1st. The wave whose motions are defined by the values of $X=\phi''(y).\sin\overline{it-mx}$ and $Y=m\left(\phi'(y)-\phi'(0)\right)\cos\overline{it-mx}$, the particular values of which at the surface we have just exhibited, is that to which we have alluded (173.) by the name of the *forced* tide-wave. Its existence depends entirely on the continuance of the action of the external forces; if those forces ceased to act, the wave depending on $\sin\overline{it-mx}$ would immediately cease to exist. Other waves however would exist, as a consequence of these forces having been previously in action; and some (as we shall presently see) will at all times exist conjointly with the *forced* tide-wave. Thus, (as we shall see,) if the canal be interrupted, there will always exist a wave depending on $\sin\overline{it\pm m'x}$, where i and m' are connected by the equation $i^2=gm'\frac{\varepsilon^{m'k}-\varepsilon^{-m'k}}{\varepsilon^{m'k}+\varepsilon^{-m'k}}$; the magnitude and other circumstances of this wave will depend on the boundaries of the canal. This is what we have called the *free* tide-wave; its period is the same as that of the *forced* tide-wave, but its length is different; the continuance of the forces is not necessary for its existence. There may exist a wave depending on $\sin\overline{nt\pm mx}$, where n and m are connected by the equation $n^2=gm\frac{\varepsilon^{mk}-\varepsilon^{-mk}}{\varepsilon^{mk}+\varepsilon^{-mk}}$, and this would also be a *free* wave; its length is the same as that of the *forced* tide-wave, but its period is different, and for this reason we shall *not* call it a *free tide-wave;* it would not exist as a consequence of interruption of the canal, but as a consequence of sudden commencement or change or cessation of the forces, and its coefficient would depend on these circumstances (as we shall see hereafter).

(279.) 2nd. The expressions may be put into the following form:

$$\text{X at the surface}=\frac{-H+G.\frac{gm}{i^2}.\frac{\varepsilon^{mk}-2+\varepsilon^{-mk}}{\varepsilon^{mk}+\varepsilon^{-mk}}}{i^2-gm.\frac{\varepsilon^{mk}-\varepsilon^{-mk}}{\varepsilon^{mk}+\varepsilon^{-mk}}}\sin\overline{it-mx}$$

$$=\frac{-H+G.\frac{n^2}{i^2}.\frac{\varepsilon^{mk}-2+\varepsilon^{-mk}}{\varepsilon^{mk}-\varepsilon^{-mk}}}{i^2-n^2}\sin\overline{it-mx},$$

Sect. IV Theory o Waves.

Subsec. When th water is under th action o Horizon and Ver cal Forc

which, since $\varepsilon^{mk}-2+\varepsilon^{-mk}=\left(\varepsilon^{\frac{mk}{2}}-\varepsilon^{-\frac{mk}{2}}\right)^2$, and $\varepsilon^{mk}-\varepsilon^{-mk}=\left(\varepsilon^{\frac{mk}{2}}+\varepsilon^{-\frac{mk}{2}}\right).\left(\varepsilon^{\frac{mk}{2}}-\varepsilon^{-\frac{mk}{2}}\right)$, becomes

$$\text{X at the surface} = \frac{-\text{H}+\text{G}\frac{n^2}{i^2}.\frac{\varepsilon^{\frac{mk}{2}}-\varepsilon^{-\frac{mk}{2}}}{\varepsilon^{\frac{mk}{2}}+\varepsilon^{-\frac{mk}{2}}}}{i^2-n^2}\sin\overline{it-mx}.$$

Similarly

$$\text{K} = \frac{-\text{H}.\frac{n^2}{gm}+\text{G}.\frac{n^2}{gm}.\frac{\varepsilon^{mk}-2+\varepsilon^{-mk}}{\varepsilon^{mk}-\varepsilon^{-mk}}}{i^2-n^2}\cos\overline{it-mx}$$

$$= \frac{-\text{H}.\frac{n^2}{gm}+\text{G}\frac{n^2}{gm}.\frac{\varepsilon^{\frac{mk}{2}}-\varepsilon^{-\frac{mk}{2}}}{\varepsilon^{\frac{mk}{2}}+\varepsilon^{-\frac{mk}{2}}}}{i^2-n^2}\cos\overline{it-mx}.$$

Now mk is a small quantity. For, putting λ for the length of the forced tide-wave, (which at the equator $=12500$ miles), $m=\frac{2\pi}{\lambda}$, and $mk=2\pi\frac{k}{\lambda}$, so that, even if the depth of the sea were 25 miles, mk would be $=\frac{2\pi}{500}=\frac{6\cdot 28}{500}$. Therefore $\varepsilon^{\frac{mk}{2}}-\varepsilon^{-\frac{mk}{2}}=mk$ very nearly, and $\varepsilon^{\frac{mk}{2}}+\varepsilon^{-\frac{mk}{2}}=2$ very nearly, and therefore the expressions become

$$\text{X at the surface} = \frac{-\text{H}+\text{G}\frac{n^2}{i^2}.\frac{mk}{2}}{i^2-n^2}\sin\overline{it-mx};$$

$$\text{K} = \frac{-\text{H}\frac{n^2}{gm}+\text{G}\frac{n^2}{gm}.\frac{mk}{2}}{i^2-n^2}\cos\overline{it-mx}.$$

Effect of the vertical force is insignificant.

Consequently, if we consider G and H to be quantities not very dissimilar in magnitude, (which we shall find to be true,) the term depending on G in each of these expressions is wholly insignificant in comparison with that depending on H; and thus we arrive at this remarkable conclusion, that *the effect of the vertical disturbing force upon the phænomena of the tides is insignificant*, the whole of the sensible effect being due to the horizontal force. In (28.) and (69.) we have found the same result from different ways of treating the tides. There is no exception to this theorem as applied to the expression for K; if i were very small, it might not hold strictly with regard to the expression for X; but that is of small importance.

If the period of the forced wave were equal to the period of a free wave, the motion would be infinite.

(280.) 3rd. If the period of the *forced* tide-wave were the same as that of a *free* wave of the second class, that is, if i were equal to n, m being the same in the two waves, the denominator in the expressions for X and K would vanish, or X and K would become infinite. In this case then the expressions fail. It would seem that, if we suppose a canal surrounding the earth to be acted on by the forces of the sun and moon following the law assumed in this Problem, and if i were equal to n, the only interpretation that can be put on this failure would be,—that the motion of the water cannot be oscillatory in the manner of a wave, but that it must be that of a torrent of unequal depth passing round the earth so as to follow the apparent motion of the sun or moon. We shall find, however, that the introduction of friction prevents the expression from ever becoming infinite.

If the period of the forced wave is smaller, there is low water under the Moon.

(281.) 4th. If the period of the forced tide-wave be less than that of a free wave of the second class, (that is, if the wave be urged along more rapidly than it would go alone, or if the water be shallow,) or if i be greater than n, (i and n being, by (166.) inversely as the periods,) the denominator is positive; and the expression for K (omitting the term depending on G) is of the form $-\text{C}\cos\overline{it-mx}$. Now conceive the Moon to go round the Earth (apparently) from east to west; x must be measured in the same direction; because then, by proper determination of the value of m, the parts of the Earth which happen to be under the Moon will always have the same certain value of $\overline{it-mx}$. Conceive the horizontal force created by the Moon's action to be 0 for the parts under the Moon; to be positive at the parts, to a certain extent, which she has passed, and to be negative at the parts, to a certain extent, on the side to which she is approaching. (This is supposing, in other words, that to a certain extent the horizontal force caused by the Moon's action urges the water towards that part of the Earth which is under the Moon; a supposition which correctly represents the actual case.) Then $\overline{it-mx}$ must be 0 for the parts under the Moon. (For then, in the parts which the Moon has left, x is less than under the Moon, $\overline{it-mx}$ is positive, and therefore the force, which we have assumed to be H $\sin\overline{it-mx}$, is positive there; in the parts to which the Moon is approaching, x is greater than under the Moon, $\overline{it-mx}$ is negative, and therefore the force or H $\sin\overline{it-mx}$ is negative there.) Consequently the elevation of the water under the Moon is $-\text{C}.\cos 0=-\text{C}$. That is, it is low water immediately under the Moon. The same conclusion will be found in (16.) and (109.).

(282.) 5th. In like manner, if the period of the forced tide-wave were greater than that of the free wave of the second class, (that is, if the water were so immensely deep that the wave would travel alone more rapidly than the disturbing forces urge it along,) or if i were less than n, the denominator would be negative, and there would be high water under the Moon.

If the period is very long, the form of the water is that of equilibrium nearly.

(283.) 6th. If the complete change of forces occupy a long time, that is if i be small, $K = +\frac{H}{gm}\cos\overline{it-mx}$ nearly. This is the same expression that would have been found from a theory of equilibrium, or by (152.); so that in this case the water assumes very nearly the form of equilibrium.

(284.) For shallow water, it will be remarked that $n^2 = gkm^2$ nearly, and the whole of the expressions may be altered by that substitution. And, as in (166.) and (165.), we may put $\frac{2\pi}{\tau'}$ for i, and $\frac{2\pi}{\lambda}$ for m: then τ' is the period of the changes of the *force*, which is the same as the period of the *forced wave*, and λ is the length of the wave. The expression for K, omitting the term depending on G, will thus be changed to

$$\frac{-H.km}{i^2-gkm^2}\cos\overline{it-mx}, \text{ or } -\frac{Hk}{2\pi}.\frac{\lambda.\tau'^2}{\lambda^2-gk.\tau'^2}\cos\overline{it-mx}:$$

and, if the depth be *very* small,

$$K = -\frac{Hk}{2\pi}.\frac{\tau'^2}{\lambda}.\cos\overline{it-mx}$$

In showing that in this case the elevation of the tide is proportional to the depth of the sea, we have obtained the same result as that deduced from Laplace's Theory of Tides, in (98.), (101.), and (107.).

(285.) The preceding conclusions are very important, as showing that the amount of elevation of the water under the action of forces depends in a most remarkable degree upon other circumstances than the magnitude of the forces. One is, the depth of the sea: another is, the periodic time of the forces. As depending upon the former, it appears that, if there were two parallel canals of different depths acted on by precisely the same forces, there might be high water in one when there was low water in the adjacent part of the other: or there might be elevations and depressions at the same time in both, but their magnitudes might have any proportion whatever. As depending upon the latter, it appears that, if there were two forces acting simultaneously upon the water in the same canal, the periods of those forces being different, (as, for instance, the forces depending upon the action of the Sun and the Moon,) the high water produced by one force might bear the same relation to the phases of that force which the low water produced by the other bears to the phases of that other force: (thus low water of the solar tide might accompany the transit of the Sun, and high water of the lunar tide might accompany the transit of the Moon, in the same canal.) Or the phases of the two tides might stand in the same relation to the phases of the two forces, but the proportion of their magnitudes to the magnitudes of the forces might differ in any degree whatever.

Coefficient of force supposed variable.

(286.) The conclusions of (93.), as to the effect of a variable coefficient of the force, apply here: but as we are able to give expressions here which could not be given in those investigations, we shall repeat a small part of the process. If the force, instead of being $H.\sin\overline{it-mx}$, were $(H+H'\cos i't).\sin\overline{it-mx}$ or $H.\sin\overline{it-mx} + \frac{H'}{2}\sin\overline{(i+i')t-mx} + \frac{H'}{2}\sin\overline{(i-i')t-mx}$, the expression for K would be (supposing the water shallow),

$$\frac{-Hkm}{i^2-gkm^2}\cos\overline{it-mx} - \frac{1}{2}.\frac{H'km}{(i+i')^2-gkm^2}\cos\overline{(i+i')t-mx} - \frac{1}{2}.\frac{H'km}{(i-i')^2-gkm^2}\cos\overline{(i-i')t-mx};$$

and if i' were very small, that is, if the change of the variable coefficient were slow, we might expand to the first power of i', and it would become

$$\frac{-Hkm}{i^2-gkm^2}\cos\overline{it-mx} - \frac{1}{2}\,\frac{H'km}{i^2-gkm^2}\left\{\cos\overline{(i+i')t-mx} + \cos\overline{(i-i')t-mx}\right\}$$

$$+\frac{1}{2}.\frac{H'km.2ii'}{(i^2-gkm^2)^2}\left\{\cos\overline{(i+i')t-mx} - \cos\overline{(i-i')t-mx}\right\}$$

$$= -\frac{km}{i^2-gkm^2}(H+H'\cos i't).\cos\overline{it-mx} - \frac{2kmii'}{(i^2-gkm^2)^2}H'.\sin i't.\sin(it-mx).$$

(287.) The time of low water on a given day (supposing the variation of $i't$ in the day to be insensible) will be found by making

$$\tan(it-mx) = \frac{2ii'}{i^2-gkm^2}.\frac{H'\sin i't}{H+H'\cos i't};$$

and, therefore, when $\sin i't$ is positive, it will be later than that determined by making $it-mx=0$, as in (281.).

(288.) The greatest amount of elevation or depression on that day, as in (93.), will be

$$\frac{km}{i^2-gkm^2}\sqrt{\left\{(H+H'\cos i't)^2 + \frac{4i^2i'^2}{(i^2-gkm^2)^2}H'^2\sin^2 i't\right\}}.$$

If H′ be much smaller than H, this expression $=\frac{km}{i^2-gkm^2}(\text{H}+\text{H}'\cos i't)$ nearly.

(289.) If the term H do not exist, the whole force being $=\text{H}'\cos i't.\sin\overline{it-mx}$, the expression for greatest elevation or depression on any day =

$$\frac{\text{H}'km}{i^2-gkm^2}\sqrt{\left\{\cos^2 i't+\frac{4i^2i'^2}{(i^2-gkm^2)^2}\sin^2 i't\right\}}.$$

This quantity never vanishes, even on the days on which $\cos i't$ vanishes: but it is, on those days, either maximum or minimum. It is maximum if $2ii'$ be greater than i^2-gkm^2, and minimum if $2ii'$ be less than i^2-gkm^2. In the former case, however, it will be necessary to use for the coefficients of $\cos i't.\cos\overline{it-mx}$ and $\sin i't.\sin\overline{it-mx}$ their accurate values

$$\frac{-\text{H}'km}{2}\left(\frac{1}{(i+i')^2-gkm^2}+\frac{1}{(i-i')^2-gkm^2}\right)\text{ and }\frac{-\text{H}'km}{2}\left(\frac{1}{(i-i')^2-gkm^2}-\frac{1}{(i+i')^2-gkm^2}\right).$$

Subsection 5.—On the Method of using the free Tide-Waves and forced Tide-Waves, and of introducing the limits of Canals in general.

(290.) Before we exhibit the method of introducing the *free tide-wave* and other *free* waves, which we have mentioned as coexisting with the *forced tide-wave*, we will shortly remark on the general solution of the partial differential equation of waves. The same remarks apply to all other linear partial differential equations.

Solution which represents the forced tide-wave may be made more general by adding any number of expressions for free tide-waves.

(291.) We have found a solution X for the equation $\frac{d^2\text{X}}{dt^2}=\text{F}+\frac{d}{dx}\left\{-g\text{K}+\int_y\frac{d^2\text{Y}}{dt^2}\right\}$: where F is a given function of x and t. Now suppose that we know that each of the quantities X_1, X_2, X_3, &c. will satisfy the equation $\frac{d^2\text{X}'}{dt^2}=0+\frac{d}{dx}\left\{-g\text{K}'+\int_y\frac{d^2\text{Y}'}{dt^2}\right\}$: the peculiarity of which, as distinguished from the former, is, that it contains no term independent of X′ $\left(\text{K}'\right.$ being a particular value of Y′, and Y′ being formed from X′ by integrating $\left.-\int_y\frac{d\text{X}'}{dx}\right)$. Then the sum of all the quantities $\text{X}+\text{X}_1+\text{X}_2+$&c. will satisfy the equation $\frac{d^2\text{X}}{dt^2}=\text{F}+\frac{d}{dx}\left\{-g\text{K}+\int_y\frac{d^2\text{Y}}{dt^2}\right\}$. For, upon substituting $\text{X}+\text{X}_1+\text{X}_2+$&c., in this last equation, instead of X, we have

$$\frac{d^2(\text{X}+\text{X}_1+\text{X}_2+\&\text{c.})}{dt^2}=\text{F}+\frac{d}{dx}\left\{-g(\text{K}+\text{K}_1+\text{K}_2+\&\text{c.})+\int_y\frac{d^2(\text{Y}+\text{Y}_1+\text{Y}_2+\&\text{c.})}{dt^2}\right\};$$

which is necessarily true, because it is the same as the sum of all the equations

$$\frac{d^2\text{X}}{dt^2}=\text{F}+\frac{d}{dx}\left\{-g\text{K}+\int_y\frac{d^2\text{Y}}{dt^2}\right\};\quad\frac{d^2\text{X}_1}{dt^2}=0+\frac{d}{dx}\left\{-g\text{K}_1+\int_y\frac{d^2\text{Y}_1}{dt^2}\right\},\ \&\text{c.}:$$

each of which is separately true. Therefore $\text{X}+\text{X}_1+\text{X}_2+$&c. may be used as a solution of the equation $\frac{d^2\text{X}}{dt^2}=\text{F}+\frac{d}{dx}\left\{-g\text{K}+\int_y\frac{d^2\text{Y}}{dt^2}\right\}$: and it is more general than X merely, and therefore can better be adapted to the circumstances of the case.

(292.) In the problem of (274.), &c., we have found $\text{C}.\cos\overline{it-mx}$* for a solution of the equation $\frac{d^2\text{X}}{dt^2}=\text{F}+\frac{d}{dx}\left\{-g\text{K}+\int_y\frac{d^2\text{Y}}{dt^2}\right\}$. But we know that $\text{A}_1\cos(n_1t-m_1x+a_1)$, $\text{B}_1\cos(n_1t+m_1x+b_1)$, $\text{A}_2\cos(n_2t-m_2x+a_2)$, $\text{B}_2\cos(n_2t+m_2x+b_2)$, &c. are solutions of the equation $\frac{d^2\text{X}'}{dt^2}=\frac{d}{dx}\left\{-g\text{K}'+\int_y\frac{d^2\text{Y}'}{dt^2}\right\}$, provided only that $n_1^2=gm_1\frac{\varepsilon^{m_1k}-\varepsilon^{-m_1k}}{\varepsilon^{m_1k}+\varepsilon^{-m_1k}}$, &c. Therefore we may add any or all of these terms to $\text{C}.\cos\overline{it-mx}$ for the solution of $\frac{d^2\text{X}}{dt^2}=\text{F}+\frac{d}{dx}\left\{-g\text{K}+\int_y\frac{d^2\text{Y}}{dt^2}\right\}$. We shall have occasion only to add terms in which $n_1=i$, or terms in which $m_1=m$. The nature of the conditions to be satisfied will determine our choice. If for some given instant of time a certain condition is to apply to all parts of the canal, the coefficient of x must be the same as in $\text{C}.\cos\overline{it-mx}$; that is, m_1 must $=m$. But if at some certain part of the canal a certain

---

* We use indifferently the sine or the cosine, as one is changed into the other by changing the origin of x or t.

condition is to hold during all time, the coefficient of t must be the same as in $C.\cos\overline{it-mx}$, or n_1 must $=i$. The following instances will illustrate this.

(293.) Problem.—The disturbing force of the Moon, represented by the formula $H.\cos\overline{it-mx}$, begins to act suddenly when $t=0$: to find the nature of the waves produced on a canal: the water having been previously at rest.

Force begins to act at a certain instant.

(294.) The value for X must be $C.\cos\overline{it-mx}+X_1+X_2+\&c.$: and the condition that the water was in its position of rest in every part of the fluid, and also was actually at rest, when $t=0$, requires that

$$C.\cos\overline{it-mx}+X_1+X_2+\&c.=0 \text{ when } t=0 \text{ for every value of } x;$$

and that $$\frac{d}{dt}(C.\cos\overline{it-mx}+X_1+X_2+\&c.)=0 \text{ when } t=0 \text{ for every value of } x.$$

The only forms of X_1 and X_2 which can satisfy these conditions are

$$A.\cos(nt-mx+\alpha) \text{ and } B.\cos(nt+mx+\beta),$$

where $n^2=gm\dfrac{\varepsilon^{mk}-\varepsilon^{-mk}}{\varepsilon^{mk}+\varepsilon^{-mk}}$. The conditions now become

$$C\cos mx+A\cos(-mx+\alpha)+B\cos(mx+\beta)=0.$$
$$iC\sin mx-nA\sin(-mx+\alpha)-nB\sin(mx+\beta)=0.$$

Expanding the sines and cosines, we obtain $C+A\cos\alpha+B\cos\beta=0$; $A\sin\alpha-B\sin\beta=0$; $iC+nA\cos\alpha-nB\cos\beta=0$; $-nA\sin\alpha-nB\sin\beta=0$. The second and fourth equations give $A\sin\alpha=0$, $B\sin\beta=0$; the first and third give $A\cos\alpha=-\dfrac{(i+n)C}{2n}$, $B\cos\beta=\dfrac{(i-n)C}{2n}$. Hence $X_1=-\dfrac{(i+n)C}{2n}\cos\overline{nt-mx}$, $X_2=\dfrac{(i-n)C}{2n}\cos\overline{nt+mx}$: and the whole expression for X is

$$C.\cos\overline{it-mx}-\frac{(i+n)C}{2n}\cos\overline{nt-mx}+\frac{(i-n)C}{2n}\cos\overline{nt+mx}.$$

(295.) This instance is one of pure curiosity, given only as an example. The following, probably, is one of real application.

Canal bounded at both ends.

Problem.—A canal, the water of which is acted on by the forces of the moon's attraction, is bounded at both extremities: to find the nature of the waves produced on it.

(296.) The condition here is, that, at each extremity, X shall $=0$, and $\dfrac{dX}{dt}$ shall $=0$, whatever be the value of t. The second equation is evidently included in the first; so that, in fact, we have only one condition for each end of the canal. A moment's consideration will show that, the term for the forced tide-wave being $C.\cos\overline{it-mx}$, the other terms must have the same multiple of t. Let the value of X, therefore, at the surface be assumed $=$

$$C.\cos\overline{it-mx}\ +A.\cos\overline{it-lx+\alpha}\ +B.\cos\overline{it+lx+\beta},$$

where $i^2=gl\dfrac{\varepsilon^{lk}-\varepsilon^{-lk}}{\varepsilon^{lk}+\varepsilon^{-lk}}$. Let the values of x at the two extremities of the canal be a and b. Then, at one end of the canal, $X=C.\cos\overline{it-ma}+A.\cos\overline{it-la+\alpha}+B.\cos\overline{it+la+\beta}$; which is to be $=0$ for all values of t. At the other end, $X=C.\cos\overline{it-mb}+A.\cos\overline{it-lb+\alpha}+B.\cos\overline{it+lb+\beta}$, which also is to be $=0$ for all values of t. Expanding, and separating the coefficients of $\cos it$ and $\sin it$, we have these four equations:

$$C.\cos ma+A.\cos\overline{\alpha-la}+B.\cos\overline{\beta+la}=0;$$
$$C.\sin ma-A.\sin\overline{\alpha-la}-B.\sin\overline{\beta+la}=0;$$
$$C.\cos mb+A.\cos\overline{\alpha-lb}+B.\cos\overline{\beta+lb}=0;$$
$$C.\sin mb-A.\sin\overline{\alpha-lb}-B.\sin\overline{\beta+lb}=0.$$

Without here going through the details of the solution, it is plain that the conditions are satisfied by the following formula:

$$X=C.\cos\overline{it-mx}-\frac{C}{\sin l(b-a)}\{\cos\overline{it-mb}.\sin\overline{lx-la}-\cos\overline{it-ma}.\sin\overline{lx-lb}\};$$

which, upon multiplying the sines and cosines together, according to the rules of Trigonometry, may be put into the form $C.\cos\overline{it-mx}+A.\cos\overline{it-lx+\alpha}+B.\cos\overline{it+lx+\beta}$, and which becomes 0 when $x=a$ or $=b$. The first term of the expression is the *forced* tide-wave; the part within the brackets represents the *free* tide-waves, which may be conceived as the combination of the reflections of the forced tide-wave from the ends of the canal, and whose speed does not depend on the speed of the Moon's change of place.

(297.) It is proper to remark, that the condition $X=0$ cannot be strictly satisfied at all depths. For in the case of the forced tide-wave the value of X at different depths depends on $\varepsilon^{my}+\varepsilon^{-my}$, and in the case of the free tide-wave it depends on $\varepsilon^{ly}+\varepsilon^{-ly}$; and these are not exactly in the same proportion at different depths. It would seem, therefore, that there must, theoretically, be a breaking of water on the coast, in consequence of the oscillation of the tide. But when the wave is of very long period, (as is true of the tide-wave,) both $\varepsilon^{ly}+\varepsilon^{-ly}$ and $\varepsilon^{my}+\varepsilon^{-my}$ are at all depths sensibly $=2$, and, therefore, the condition $X=0$ may be considered as satisfied at all depths.

(298.) The corresponding value of K, or $-\int_y \frac{dX}{dx}(0 \text{ to } k)$, $\left(\text{observing that } \int_y (\varepsilon^{my}+\varepsilon^{-my}) = \frac{1}{m}(\varepsilon^{my}-\varepsilon^{-my}) = \frac{2my}{m}\right.$ nearly $= y \times (\varepsilon^{my}+\varepsilon^{-my})$ nearly, and that the same holds when l is put for m, $\Big)$ is

$$-Cmk.\sin\overline{it-mx}+\frac{Clk}{\sin(lb-la)}\{\cos\overline{it-mb}.\cos\overline{lx-la}-\cos\overline{it-ma}.\cos\overline{lx-lb}\}.$$

In this case the disturbance may become infinite.

It may be interesting to examine the value of this expression in some particular cases.

(299.) 1st. If $\sin\overline{lb-la}=0$, that is, if $\overline{lb-la}=\pi$, or 2π, or 3π, &c., or if the length of the canal is any multiple of half the length of the free tide-wave, this expression becomes infinite. In reality the wave will become so large that the amount of friction, &c. will be so great as to neutralize the moon's force. This will be seen more clearly in the next section.

Tides in a canal of small extent.

(300.) 2d. If $\overline{lb-la}$ be small, that is, if the canal be short, we may proceed by approximation. Suppose a and b to be small quantities: x must also be a small quantity of the same order. Expanding $\sin\overline{it-mx}$, $\sin\overline{lx-la}$, &c., and substituting for the sines and cosines of the small arcs the series in terms of the arc, and preserving only the first power which remains in the resulting expressions, we find the following:

$$X=\cos it.C.\frac{m^2-l^2}{2}.\overline{x-a}.\overline{b-x}$$

$$K=\cos it.Ck(m^2-l^2).\left(x-\frac{a+b}{2}\right).$$

Consist simply of oscillations from one end to the other.

The first of these expressions shows that the horizontal motion will be greatest in the middle of the canal's length, and will diminish gradually both ways to the ends, where it is 0. The second shows that there is no variation of level at the middle of the canal's length, but that the variation of level in other parts is proportional to the distance from the middle, elevation taking place on one side of the middle at the same time as depression on the other side, so that the surface of the fluid remains sensibly plane, though inclined to the horizon. The law of motion as regards the time is the usual oscillatory law expressed by $\cos it$; but the motion of every particle differs in this respect from the motion of particles in an open sea affected by the tide: that here, the greatest horizontal displacement happens at the same time as the greatest vertical displacement; whereas, in an open sea, the greatest horizontal displacement happens when the vertical displacement is 0, and *vice versâ*. (182.) and (184.).

Solution in general case when one term is more important than the others.

(301.) 3d. In the general case, if we take the centre of the canal for the origin of our measures, or make $a=-b$, we have

$$X=C\cos it\left\{\cos mx-\frac{\cos mb}{\cos lb}\cos lx\right\}+C\sin it\left\{\sin mx-\frac{\sin mb}{\sin lb}\sin lx\right\}$$

$$K=Ck\cos it\left\{m.\sin mx-\frac{l.\cos mb}{\cos lb}\sin lx\right\}+Ck\sin it\left\{-m\cos mx+\frac{l\sin mb}{\sin lb}\cos lx\right\}.$$

In general, no simple meaning can be given to these expressions. In the particular case of $\cos lb$ being very small, the principal term of K is $-\cos it.\frac{Ckl\cos mb}{\cos lb}\sin lx$, which shows that, though there may be many oscillating elevations and depressions, yet all the waves will be of a stationary character in regard of space; that all the oscillations take place at the same time; and that an elevation on one side of the middle happens at the same instant as a depression at the same distance on the other side of the middle. If $\sin lb$ is very small, then the principal term in the expression for K is $\sin it.\frac{Ckl\sin mb}{\sin lb}\cos lx$: in this case the waves are stationary in place, and all the oscillations happen at the same time: but the elevations or depressions at equal distances from the middle towards both ends are similar.

(302.) Problem.—A canal, whose waters are acted on by the forces of the Moon, &c., communicates at one end with an open sea, whose waters have a tidal fluctuation, and is closed at the other end: to find the circumstances of tidal motion of the waters in the canal.

Tides in a deep gulf.

(303.) Let the mouth of the canal be the origin of the measures, its length being a; let the elevation of the sea-waters at the mouth of the canal be expressed by $A.\sin\overline{nt+B}$. Then the conditions to which our expressions for X and K must be subject, are these: that when $x=0$, K must $=A.\sin\overline{nt+B}$, and when $x=a$, X must

$=0$ for all values of t. Suppose, then, that the value of X given by the solution of the differential equations is $C.\cos\overline{nt-px}$. The complete value of X, as before (296.), will be

$$C.\cos\overline{nt-px}+D.\cos\overline{nt-mx+E}+F.\cos\overline{nt+mx+G},$$

where $n^2=gm\frac{\varepsilon^{mk}-\varepsilon^{-mk}}{\varepsilon^{mk}+\varepsilon^{-mk}}$. And the complete value of K, as in (298.), will be

$$-Cpk.\sin\overline{nt-px}-Dmk.\sin\overline{nt-mx+E}+Fmk.\sin\overline{nt+mx+G}.$$

Our two conditions, therefore, become the following:

$$-Cpk.\sin nt-Dmk.\sin\overline{nt+E}+Fmk.\sin\overline{nt+G}=A.\sin\overline{nt+B}$$

$$C.\cos\overline{nt-pa}+D.\cos\overline{nt-ma+E}+F.\cos\overline{nt+ma+G}=0.$$

Expanding the sines and cosines, and equating the coefficients of $\sin nt$ and $\cos nt$, we obtain the following equations for the determination of $D\sin E$, $D\cos E$, $F\sin G$, and $F\cos G$:

$$-Cpk-mk.D\cos E+mk.F\cos G=A\cos B$$

$$-mk.D\sin E+mk.F\sin G=A\sin B$$

$$C\cos pa+\cos ma.D\cos E+\sin ma.D\sin E+\cos ma.F\cos G-\sin ma.F\sin G=0$$

$$C\sin pa-\cos ma.D\sin E+\sin ma.D\cos E-\cos ma.F\sin G-\sin ma.F\cos G=0.$$

Solving these equations, and substituting the values so found in the expression for X, we find at length

$$X=\frac{A}{mk\cos ma}\sin\overline{nt+B}.\sin\overline{ma-mx}+C\cos\overline{nt-px}+\frac{Cp}{m\cos ma}\sin nt.\sin\overline{ma-mx}-\frac{C}{\cos ma}\cos\overline{nt-pa}.\cos mx\,;$$

from which

$$K=\frac{A}{\cos ma}\sin\overline{nt+B}.\cos\overline{ma-mx}-Cpk.\sin\overline{nt-px}+\frac{Cpk}{\cos ma}\sin nt.\cos\overline{ma-mx}-\frac{Cmk}{\cos ma}\cos\overline{nt-pa}.\sin mx\,;$$

which, it is easily seen, satisfy our equations of condition. The following considerations suggest themselves from the examination of this expression.

(304.) 1st. In a river or sea, such as we have supposed, the expression for the elevation of the tide is by no means a simple one: it may be represented by the combination of three stationary waves (of the nature of free waves) and one progressive wave (a forced tide-wave), whose compounded effects cannot easily be represented by those of a single wave, even though considered changeable.

(305.) 2nd. If we put the expression for K under the form $P\sin nt-Q\cos nt$, and make $\frac{Q}{P}=\tan\theta$, then $K=\sqrt{P^2+Q^2}.\sin(nt-\theta)$, and the time of high water will be determined by making $nt=\theta+90°$, or $\tan nt=-\cot\theta=-\frac{P}{Q}$; and the whole rise of tide will be $2\sqrt{P^2+Q^2}$. In the case before us,

$$P=\frac{A.\cos B.\cos\overline{ma-mx}}{\cos ma}-Cpk.\cos px+\frac{Cpk.\cos\overline{ma-mx}}{\cos ma}-\frac{Cmk.\sin pa.\sin mx}{\cos ma}$$

$$-Q=\frac{A.\sin B.\cos\overline{ma-mx}}{\cos ma}+Cpk.\sin px-\frac{Cmk.\cos pa.\sin mx}{\cos ma}.$$

The expression, therefore, for nt at high water, as depending on x, will be one of great complexity; and that for $\frac{d\theta}{dx}$, on which the apparent velocity of the tide-wave will depend, will be complicated. It does not appear that in the general case we have any reason to think that the tide-wave will appear to travel always in the same direction.

(306.) 3rd. If the tidal oscillations of the sea be insensible, or $A=0$, the remaining terms still have the same kind of complexity as in the last problem. But if $\cos ma$ be also very small, then the expression may be reduced to a single term multiplying $\sin mx$; and the tidal oscillation will consist of a stationary wave, or a series of stationary waves, in all which the oscillations take place simultaneously, and in which the horizontal motion of the particles and the vertical motion are greatest at the same time, or vanish at the same time.

Tide in a river stopped by a barrier.

(307.) 4th. If the effect of the moon's forces on the waters of the canal is insensible, then $C=0$, and the value of K is reduced to $\frac{A}{\cos ma}.\sin\overline{nt+B}.\cos\overline{ma-mx}$. This shows that all the oscillations in different parts of the canal take place at the same time; or, if ma is less than 90°, that it is high water in every part of the canal at the same time. But the whole rise of the waters $=\frac{2A}{\cos ma}\cos\overline{ma-mx}$ is different in different parts of the canal; and, if ma is less than 90°, it increases from the mouth of the canal to its termination. The corresponding value of X is $\frac{A}{mk\cos ma}.\sin\overline{nt+B}.\sin\overline{ma-mx}$: this shows that the greatest horizontal displacement of the particles occurs at the same time as the greatest vertical displacement; and the whole horizontal motion, or $\frac{2A}{mk\cos ma}\sin\overline{ma-mx}$ diminisnes from the mouth of the canal to its termination.

(308.) As this investigation applies in some degree to the case of various gulfs and rivers, it may be proper to examine how far it is modified by taking into account the extent of the fluctuation.

Problem.—A canal is closed at one end and open at the other end to a tidal sea: to find the nature of the tide-wave in the canal, the elevation of the water being supposed to bear a sensible proportion to the whole depth.

Tide in a river stopped by a barrier, when the motion of the particles is large.

(309.) The equation, as in (196.), will be

$$\frac{d^2X}{dt^2}-v^2\frac{d^2X}{dx^2}=v^2\frac{d^2X}{dx^2}\times\left\{-3\frac{dX}{dx}+6\left(\frac{dX}{dx}\right)^2-\&c.\right\},$$

where $v^2=gk$. An approximate value of X is

$$\frac{A}{mk\cos ma}.\sin\overline{mvt+B}.\sin\overline{ma-mx}.$$

Substituting this value in the second side of the equation, as far as the term $\frac{dX}{dx}$, and proceeding in the solution exactly in the same manner as in (198.) &c., we find the following expression for X:

$$\begin{aligned}X=&\frac{A}{mk\cos ma}.\sin\overline{ma-mx}.\sin\overline{mvt+B}\\&+\frac{A^2}{k^2\cos^2 ma}\left\{-\frac{3}{16m}\sin\overline{2ma-2mx}-\frac{3}{16}x.\cos\overline{2ma-2mx}.\cos\overline{2mvt+2B}\right\}\\&+\phi(vt+x)+\psi(vt-x);\end{aligned}$$

from which we find the elevation of the water, at the place whose distance from the mouth of the canal, measured along the canal-bank, is $=x'$, to be represented by the following expression:

$$\begin{aligned}&\frac{A}{\cos ma}.\cos\overline{ma-mx'}.\sin\overline{mvt+B}\\&+\frac{1}{8}.\frac{A^2}{k\cos^2 ma}\left(\cos\overline{2ma-2mx'}-\cos 2ma\right)+\frac{3}{8}.\frac{A^2}{k\cos^2 ma}.mx'.\sin\overline{2ma-2mx'}.\cos\overline{2mvt+2B}.\end{aligned}$$

In this case there are sometimes two high waters at every tide.

The law of the rise and fall of the water, at every part of the canal except its mouth, is now different from that which holds on the supposition that the oscillation is small in proportion to the depth of the canal. But the times of high water and of low water are still the same as before, and the high water and the low water are still simultaneous through the whole length of the canal. The second term of the expression above is constant for any given place; the first and third may be represented by $C.\sin\overline{mvt+B}+D.\cos\overline{2mvt+2B}$. In figures 16 and 17 we have represented these expressions by the ordinates of two curves: in fig. 16, $\frac{D}{C}=\frac{1}{6}$; in fig. 17, $\frac{D}{C}=\frac{1}{3}$. In the latter there are two high waters at each tide.

(310.) Problem.—A canal, on whose waters the action of the moon is insensible, communicates at both ends with tidal seas, in which the whole rise of the tide and the corresponding phases of the tide are different: to find the nature of the waves upon it.

Canal between two tidal seas.

(311.) The elevation of the water in the canal will evidently be represented by a combination of *free* tide-waves, of the form $P.\sin\overline{nt-mx+p}+Q.\sin\overline{nt+mx+q}$, or of a form equivalent to this; and the constants must be so determined as to make the elevations at the two extremities of the canal the same as those of the seas. Let a and b be the ordinates of the two extremities of the canal; $A.\sin(nt+\alpha)$ the elevation of the water at one extremity, $B.\sin(nt+\beta)$ that at the other extremity. Then, without going through the whole investigation, it is evident that all the conditions are satisfied by the following expression:

$$K=\frac{A}{\sin\overline{mb-ma}}.\sin\overline{mb-mx}.\sin\overline{nt+\alpha}+\frac{B}{\sin\overline{mb-ma}}.\sin\overline{mx-ma}.\sin\overline{nt+\beta}.$$

The time of high water or low water at any part of the canal will be found by making $\frac{dY}{dt}=0$, from which we obtain

$$\tan nt'=\frac{A\cos\alpha.\sin\overline{mb-mx}+B\cos\beta.\sin\overline{mx-ma}}{A\sin\alpha.\sin\overline{mb-mx}+B\sin\beta.\sin\overline{mx-ma}};$$

and the velocity with which the phase of high water travels along the canal $= \frac{dt'}{dx} =$

$$\frac{m}{n} \cdot \frac{\text{AB} \,.\, \sin \overline{\alpha-\beta} \,.\, \sin \overline{mb-ma}}{\text{A}^2 . \sin^2 \overline{mb-mx} + \text{B}^2 . \sin^2 \overline{mx-ma} + 2\text{AB} . \cos \overline{\alpha-\beta} . \sin \overline{mb-mx} . \sin \overline{mx-ma}}.$$

This expression has the same sign for all values of x; and therefore the high water travels in the same direction along all parts of the canal.

(312.) The expression for K at high water is

$$\frac{1}{\sin \overline{mb-ma}} \sqrt{\{\text{A}^2 . \sin^2 \overline{mb-mx} + \text{B}^2 . \sin^2 \overline{mx-ma} + 2\text{AB} . \cos \overline{\alpha-\beta} . \sin mb-mx . \sin \overline{mx-ma}\}}.$$

If $\overline{mb-ma}$ be nearly $=180°$ and $\overline{\alpha-\beta}$ small, then for all values of x which make $\overline{mb-mx}$ or $\overline{mx-ma}$ not very different from 90°, this value of K may much exceed the values when $x=a$ or $x=b$; that is, the rise of tide in the middle of the canal may be much greater than at its extremities. The velocity of the tide-wave at different points of the canal is inversely as the square of the rise of the tide at those points.

The time and height of high water depend upon the period of the waves.

It is to be remarked, that though in the theory of the tides, (439.) &c., α and β are found to be independent of n, yet m depends on n, and therefore $mb-mx$ and $mx-ma$ depend on n. If, then, the value of n alters, the time of high water determined from the expression for nt', and the height of high water, or K above, will be altered. This is the theorem used by Laplace, and to which reference is made in (121.).

(313.) The general expression for X, corresponding to the general expression for Y (remarking that $\text{Y} = \frac{\text{K}y}{k}$ nearly), is

$$-\frac{\text{A}}{mk . \sin \overline{mb-ma}} \cos \overline{mb-mx} . \sin \overline{nt+\alpha} + \frac{\text{B}}{mk . \sin \overline{mb-ma}} \cos \overline{mx-ma} . \sin \overline{nt+\beta}.$$

This expression vanishes when

$$\tan nt'' = -\frac{-\text{A} \sin \alpha . \cos \overline{mb-mx} + \text{B} \sin \beta . \cos \overline{mx-ma}}{-\text{A} \cos \alpha . \cos \overline{mb-mx} + \text{B} \cos \beta . \cos \overline{mx-ma}}.$$

Thus it appears that the time at which the particles of water are in their mean horizontal position does not coincide with or bear any simple relation to the time at which they have the greatest elevation.

The greatest value of X for any given place (to which the greatest velocity of the particles is proportional) is

$$\frac{1}{mk . \sin \overline{mb-ma}} \sqrt{\{\text{A}^2 . \cos^2 \overline{mb-mx} + \text{B}^2 . \cos^2 \overline{mx-ma} - 2\text{AB} . \cos \overline{\alpha-\beta} . \cos \overline{mb-mx} . \cos \overline{mx-ma}\}}.$$

Canal between a tidal sea and a tideless sea.

(314.) If one of the seas have no tide, let A=0. Then, for high water in every part, $\tan nt' = \cot \beta$, or the high water is simultaneous throughout the canal: the elevation is $\frac{\text{B} . \sin \overline{mx-ma}}{\sin \overline{mb-ma}}$; the greatest value of X is $\frac{\text{B} . \cos \overline{mx-ma}}{mk . \sin \overline{mb-ma}}$, or the water moves most rapidly where the canal joins the tideless sea; and the greatest horizontal displacement occurs at the same instant as the greatest vertical displacement.

Subsection 6.—Theory of Waves on Canals when Friction is taken into account.

(315.) It cannot be supposed that we can give a theory of friction among particles of water, and between water and land, which will pretend to any great degree of exactness. Nevertheless, we can give one of very plausible character, and one which, it is quite certain, will represent *generally* the effects of friction. We conceive that it will be found valuable, as assisting to explain some circumstances of the tides which hitherto have received no explanation.

Friction supposed to be proportional to the velocity.

(316.) It is well known that the resistance to bodies moving in fluids (to which the friction of fluids, running over an uneven surface, is entirely analogous) is nearly proportional to the square of the velocity, when that velocity is considerable. But all experiments have agreed in showing that, when the velocity is small, the resistance is greater than that which is given by this law. In fact, when the velocity is very small, the resistance may be represented as nearly, or more nearly, by supposing it proportional to the first power of the velocity. The velocity of tide-currents, for the most part, is so small that this law may be supposed to apply without great error to them. And it possesses the very great advantage of presenting equations which admit of solution with comparatively little trouble. We shall, therefore, suppose the friction proportional to the velocity, and shall measure it by $f \times$ velocity. And as the velocity (using the same notation which we have throughout employed) is represented by $\frac{d\text{X}}{dt}$, and as the friction tends always to diminish the velocity, and therefore acts backwards when the particles are moving forwards, and acts forwards when the particles are moving backwards, we shall represent the force of friction correctly, in conformity with our supposition, by the expression $-f\frac{dX}{dt}$.

(317.) Confining ourselves to the case of long waves, and supposing the rise and fall of the water to be small in proportion to its depth, we shall have, from the equation of (236.),

$$\frac{d^2X}{dt^2}=F+gk\frac{d^2X}{dx^2},$$

where k is the depth of the water, and F the whole force (independent of the pressure of the water) which acts upon any particle. If, then, the horizontal force produced by external causes is F′, and the force produced by friction is $-f\frac{dX}{dt}$, we must for F put $F'-f\frac{dX}{dt}$, and the equation becomes

$$\frac{d^2X}{dt^2}=F'-f\frac{dX}{dt}+gk\frac{d^2X}{dx^2}$$

or if $gk=v^2$,

$$\frac{d^2X}{dt^2}=F'-f\frac{dX}{dt}+v^2\frac{d^2X}{dx^2}.$$

Investigation when the external force is similar to tidal forces, and there is also friction.

(318.) Problem.—The external force, tending to urge the water of a canal forwards, is represented by $H.\sin\overline{it-mx}$: to find the motion of the water, taking friction into account.

(319.) As the motion for which we desire to obtain an expression is only that which is periodical, and in which the period of the motions is the same as the period of the forces, we must take the most general expression depending upon it which will satisfy the equation. Assume then $X=A.\cos it+B.\sin it$, A and B being functions of x to be discovered. Then $\frac{dX}{dt}=-iA.\sin it+iB.\cos it$; $\frac{d^2X}{dt^2}=-i^2A.\cos it-i^2B.\sin it$; $\frac{d^2X}{dx^2}=\frac{d^2A}{dx^2}.\cos it+\frac{d^2B}{dx^2}.\sin it$. Substituting these in the equation, and putting for F′ its value $H.\sin\overline{it-mx}$, and expanding the sine,

$$\begin{aligned}-i^2A.\cos it-i^2B.\sin it=&\,H.\cos mx.\sin it-H.\sin mx.\cos it\\&+fiA.\sin it-fiB.\cos it\\&+v^2\frac{d^2A}{dx^2}\cos it+v^2\frac{d^2B}{dx^2}\sin it.\end{aligned}$$

As this equation is to hold for all values of it, it will be equivalent to the two following:

$$-i^2A=-H.\sin mx-fiB+v^2\frac{d^2A}{dx^2} \qquad (1.)$$

$$-i^2B=H.\cos mx+fiA+v^2\frac{d^2B}{dx^2}. \qquad (2.)$$

From the former of these,

$$fiB=v^2\frac{d^2A}{dx^2}+i^2A-H.\sin mx \qquad (3.)$$

therefore

$$fi\frac{d^2B}{dx^2}=v^2\frac{d^4A}{dx^4}+i^2\frac{d^2A}{dx^2}+m^2H.\sin mx. \qquad (4.)$$

Multiplying (2.) by fi, and transposing its terms,

$$-fi^3B-fiv^2\frac{d^2B}{dx^2}=f^2i^2A+fiH.\cos mx.$$

Multiplying (3.) by i^2

$$fi^3B=i^2v^2\frac{d^2A}{dx^2}+i^4A-i^2H.\sin mx.$$

Multiplying (4.) by v^2

$$fiv^2\frac{d^2B}{dx^2}=v^4\frac{d^4A}{dx^4}+v^2i^2\frac{d^2A}{dx^2}+v^2m^2H.\sin mx.$$

Adding together the three last equations,

$$0=v^4\frac{d^4A}{dx^4}+2v^2i^2\frac{d^2A}{dx^2}+(i^4+f^2i^2)A+(v^2m^2-i^2)H.\sin mx+fiH.\cos mx.$$

Differential equation for coefficient.

(320.) The equation just found is one of which the solution is well known. Its most general expression is the following. Let the four roots of the equation $0=v^4z^4+2v^2i^2z^2+(i^4+f^2i^2)$ be $\pm p\pm q\sqrt{-1}$: (it is easily found that $p^2=-\frac{i^2}{2v^2}+\sqrt{\left(\frac{i^4+f^2i^2}{4v^4}\right)}$, $q^2=\frac{i^2}{2v^2}+\sqrt{\left(\frac{i^4+f^2i^2}{4v^4}\right)}$:), and put M for $(v^2m^2-i^2)H.\sin mx+fiH.\cos mx$.

Then the expression for A is

$$-\frac{1}{v^4}\varepsilon^{px}.\cos qx\int_x\frac{1}{\cos^2 qx}\int_x\varepsilon^{-2px}.\cos^2 qx\int_x\frac{1}{\cos^2 qx}\int_x\varepsilon^{px}.\cos qx.\,\mathrm{M}.$$

the right hand integration being performed first, and arbitrary constants being added at each integration. But without going through the trouble of this integration, remarking that the part depending on the arbitrary constants will have the form $\mathrm{C}\varepsilon^{px}.\cos qx+\mathrm{C}'\varepsilon^{px}.\sin qx+\mathrm{C}''\varepsilon^{-px}.\cos qx+\mathrm{C}'''\varepsilon^{-px}.\sin qx$ (which may be proved more easily by substitution in the three first terms of the differential equation); and remarking that the substitution of $\frac{\sin mx}{\cos mx}$ in the three first terms will produce $(m^4v^4-2m^2v^2i^2+i^4+f^2i^2)\frac{\sin mx}{\cos mx}$; we easily find for the complete value of A

Solution of differential equation.

$$\frac{(i^2-v^2m^2)\,\mathrm{H}}{v^4m^4-2v^2m^2i^2+i^4+f^2i^2}\sin mx-\frac{fi\,\mathrm{H}}{v^4m^4-2v^2m^2i^2+i^4+f^2i^2}\cos mx$$
$$+\mathrm{C}\,\varepsilon^{px}.\cos qx+\mathrm{C}'\,\varepsilon^{px}.\sin qx+\mathrm{C}''.\varepsilon^{-px}.\cos qx+\mathrm{C}'''.\varepsilon^{-px}.\sin qx.$$

(321.) Substituting this value of A in equation (3.), and remarking that $v^2\frac{d^2}{dx^2}(\varepsilon^{px}.\cos qx)+i^2.\varepsilon^{px}.\cos qx=\varepsilon^{px}\{(p^2v^2-q^2v^2+i^2)\cos qx-2v^2pq.\sin qx\}$: which, on putting for p and q their values, is reduced to $-fi\,\varepsilon^{px}.\sin qx$; we obtain

$$fi\,\mathrm{B}=\frac{(i^2-v^2m^2)^2.\,\mathrm{H}}{v^4m^4-2v^2m^2i^2+i^4+f^2i^2}\sin mx-\mathrm{H}\sin mx-\frac{fi\,(i^2-v^2m^2)\,\mathrm{H}}{v^4m^4-2v^2m^2i^2+i^4+f^2i^2}\cos mx$$
$$+fi\,\{-\mathrm{C}.\varepsilon^{px}.\sin qx+\mathrm{C}'.\varepsilon^{px}.\cos qx+\mathrm{C}''.\varepsilon^{-px}\sin qx-\mathrm{C}'''.\varepsilon^{-px}.\cos qx\},$$

or

$$\mathrm{B}=\frac{-fi\,\mathrm{H}}{v^4m^4-2v^2m^2i^2+i^4+f^2i^2}\sin mx-\frac{(i^2-v^2m^2)\,\mathrm{H}}{v^4m^4-2v^2m^2i^2+i^4+f^2i^2}\cos mx$$
